Let P^* be the polymatroid associated with f^*, and call P^* the *dual* polymatroid of P (with respect to a). Now the maximal vertices of P and P^* are given by (44.49) by choosing $k = n$. It follows that x is a maximal vertex of P if and only if $a - x$ is a maximal vertex of P^*. Since the maximal vectors of a polymatroid form just the convex hull of the maximal vertices, we may replace in the previous sentence the word 'vertex' by 'vector'. So the set of maximal vectors of P^* arises from the set of maximal vectors of P by reflection in the point $\frac{1}{2}a$.

Clearly, duals of matroids correspond in the obvious way to duals of the related polymatroids (with respect to the vector $\mathbf{1}$).

44.6g. Induction of polymatroids

Let $G = (V, E)$ be a bipartite graph, with colour classes S and T. Let f be a nondecreasing submodular set function on S with $f(\emptyset) = 0$, and define

(44.74) $$g(U) := f(N(U))$$

for $U \subseteq T$ (cf. Section 44.1a). (As usual, $N(U)$ denotes the set of vertices not in U adjacent to at least one vertex in U.)

The function g again is nondecreasing and submodular. Similarly to Rado's theorem (Corollary 41.1c), one may prove that a vector x belongs to P_g if and only if there exist $y \in \mathbb{R}^E_+$ and $z \in P_f$ such that

(44.75) $$y(\delta(t)) = x_t \quad (t \in T),$$
$$y(\delta(s)) = z_s \quad (s \in S).$$

Moreover, if f and g are integer, we can take y and z to be integer. This procedure gives an 'induction' of polymatroids through bipartite graphs, and yields 'Rado's theorem for polymatroids' (cf. McDiarmid [1975c]).

In case f is the rank function of a matroid on S, a 0,1 vector x belongs to P_g if and only if there exists a matching in G whose end vertices in S form an independent set of the matroid, and the end vertices in T have x as incidence vector. So these 0,1 vectors determine a matroid on T, with rank function r given by

(44.76) $$r(U) = \min_{W \subseteq U} (|U \setminus W| + f(N(W)))$$

for $U \subseteq T$ (cf. (44.45) and (44.74)).

Another extension is the following. Let $D = (V, A)$ be a directed graph and let V be partitioned into classes S and T. Let furthermore a 'capacity' function $c : A \to \mathbb{R}_+$ be given. Define the set function g on T by

(44.77) $$g(U) := c(\delta^{\text{out}}(U))$$

for $U \subseteq T$, where $\delta^{\text{out}}(U)$ denotes the set of arcs leaving U. Then g is nonnegative and submodular, and it may be derived straightforwardly from the max-flow min-cut theorem (Theorem 10.3) that a vector x in $\mathbb{R}^T_+$ belongs to P_g if and only if there exist $T - S$ paths $Q_1, \ldots, Q_k$ and nonnegative numbers $\lambda_1, \ldots, \lambda_k$ (for some k), such that

(44.78) $$\sum_{i=1}^{k} \lambda_i \chi^{AQ_i} \leq c \text{ and } \sum_{i=1}^{k} \lambda_i \chi^{b(Q_i)} = x,$$

where $b(Q_i)$ is the beginning vertex of Q_i. If the c and x are integer, we can take also the λ_i integer.

Here the function g in general is not nondecreasing, but the value

(44.79) $$\bar{g}(U) = \min\{g(W) \mid U \subseteq W \subseteq T\}$$

of the associated nondecreasing submodular function (cf. (44.35)) is equal to the minimum capacity of a cut separating U and S, which is equal to the maximum amount of flow from U to S, subject to the capacity function c (by the max-flow min-cut theorem).

In an analogous way, one can construct polymatroids by taking vertex-capacities instead of arc-capacities. Moreover, the notion of induction of polymatroids through bipartite graphs can be extended in a natural way to the induction of polymatroids through directed graphs (cf. McDiarmid [1975c], Schrijver [1978]).

44.6h. Lovász's generalization of Kőnig's matching theorem

Lovász [1970a] gave the following generalization of Kőnig's matching theorem (Theorem 16.2).

For a graph $G = (V, E)$, $U \subseteq V$, and $F \subseteq E$, let $N_F(U)$ denote the set of vertices not in U that are adjacent in (V, F) to at least one vertex in U. Kőnig's matching theorem follows by taking $g(X) := |X|$ in the following theorem.

Theorem 44.7. *Let $G = (V, E)$ be a simple bipartite graph, with colour classes S and T. Let g be a supermodular set function on S, such that $g(\{v\}) \geq 0$ for each $v \in S$ and such that*

(44.80) $$g(U \cup \{v\}) \leq g(U) + g(\{v\}) \text{ for nonempty } U \subseteq S \text{ and } v \in S \setminus U.$$

Then E has a subset F with $\deg_F(v) = g(\{v\})$ for each $v \in V$ and $|N_F(U)| \geq g(U)$ for each nonempty $U \subseteq S$ if and only if $|N_E(U)| \geq g(U)$ for each nonempty $U \subseteq S$.

Proof. Necessity being trivial, we show sufficiency. Choose $F \subseteq E$ such that

(44.81) $$|N_F(U)| \geq g(U)$$

for each nonempty $U \subseteq S$, with $|F|$ as small as possible. We show that F is as required.

Suppose to the contrary that $\deg_F(v) > g(\{v\})$ for some $v \in S$. By the minimality of F, for each edge $e = vw \in F$, there is a subset U_e of S with $v \in U_e$, $|N_F(U_e)| = g(U_e)$, and $w \notin N_F(U_e \setminus \{v\})$. Since the function $|N_F(U)|$ is submodular, the intersection U of the U_e over $e \in \delta(v)$ satisfies $|N_F(U)| = g(U)$ (using (44.81)). Then no neighbour w of v is adjacent to U. Hence $N_F(v)$ and $N_F(U \setminus \{v\})$ are disjoint. Moreover, $U \neq \{v\}$, since $N_F(U) = g(U)$ and $N_F(\{v\}) > g(v)$. This gives the contradiction

(44.82) $$g(U) \leq g(U \setminus \{v\}) + g(\{v\}) < |N_F(U \setminus \{v\})| + |N_F(v)| = |N_F(U)|. \quad \blacksquare$$

For a derivation of this theorem with the Edmonds-Giles method, see Frank and Tardos [1989].

44.6i. Further notes

Edmonds [1970b] and D.A. Higgs (as mentioned in Edmonds [1970b]) observed that if f is a set function on a set S, we can define recursively a submodular function $\bar{f}$ as follows:

(44.83) $$\bar{f}(T) := \min\{f(T), \min(\bar{f}(S_1) + \bar{f}(S_2) - \bar{f}(S_1 \cap S_2))\},$$

where the second minimum ranges over all pairs S_1, S_2 of proper subsets of T with $S_1 \cup S_2 = T$.

Lovász [1983c] gave the following characterization of submodularity in terms of convexity. Let f be a set function on S and define for each $c \in \mathbb{R}^S_+$

(44.84) $$\hat{f}(c) := \sum_{i=1}^{k} \lambda_i f(U_i),$$

where $\emptyset \neq U_1 \subset U_2 \subset \cdots \subset U_k \subseteq S$ and $\lambda_1, \ldots, \lambda_k > 0$ are such that $c = \sum_{i=1}^k \lambda_i \chi^{U_i}$. Then f is submodular if and only if $\hat{f}$ is convex. Similarly, f is supermodular if and only if $\hat{f}$ is concave. Related is the 'subdifferential' of a submodular function, investigated by Fujishige [1984d].

Korte and Lovász [1985c] and Nakamura [1988a] studied polyhedral structures where the greedy algorithm applies. Federgruen and Groenevelt [1986] extended the greedy method for polymatroids to 'weakly concave' objective functions (instead of linear functions). (Related work was reported by Bhattacharya, Georgiadis, and

Tsoucas [1992].) Nakamura [1993] extended polymatroids and submodular functions to $\varDelta$-polymatroids and $\varDelta$-submodular functions.

Gröflin and Liebling [1981] studied the following example of 'transversal polymatroids'. Let $G = (V, E)$ be an undirected graph, and define the submodular set function f on E by $f(F) := \left|\bigcup F\right|$ for $F \subseteq E$. Then the vertices of the associated polymatroid are all $\{0, 1, 2\}$ vectors x in $\mathbb{R}^E$ with the property that the set $F := \{e \in E \mid x_e \geq 1\}$ forms a forest each component of which contains at most one edge e with $x_e = 2$. If x is a maximal vertex, then each component contains exactly one edge e with $x_e = 2$.

Narayanan [1991] studied, for a given submodular function f on S, the lattice of all partitions $\mathcal{P}$ of S into nonempty sets such that there exists a $\lambda \in \mathbb{R}$ for which $\mathcal{P}$ attains $\min \sum_{U \in \mathcal{P}} (f(U) - \lambda)$ (taken over all partitions $\mathcal{P}$). Fujishige [1980b] studied minimum values of submodular functions.

For results on the (NP-hard) problems of *maximizing* a submodular function and of submodular set cover, see Fisher, Nemhauser, and Wolsey [1978], Nemhauser and Wolsey [1978,1981], Nemhauser, Wolsey, and Fisher [1978], Wolsey [1982a,1982b], Conforti and Cornuéjols [1984], and Fujito [1999].

Cunningham [1983], Fujishige [1983], and Nakamura [1988c] presented decomposition theories for submodular functions. Benczúr and Frank [1999] considered covering symmetric supermodular functions by graphs.

For surveys and books on polymatroids and submodular functions, see McDiarmid [1975c], Welsh [1976], Lovász [1983c], Lawler [1985], Nemhauser and Wolsey [1988], Fujishige [1991], Narayanan [1997], and Murota [2002]. For a survey on applications of submodular functions, see Frank [1993a].

Historically, submodular functions arose in lattice theory (Bergmann [1929], Birkhoff [1933]), while submodularity of the rank function of a matroid was shown by Bergmann [1929] and Whitney [1935]. Choquet [1951,1955] and Kelley [1959] studied submodular functions in relation to the Newton capacity and to measures in Boolean algebras. The relevance of submodularity for optimization was revealed by Edmonds [1970b].

Several alternative names have been proposed for submodular functions, like sub-valuation (Choquet [1955]), β-function (Edmonds [1970b]), and ground set rank function (McDiarmid [1975c]). The set of integer vectors in an integer polymatroid was called a hypermatroid by Helgason [1974] and Lovász [1977c]. A generalization of polymatroids (called supermatroids) was studied by Dunstan, Ingleton, and Welsh [1972].

Chapter 45

Submodular function minimization

This chapter describes a strongly polynomial-time algorithm to find the minimum value of a submodular function. It suffices that the submodular function is given by a value giving oracle.
One application of submodular function minimization is optimizing over the intersection of two polymatroids. This will be discussed in Chapter 47.

45.1. Submodular function minimization

It was shown by Grötschel, Lovász, and Schrijver [1981] that the minimum value of a rational-valued submodular set function f on S can be found in polynomial time, if f is given by a value giving oracle and an upper bound B is given on the numerators and denominators of the values of f. The running time is bounded by a polynomial in $|S|$ and $\log B$. This algorithm is based on the ellipsoid method: we can assume that $f(\emptyset) = 0$ (by resetting $f(U) := f(U) - f(\emptyset)$ for all $U \subseteq S$); then with the greedy algorithm, we can optimize over EP_f in polynomial time (Corollary 44.3b), hence the separation problem for EP_f is solvable in polynomial time, hence also the separation problem for

(45.1) $\qquad P := EP_f \cap \{x \mid x \leq \mathbf{0}\},$

and therefore also the optimization problem for P. Now the maximum value of $x(S)$ over P is equal to the minimum value of f (by (44.8), (44.9), and (44.34)).

Having a polynomial-time method to find the minimum value of a submodular function, we can turn it into a polynomial-time method to find a subset T of S minimizing $f(T)$: For each $s \in S$, we can determine if the minimum value of f over all subsets of S is equal to the minimum value of f over subsets of $S \setminus \{s\}$. If so, we reset $S := S \setminus \{s\}$. Doing this for all elements of S, we are left with a set T minimizing f over all subsets of (the original) S.

Grötschel, Lovász, and Schrijver [1988] showed that this algorithm can be turned into a strongly polynomial-time method. Cunningham [1985b] gave a combinatorial, pseudo-polynomial-time algorithm for minimizing a submodular function f (polynomial in the size of the underlying set and the maximum absolute value of f (assuming f to be integer)). Inspired by Cunningham's method, combinatorial strongly polynomial-time algorithms were found by Iwata, Fleischer, and Fujishige [2000,2001] and Schrijver [2000a]. We will describe the latter algorithm.

45.2. Orders and base vectors

Let f be a submodular set function on a set S. In finding the minimum value of f, we can assume $f(\emptyset) = 0$, as resetting $f(U) := f(U) - f(\emptyset)$ for all $U \subseteq S$ does not change the problem. So throughout we assume that $f(\emptyset) = 0$.

Moreover, we assume that f is given by a *value giving oracle*, that is, an oracle that returns $f(U)$ for any given subset U of S. We also assume that the numbers returned by the oracle are rational (or belong to any ordered field in which we can perform the elementary arithmetic operations algorithmically).

Recall that the *base polytope* B_f of f is defined as the set of base vectors of f:

(45.2) $$B_f := \{x \in \mathbb{R}^S \mid x(U) \leq f(U) \text{ for all } U \subseteq S, x(S) = f(S)\}.$$

Consider any total order $\prec$ on S.[35] For any $v \in S$, denote

(45.3) $$v_\prec := \{u \in S \mid u \prec v\}.$$

Define a vector $b^\prec$ in $\mathbb{R}^S$ by:

(45.4) $$b^\prec(v) := f(v_\prec \cup \{v\}) - f(v_\prec)$$

for $v \in S$. Theorem 44.3 implies that $b^\prec$ belongs to B_f.

Note that $b^\prec(U) = f(U)$ for each lower ideal U of $\prec$ (where a *lower ideal* of $\prec$ is a subset U of S such that if $v \in U$ and $u \prec v$, then $u \in U$).

45.3. A subroutine

In this section we describe a subroutine that is important in the algorithm. It replaces a total order $\prec$ by other total orders, thereby reducing some interval $(s,t]_\prec$, where

(45.5) $$(s,t]_\prec := \{v \mid s \prec v \preceq t\}$$

for $s, t \in S$.

Let $\prec$ be a total order on S. For any $s, u \in S$ with $s \prec u$, let $\prec^{s,u}$ be the total order on S obtained from $\prec$ by resetting $v \prec u$ to $u \prec v$ for each

[35] As usual, we use $\prec$ for strict inequality and $\preceq$ for nonstrict inequality. We refer to the order by the strict inequality sign $\prec$.

v satisfying $s \preceq v \prec u$. Thus in the ordering, we move u to the position just before s. Hence $(s,t]_{\prec^{s,u}} = (s,t]_\prec \setminus \{u\}$ if $u \in (s,t]_\prec$.

We show that there is a strongly polynomial-time subroutine that

(45.6) for any $s,t \in S$ with $s \prec t$, finds a $\delta \geq 0$ and describes $b^\prec + \delta(\chi^t - \chi^s)$ as a convex combination of the $b^{\prec^{s,u}}$ for $u \in (s,t]_\prec$.

To describe the subroutine, we can assume that $b^\prec = \mathbf{0}$, by replacing (temporarily) $f(U)$ by $f(U) - b^\prec(U)$ for each $U \subseteq S$.

We investigate the signs of the vector $b^{\prec^{s,u}}$. We show that for each $v \in S$:

(45.7)
$$\begin{aligned} &b^{\prec^{s,u}}(v) \leq 0 \text{ if } s \preceq v \prec u,\\ &b^{\prec^{s,u}}(v) \geq 0 \text{ if } v = u,\\ &b^{\prec^{s,u}}(v) = 0 \text{ otherwise.} \end{aligned}$$

To prove this, observe that if $T \subseteq U \subseteq S$, then for any $v \in S \setminus U$ we have by the submodularity of f:

(45.8)
$$f(U \cup \{v\}) - f(U) \leq f(T \cup \{v\}) - f(T).$$

To see (45.7), if $s \preceq v \prec u$, then by (45.8),

(45.9)
$$\begin{aligned} b^{\prec^{s,u}}(v) &= f(v_{\prec^{s,u}} \cup \{v\}) - f(v_{\prec^{s,u}}) \leq f(v_\prec \cup \{v\}) - f(v_\prec)\\ &= b^\prec(v) = 0, \end{aligned}$$

since $v_{\prec^{s,u}} = v_\prec \cup \{u\} \supset v_\prec$.

Similarly,

(45.10)
$$\begin{aligned} b^{\prec^{s,u}}(u) &= f(u_{\prec^{s,u}} \cup \{u\}) - f(u_{\prec^{s,u}}) \geq f(u_\prec \cup \{u\}) - f(u_\prec)\\ &= b^\prec(u) = 0, \end{aligned}$$

since $u_{\prec^{s,u}} = s_\prec \subset u_\prec$.

Finally, if $v \prec s$ or $u \prec v$, then $v_{\prec^{s,u}} = v_\prec$, and hence $b^{\prec^{s,u}}(v) = b^\prec(v) = 0$. This shows (45.7).

By (45.7), the matrix $M = (b^{\prec^{s,u}}(v))_{u,v}$ with rows indexed by $u \in (s,t]_\prec$ and columns indexed by $v \in S$, in the order given by $\prec$, has the following, partially triangular, shape, where $+$ means that the entry is ≥ 0, and $-$ that the entry is ≤ 0:

$$\begin{array}{c|cccccccccccccc}
 & & & & s & & & & & & & t & & & \\
\hline
 & 0 & \cdots & 0 & - & + & 0 & \cdots & \cdots & \cdots & 0 & 0 & 0 & \cdots & 0\\
 & \vdots & & \vdots & - & - & + & \ddots & & & \vdots & \vdots & \vdots & & \vdots\\
 & \vdots & & \vdots & - & - & - & \ddots & \ddots & & \vdots & \vdots & \vdots & & \vdots\\
 & \vdots & & \vdots & \vdots & \vdots & \vdots & \ddots & \ddots & \ddots & \vdots & \vdots & \vdots & & \vdots\\
 & \vdots & & \vdots & \vdots & \vdots & \vdots & & \ddots & \ddots & 0 & 0 & \vdots & & \vdots\\
 & \vdots & & \vdots & \vdots & \vdots & \vdots & & & \ddots & + & 0 & \vdots & & \vdots\\
t & 0 & \cdots & 0 & - & - & - & \cdots & \cdots & \cdots & - & + & 0 & \cdots & 0
\end{array}$$

As each row of M represents a vector $b^{\prec^{s,u}}$, to obtain (45.6) we must describe $\delta(\chi^t - \chi^s)$ as a convex combination of the rows of M, for some $\delta \geq 0$.

We call the $+$ entries in the matrix the 'diagonal' elements. Now for each row of M, the sum of its entries is 0, as $b^{\prec^{s,u}}(S) = f(S) = b^{\prec}(S) = 0$. Hence, if a 'diagonal' element $b^{\prec^{s,u}}(u)$ is equal to 0 for some $u \in (s,t]_{\prec}$, then the corresponding row of M is all-zero. So in this case we can take $\delta = 0$ in (45.6).

If $b^{\prec^{s,u}}(u) > 0$ for each $u \in (s,t]_{\prec}$ (that is, if each 'diagonal' element is strictly positive), then $\chi^t - \chi^s$ can be described as a nonnegative combination of the rows of M (by the sign pattern of M and since the entries in each row of M add up to 0). Hence $\delta(\chi^t - \chi^s)$ is a convex combination of the rows of M for some $\delta > 0$, yielding again (45.6).

45.4. Minimizing a submodular function

We now describe the algorithm to find the minimum value of a submodular set function f on S. We assume $f(\emptyset) = 0$ and $S = \{1, \ldots, n\}$.

We iteratively update a vector $x \in B_f$, given as a convex combination

(45.11) $\qquad x = \lambda_1 b^{\prec_1} + \cdots + \lambda_k b^{\prec_k},$

where the $\prec_i$ are total orders of S, and where the λ_i are positive and sum to 1. Initially, we choose an arbitrary total order $\prec$ and set $x := b^{\prec}$ (so $k = 1$ and $\prec_1 = \prec$).

We describe the iteration. Consider the directed graph $D = (S, A)$, with

(45.12) $\qquad A := \{(u, v) \mid \exists i = 1, \ldots, k : u \prec_i v\}.$

Define

(45.13) $\qquad P := \{v \in S \mid x(v) > 0\}$ and $N := \{v \in S \mid x(v) < 0\}.$

Case 1: D has no path from P to N. Then let U be the set of vertices of D that can reach N by a directed path. So $N \subseteq U$ and $U \cap P = \emptyset$; that is, U contains all negative components of x and no positive components. Hence $x(W) \geq x(U)$ for each $W \subseteq S$. As no arcs of D enter U, U is a lower ideal of $\prec_i$, and hence $b^{\prec_i}(U) = f(U)$, for each $i = 1, \ldots, k$. Therefore, for each $W \subseteq S$:

(45.14) $$f(U) = \sum_{i=1}^{k} \lambda_i b^{\prec_i}(U) = x(U) \leq x(W) \leq f(W).$$

So U minimizes f.

Case 2: D has a path from P to N. Let $d(v)$ denote the distance in D from P to v (= minimum number of arcs in a directed path from P to v). Set $d(v) := \infty$ if v is not reachable from P. Choose $s, t \in S$ as follows.

Let t be the element in N reachable from P with $d(t)$ maximum, such that t is largest. Let s be the element with $(s,t) \in A$, $d(s) = d(t) - 1$, and s largest. Let α be the maximum of $|(s,t]_{\prec_i}|$ over $i = 1, \ldots, k$. Reorder indices such that $|(s,t]_{\prec_1}| = \alpha$.

By (45.6), we can find $\delta \geq 0$ and describe

(45.15) $\qquad b^{\prec_1} + \delta(\chi^t - \chi^s)$

as a convex combination of the $b^{\prec_1^{s,u}}$ for $u \in (s,t]_{\prec_1}$. Then with (45.11) we obtain

(45.16) $\qquad y := x + \lambda_1 \delta(\chi^t - \chi^s)$

as a convex combination of $b^{\prec_i}$ $(i = 2, \ldots, k)$ and $b^{\prec_1^{s,u}}$ $(u \in (s,t]_{\prec_1})$.

Let x' be the point on the line segment $\overline{xy}$ closest to y satisfying $x'(t) \leq 0$. (So $x'(t) = 0$ or $x' = y$.) We can describe x' as a convex combination of $b^{\prec_i}$ $(i = 1, \ldots, k)$ and $b^{\prec_1^{s,u}}$ $(u \in (s,t]_{\prec_1})$. Moreover, if $x'(t) < 0$, then we can do without $b^{\prec_1}$.

We reduce the number of terms in the convex decomposition of x' to at most $|S|$ by linear algebra: any affine dependence of the vectors in the decomposition yields a reduction of the number of terms in the decomposition, as in the standard proof of Carathéodory's theorem (subtract an appropriate multiple of the linear expression giving the affine dependence, from the linear expression giving the convex combination, such that all coefficients remain nonnegative, and at least one becomes 0). As all $b^{\prec}$ belong to a hyperplane, this reduces the number of terms to at most $|S|$.

Then reset $x := x'$ and iterate. This finishes the description of the algorithm.

45.5. Running time of the algorithm

We show that the number of iterations is at most $|S|^6$. Consider any iteration. Let

(45.17) $\qquad \beta :=$ number of $i \in \{1, \ldots, k\}$ with $|(s,t]_{\prec_i}| = \alpha$.

Let x', d', A', P', N', t', s', α', β' be the objects x, d, A, P, N, t, s, α, β in the next iteration (if any). Then

(45.18) $\qquad$ for all $v \in S$, $d'(v) \geq d(v)$,

and

(45.19) $\qquad$ if $d'(v) = d(v)$ for all $v \in S$, then $(d'(t'), t', s', \alpha', \beta')$ is lexicographically less than $(d(t), t, s, \alpha, \beta)$.

Since each of $d(t), t, s, \alpha, \beta$ is at most $|S|$, and since (if $d(v)$ is unchanged for all v) there are at most $|S|$ pairs $(d(t), t)$, (45.19) implies that in at most $|S|^4$

iterations $d(v)$ increases for at least one v. Any fixed v can have at most $|S|$ such increases, and hence the number of iterations is at most $|S|^6$.

In order to prove (45.18) and (45.19), notice that

(45.20) for each arc $(v,w) \in A' \setminus A$ we have $s \preceq_1 w \prec_1 v \preceq_1 t$.

Indeed, as $(v,w) \notin A$ we have $w \prec_1 v$. As $(v,w) \in A'$, we have $v \prec_1^{s,u} w$ for some $u \in (s,t]_{\prec_1}$. Hence the definition of $\prec_1^{s,u}$ gives $v = u$ and $s \preceq_1 w \prec_1 u$. This shows (45.20).

If (45.18) does not hold, then $A' \setminus A$ contains an arc (v,w) with $d(w) \geq d(v) + 2$ (using that $P' \subseteq P$). By (45.20), $s \preceq_1 w \prec_1 v \preceq_1 t$, and so $d(w) \leq d(s) + 1 = d(t) \leq d(v) + 1$, a contradiction. This shows (45.18).

To prove (45.19), assume that $d'(v) = d(v)$ for all $v \in S$. As $x'(t') < 0$, we have $x(t') < 0$ or $t' = s$. So by our criterion for choosing t (maximizing $(d(t), t)$ lexicographically), and since $d(s) < d(t)$, we know that $d(t') \leq d(t)$, and that if $d(t') = d(t)$, then $t' \leq t$.

Next assume that moreover $d(t') = d(t)$ and $t' = t$. As $(s', t) \in A'$, and as (by (45.20)) $A' \setminus A$ contains no arc entering t, we have $(s', t) \in A$, and so $s' \leq s$, by the maximality of s.

Finally assume that moreover $s' = s$. As $(s,t]_{\prec_1^{s,u}}$ is a proper subset of $(s,t]_{\prec_1}$ for each $u \in (s,t]_{\prec_1}$, we know that $\alpha' \leq \alpha$. Moreover, if $\alpha' = \alpha$, then $\beta' < \beta$, since $\prec_1$ does not occur anymore among the linear orders making the convex combination, as $x'(t) < 0$. This proves (45.19).

We therefore have proved:

Theorem 45.1. *Given a submodular function f by a value giving oracle, a set U minimizing $f(U)$ can be found in strongly polynomial time.*

Proof. See above. ∎

This algorithm performs the elementary arithmetic operations on function values, including multiplication and division (in order to solve certain systems of linear equations). One would wish to have a 'fully combinatorial' algorithm, in which the function values are only compared, added, and subtracted. The existence of such an algorithm was shown by Iwata [2002a, 2002c], by extending the algorithm of Iwata, Fleischer, and Fujishige [2000, 2001].

Notes. In the algorithm, we have chosen t and s largest possible, in some fixed order of S. To obtain the above running time bound it only suffices to choose t and s in a consistent way. That is, if the set of choices for t is the same as in the previous iteration, then we should choose the same t — and similarly for s. This roots in the idea of 'consistent breadth-first search' of Schönsleben [1980].

The observation that the number of iterations in the algorithm of Section 45.4 is $O(|S|^6)$ instead of $O(|S|^7)$ is due to L.K. Fleischer. Vygen [2002] showed that the number of iterations can in fact be bounded by $O(|S|^5)$.

The algorithm described above has been speeded up by Fleischer and Iwata [2000,2002], by incorporating a push-relabel type of iteration based on approximate distances instead of precise distances (like Goldberg's method for maximum flow, given in Section 10.7). Iwata [2002b] combined the approaches of Iwata, Fleischer, and Fujishige [2000,2001] and Schrijver [2000a] to obtain a faster algorithm. A descent method for submodular function minimization based on an oracle for membership of the base polytope was given by Fujishige and Iwata [2002].

Surveys and background on submodular function minimization are given by Fleischer [2000b] and McCormick [2001].

45.6. Minimizing a symmetric submodular function

A set function f on S is called *symmetric* if $f(U) = f(S \setminus U)$ for each $U \subseteq S$. The minimum of a symmetric submodular function f is attained by $\emptyset$, since for each $U \subseteq S$ one has

(45.21) $$2f(U) = f(U) + f(S \setminus U) \geq f(\emptyset) + f(S) = 2f(\emptyset).$$

By extending a method of Nagamochi and Ibaraki [1992b] for finding the minimum nonempty cut in an undirected graph, Queyranne [1995,1998] gave an easy combinatorial algorithm to find a nonempty proper subset U of S minimizing $f(U)$, where f is given by a value giving oracle. We may assume that $f(\emptyset) = f(S) = 0$, by resetting $f(U) := f(U) - f(\emptyset)$ for all $U \subseteq S$.

Call an ordering $s_1, \ldots, s_n$ of the elements of S a *legal order* of S for f, if, for each $i = 1, \ldots, n$,

(45.22) $$f(\{s_1, \ldots, s_{i-1}, x\}) - f(\{x\})$$

is minimized over $x \in S \setminus \{s_1, \ldots, s_{i-1}\}$ by $x = s_i$. One easily finds a legal order, by $O(|S|^2)$ oracle calls (for the value of f).

Now the algorithm is (where a set U *splits* a set X if both $X \cap U$ and $X \setminus U$ are nonempty):

(45.23) Find a legal order $(s_1, \ldots, s_n)$ of S for f.
Determine (recursively) a nonempty proper subset T of S not splitting $\{s_{n-1}, s_n\}$, minimizing $f(T)$. (This can be done by identifying s_{n-1} and s_n.)
Then the minimum value of $f(U)$ over nonempty proper subsets U of S is equal to $\min\{f(T), f(\{s_n\})\}$.

The correctness of the algorithm follows from, for $n \geq 2$:

(45.24) $f(U) \geq f(\{s_n\})$ for each $U \subseteq S$ splitting $\{s_{n-1}, s_n\}$.

This can be proved as follows. Define $t_0 := s_1$. For $i = 1, \ldots, n-1$, define $t_i := s_j$, where j is the smallest index such that $j > i$ and such that U splits $\{s_i, s_j\}$. For $i = 0, \ldots, n$, let $U_i := \{s_1, \ldots, s_i\}$. Note that for each $i = 1, \ldots, n-1$ one has

(45.25) $$f(U_{i-1} \cup \{t_i\}) - f(\{t_i\}) \geq f(U_{i-1} \cup \{t_{i-1}\}) - f(\{t_{i-1}\}),$$

since if $t_{i-1} = t_i$ this is trivial, and if $t_{i-1} \neq t_i$, then $t_{i-1} = s_i$, in which case (45.25) follows from the legality of the order.

Moreover, for each $i = 1, \ldots, n-1$ (setting $\overline{U} := S \setminus U$):

(45.26) $$\begin{aligned} & f(U_i \cup U) - f(U_{i-1} \cup U) + f(U_i \cup \overline{U}) - f(U_{i-1} \cup \overline{U}) \\ & \leq f(U_i \cup \{t_i\}) - f(U_{i-1} \cup \{t_i\}). \end{aligned}$$

In proving this, we may assume (by symmetry of U and $\overline{U}$) that $s_i \in \overline{U}$. Then $U_i \cup \overline{U} = U_{i-1} \cup \overline{U}$ and $t_i \in U$. So $f(U_i \cup \{t_i\}) + f(U_{i-1} \cup U) \geq f(U_{i-1} \cup \{t_i\}) + f(U_i \cup U)$, by submodularity. This gives (45.26).

Then we have:

(45.27) $$\begin{aligned} & f(s_n) - 2f(U) \\ & = f(U_{n-1} \cup U) + f(U_{n-1} \cup \overline{U}) - f(U_0 \cup U) - f(U_0 \cup \overline{U}) \\ & = \sum_{i=1}^{n-1} (f(U_i \cup U) - f(U_{i-1} \cup U) + f(U_i \cup \overline{U}) - f(U_{i-1} \cup \overline{U})) \\ & \leq \sum_{i=1}^{n-1} (f(U_i \cup \{t_i\}) - f(U_{i-1} \cup \{t_i\})) \\ & \leq \sum_{i=1}^{n-1} (f(U_i \cup \{t_i\}) - f(U_{i-1} \cup \{t_{i-1}\}) + f(\{t_{i-1}\}) - f(\{t_i\})) \\ & = f(U_{n-1} \cup \{t_{n-1}\}) - f(\{t_{n-1}\}) - f(\{t_0\}) + f(\{t_0\}) = -f(s_n) \end{aligned}$$

(where the first inequality follows from (45.26), and the second inequality from (45.25)). This shows (45.24).

Notes. Fujishige [1998] gave an alternative correctness proof. Nagamochi and Ibaraki [1998] extended the algorithm to minimizing submodular functions f satisfying

(45.28) $$f(T) + f(U) \geq f(T \setminus U) + f(U \setminus T)$$

for all $T, U \subseteq S$. Rizzi [2000b] gave an extension.

45.7. Minimizing a submodular function over the odd sets

From the strong polynomial-time solvability of submodular function minimization, one can derive that also a set of odd cardinality minimizing f (over the odd sets) is solvable in strongly polynomial time (Grötschel, Lovász, and Schrijver [1981,1984a,1988] (the second paper corrects a wrong argument given in the first paper)).

Theorem 45.2. *Given a submodular set function f on S (by a value giving oracle) and a nonempty subset T of S, one can find in strongly polynomial time a set $W \subseteq S$ minimizing $f(W)$ over W with $|W \cap T|$ odd.*

Proof. The case T odd can be reduced to the case T even as follows. Find for each $t \in T$ a subset W_t of $S - t$ with $W_t \cap (T - t)$ odd, and minimizing $f(W_t)$. Moreover, find a subset U of S minimizing $f(U)$ over $U \supseteq T$. Then a set that attains the minimum among $f(U)$ and the $f(W_t)$, is an output as required.

So we can assume that T is even. We describe a recursive algorithm. Say that a set U *splits* T if both $T \cap U$ and $T \setminus U$ are nonempty. First find a set U minimizing $f(U)$ over all subsets U of S splitting T. This can be done by finding for all $s, t \in T$ a set $U_{s,t}$ minimizing $f(U_{s,t})$ over all subsets of S containing s and not containing t (this amounts to submodular function minimization), and taking for U a set that minimizes $f(U_{s,t})$ over all such s, t.

If $U \cap T$ is odd, we output $W := U$. If $U \cap T$ is even, then recursively we find a set X minimizing $f(X)$ over all X with $X \cap (T \cap U)$ odd, and not splitting $T \setminus U$. This can be done by shrinking $T \setminus U$ to one element. Also, recursively we can find a set Y minimizing $f(Y)$ over all Y with $Y \cap (T \setminus U)$ odd, and not splitting $T \cap U$. Output an X or Y attaining the minimum of $f(X)$ and $f(Y)$.

This gives a strongly polynomial-time algorithm as the total number of recursive calls is at most $|T| - 2$ (since $2 + (|T \cap U| - 2) + (|T \setminus U| - 2) = |T| - 2$).

To see the correctness, let W minimize $f(W)$ over those W with $|W \cap T|$ odd. Suppose that $f(W) < f(X)$ and $f(W) < f(Y)$. As $f(W) < f(X)$, W splits $T \setminus U$, and hence $W \cup U$ splits T. Similarly, $f(W) < f(Y)$ implies that $W \cap U$ splits T.

Since $W \cap T$ is odd and $U \cap T$ is even, either $(W \cap U) \cap T$ or $(W \cup U) \cap T$ is odd.

If $(W \cap U) \cap T$ is odd, then $f(W \cap U) \geq f(W)$ (as W minimizes $f(W)$ over W with $W \cap T$ odd) and $f(W \cup U) \geq f(U)$ (as $W \cup U$ splits T and as U minimizes $f(U)$ over U splitting T). Hence, by the submodularity of f, $f(W \cap U) = f(W)$. Since $(W \cap U) \cap (T \cap U) = (W \cap U) \cap T$ is odd and since $W \cap U$ does not split $T \setminus U$, we have $f(W) = f(W \cap U) \geq f(X)$, contradicting our assumption.

If $(W \cup U) \cap T$ is odd, a symmetric argument gives a contradiction. ∎

This generalizes the strong polynomial-time solvability of finding a minimum-capacity odd cut in a graph, proved by Padberg and Rao [1982] (Corollary 25.6a). For a further generalization, see Section 49.11a.

Chapter 46

Polymatroid intersection

The intersection of two polymatroids behaves as nice as the intersection of two matroids, as was shown by Edmonds again. We study in this chapter min-max relations, polyhedral characterizations, and total dual integrality results. In the next chapter we go over to the algorithmic questions.

46.1. Box-total dual integrality of polymatroid intersection

We saw in Section 44.2 that the greedy algorithm yields a proof that an integer-valued submodular function gives an integer polymatroid. The interest of polymatroids for combinatorial optimization is enlarged by the fundamental result of Edmonds [1970b] that also the intersection of two integer polymatroids is integer, thus generalizing the matroid intersection theorem. In order to obtain this result, we first show a more general theorem (also due to Edmonds [1970b]).

Consider, for submodular set functions f_1, f_2 on S, the system:

(46.1) $$\begin{aligned} x(U) &\leq f_1(U) \quad \text{for } U \subseteq S, \\ x(U) &\leq f_2(U) \quad \text{for } U \subseteq S. \end{aligned}$$

Then:

Theorem 46.1. *If f_1 and f_2 are submodular, then* (46.1) *is box-TDI.*

Proof. Choose $w : S \to \mathbb{R}$. Let y_1, y_2 attain

(46.2) $$\min\{\sum_{U \subseteq S} (y_1(U)f_1(U) + y_2(U)f_2(U)) \mid y_1, y_2 \in \mathbb{R}_+^{\mathcal{P}(S)}, \sum_{U \subseteq S} (y_1(U) + y_2(U))\chi^U = w\}.$$

For $i = 1, 2$, define $w_i : S \to \mathbb{R}$ by

(46.3) $$w_i := \sum_{U \subseteq S} y_i(U)\chi^U.$$

Then y_i attains

(46.4) $$\min\{\sum_{U\subseteq S} y_i(U)f_i(U) \mid y_i \in \mathbb{R}_+^{\mathcal{P}(S)}, \sum_{U\subseteq S} y_i(U)\chi^U = w_i\}.$$

So by Theorem 44.3, we can assume that the collections

(46.5) $$\mathcal{F}_i := \{U \subseteq S \mid y_i(U) > 0\}$$

are chains. Hence, by Theorem 41.11, (46.2) has an optimum solution such that the inequalities with positive coefficients have a totally unimodular constraint matrix. Therefore, by Theorem 5.35, (46.1) is box-TDI. ∎

(This proof method is due to Edmonds [1970b].)

46.2. Consequences

Theorem 46.1 has the following consequences. First, the integrality of the intersection of two polymatroids:

Corollary 46.1a (polymatroid intersection theorem)**.** *The intersection of two integer (extended) polymatroids is box-integer.*

Proof. If P_{f_1} and P_{f_2} are integer polymatroids, f_1 and f_2 can be taken to be integer-valued, by Corollary 44.3g. Hence (46.1) determines a box-integer polyhedron. ∎

Next, a min-max relation:

Corollary 46.1b. *Let f_1 and f_2 be submodular set functions on S with $f_1(\emptyset) = f_2(\emptyset) = 0$. Then*

(46.6) $$\max\{x(U) \mid x \in EP_{f_1} \cap EP_{f_2}\} = \min_{T\subseteq U}(f_1(T) + f_2(U \setminus T))$$

for each $U \subseteq S$.

Proof. This follows by maximizing $w^{\mathsf{T}}x$ over (46.1) for $w := \chi^U$, and applying Theorem 46.1. ∎

Similarly, for (nonextended) polymatroids:

Corollary 46.1c. *Let f_1 and f_2 be nondecreasing submodular set functions on S with $f_1(\emptyset) = f_2(\emptyset) = 0$. Then*

(46.7) $$\max\{x(U) \mid x \in P_{f_1} \cap P_{f_2}\} = \min_{T\subseteq U}(f_1(T) + f_2(U \setminus T))$$

for each $U \subseteq S$.

Proof. As the previous corollary. ∎

Let f_1 and f_2 be submodular set functions on S with $f_1(\emptyset) = f_2(\emptyset) = 0$. Define

(46.8) $$f(U) := \min_{T \subseteq U}(f_1(T) + f_2(U \setminus T))$$

for $U \subseteq S$. It is easy to see that a vector x belongs to $P_{f_1} \cap P_{f_2}$ if and only if

(46.9) $$\begin{array}{ll} x_s \geq 0 & (s \in S), \\ x(U) \leq f(U) & (U \subseteq S). \end{array}$$

Moreover, system (46.9) is box-totally dual integral, since $f(U) \leq f_i(U)$ for each $U \subseteq S$ and $i = 1, 2$.

A consequence is that $P_{f_1} \cap P_{f_2}$ is integer if and only if f is integer. It may occur that P_{f_1} and P_{f_2} are not integer (i.e., f_1 and f_2 are not integer), while $P_{f_1} \cap P_{f_2}$ is integer (i.e., f is integer). For instance, take $P_{f_1} = \{(x_1, x_2) \mid 0 \leq x_1 \leq 1, 0 \leq x_2 \leq \frac{3}{2}\}$ and $P_{f_2} = \{(x_1, x_2) \mid (x_2, x_1) \in P_{f_1}\}$.

Many other results on polymatroid intersection may be deduced from Theorem 46.1, by considering derived polymatroids (cf. McDiarmid [1978]). For instance, if P_{f_1} and P_{f_2} are integer polymatroids in $\mathbb{R}^S$, v and w are integer vectors, and k and ℓ are integers, then the polytope

(46.10) $$\{x \in P_{f_1} \cap P_{f_2} \mid v \leq x \leq w, k \leq x(S) \leq \ell\}$$

is integer again. To see this, it suffices to show that the polytope $P_{f_1} \cap P_{f_2} \cap \{x \mid x(S) = k\}$ is integer for any integer k. We can reset $f_1(S) := \min\{f_1(S), k\}$. Then the polytope is a face of $P_{f_1} \cap P_{f_2}$, and hence is integer. In fact, the system determining (46.10) is box-TDI — see Corollary 49.12d.

The intersection of *three* integer polymatroids can have noninteger vertices, as the following example shows. Let $S = \{1, 2, 3, 4\}$ and let P_1, P_2 and P_3 be the following polymatroids:

(46.11) $$\begin{aligned} P_1 &:= \{x \in \mathbb{R}^S \mid x \geq \mathbf{0}, x(\{1,2\}) \leq 1, x(\{3,4\}) \leq 1\}, \\ P_2 &:= \{x \in \mathbb{R}^S \mid x \geq \mathbf{0}, x(\{1,3\}) \leq 1, x(\{2,4\}) \leq 1\}, \\ P_3 &:= \{x \in \mathbb{R}^S \mid x \geq \mathbf{0}, x(\{1,4\}) \leq 1, x(\{2,3\}) \leq 1\}. \end{aligned}$$

(So each P_i is the independent set polytope of a partition matroid.) Now the vector $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ is in $P_1 \cap P_2 \cap P_3$, but the only integer vectors in $P_1 \cap P_2 \cap P_3$ are the 0,1 vectors with at most one 1.

46.3. Contrapolymatroid intersection

Similar results as in the previous sections can be shown for the intersection of two contrapolymatroids. Such results can be proved similarly, or can be derived from the corresponding results for polymatroids.

Consider the system, for set functions g_1, g_2 on S:

(46.12) $$\begin{array}{ll} x(U) \geq g_1(U) & \text{for } U \subseteq S, \\ x(U) \geq g_2(U) & \text{for } U \subseteq S. \end{array}$$

Then Theorem 46.1 gives:

Corollary 46.1d. *If g_1 and g_2 are supermodular, then* (46.12) *is box-TDI.*

Proof. This follows from the box-total dual integrality of (46.1) taking $f_i := -g_i$ for $i = 1, 2$. ∎

46.4. Intersecting a polymatroid and a contrapolymatroid

Let S be a finite set. For set functions f and g on S consider the system

$$\begin{aligned} &x(U) \leq f(U) && \text{for } U \subseteq S, \\ &x(U) \geq g(U) && \text{for } U \subseteq S. \end{aligned} \tag{46.13}$$

Theorem 46.2. *If f is submodular and g is supermodular, then system* (46.13) *is box-TDI.*

Proof. We can assume that $f(\emptyset) \geq 0$ and $g(\emptyset) \leq 0$. Choose $w \in \mathbb{R}^S$, and consider the dual problem of maximizing $w^{\mathsf{T}}x$ over (46.13):

$$\begin{aligned} \min\{ &\sum_{U \subseteq S} y(U)f(U) - \sum_{U \subseteq S} z(U)g(U) \mid \\ &y, z \in \mathbb{R}_+^{\mathcal{P}(S)}, \sum_{U \subseteq S} y(U)\chi^U - \sum_{U \subseteq S} z(U)\chi^U = w\}. \end{aligned} \tag{46.14}$$

Let y, z attain this minimum. Define

$$u := \sum_{U \subseteq S} y(U)\chi^U \text{ and } v := \sum_{U \subseteq S} z(U)\chi^U. \tag{46.15}$$

So y attains

$$\min\{\sum_{U \subseteq S} y(U)f(U) \mid y \in \mathbb{R}_+^{\mathcal{P}(S)}, \sum_{U \subseteq S} y(U)\chi^U = u\} \tag{46.16}$$

and z attains

$$\max\{\sum_{U \subseteq S} z(U)g(U) \mid z \in \mathbb{R}_+^{\mathcal{P}(S)}, \sum_{U \subseteq S} z(U)\chi^U = v\}. \tag{46.17}$$

By Theorem 44.3, (46.16) has an optimum solution y with $\mathcal{F} := \{U \mid y(U) > 0\}$ is a chain. Similarly, (46.17) has an optimum solution z with $\mathcal{G} := \{U \mid z(U) > 0\}$ is a chain. Hence by Theorem 41.11, minimum (46.14) has an optimum solution such that the inequalities corresponding to positive coefficients have a totally unimodular constraint matrix. Hence by Theorem 5.35, (46.13) is box-TDI. ∎

So for the intersection of a polymatroid and a contrapolymatroid one gets:

Corollary 46.2a. *The intersection of an integer extended polymatroid and an integer extended contrapolymatroid is integer.*

Proof. Directly from the fact that an integer extended polymatroid is the solution set of $x(U) \leq f(U)$ ($U \subseteq S$) for some integer submodular set function on S, and an integer extended contrapolymatroid is the solution set of $x(U) \geq g(U)$ ($U \subseteq S$) for some integer submodular set function on S. Hence, by Theorem 46.2, the intersection is determined by a TDI system with integer right-hand sides. So the intersection is integer. ∎

46.5. Frank's discrete sandwich theorem

Frank [1982b] showed the following 'discrete sandwich theorem' (analogous to the 'continuous sandwich theorem', stating the existence of a linear function between a convex and a concave function):

Corollary 46.2b (Frank's discrete sandwich theorem)**.** *Let f be a submodular and g a supermodular set function on S, with $g \leq f$. Then there exists a modular set function h on S with $g \leq h \leq f$. If f and g are integer, h can be taken integer.*

Proof. We can assume that $g(\emptyset) = 0 = f(\emptyset)$, by resetting $f(U) := f(U) - f(\emptyset)$ and $g(U) := g(U) - f(\emptyset)$, for each $U \subseteq S$, and $g(\emptyset) := 0$.

Define $f'(U) := f(S) - g(S \setminus U)$ for each $U \subseteq S$. Then f' is submodular. Now by Corollary 46.1b:

(46.18) $$\max\{x(S) \mid x(U) \leq f(U), x(U) \leq f'(U) \text{ for each } U \subseteq S\} \\ = \min\{f(T) + f'(S \setminus T) \mid T \subseteq S\}.$$

The minimum is at least $f(S)$, since $f(T) + f'(S \setminus T) = f(T) + f(S) - g(T) \geq f(S)$. Hence there exists an $x \in \mathbb{R}^S$ with $x(U) \leq f(U)$ and $x(U) \leq f'(U)$ for each $U \subseteq S$ and with $x(S) = f(S)$. Defining $h(U) := x(U)$, gives the modular function as required, since for each $U \subseteq S$:

(46.19) $$g(U) = f(S) - f'(S \setminus U) \leq x(S) - x(S \setminus U) = x(U) \leq f(U).$$

If f and g are integer, we can choose x integer, implying that h is integer. ∎

As Lovász [1983c] observed, the first part of this result can be derived from the continuous sandwich theorem: define $\tilde{f} : \mathbb{R}^S_+ \to \mathbb{R}$ by

(46.20) $$\tilde{f}(x) := \sum_{i=1}^{k} \lambda_i f(U_i),$$

where $\emptyset \neq U_1 \subset U_2 \subset \cdots \subset U_n \subseteq S$ and $\lambda_1, \ldots, \lambda_k > 0$ are such that $x = \sum_{i=1}^{k} \lambda_i \chi^{U_i}$. Define $\tilde{g}$ similarly. Then $\tilde{f}$ is convex and $\tilde{g}$ is concave, and $\tilde{g} \leq \tilde{f}$. Hence there is a linear function $\tilde{h}$ satisfying $\tilde{g} \leq \tilde{h} \leq \tilde{f}$. This gives the function h as required.

46.6. Integer decomposition

Integer polymatroids have the integer decomposition property. More generally:

Corollary 46.2c. *Let $P_1, \ldots, P_k$ be integer polymatroids. Then each integer vector in $P_1 + \cdots + P_k$ is a sum $x_1 + \cdots + x_k$ of integer vectors $x_1 \in P_1, \ldots, x_k \in P_k$.*

Proof. It suffices to show this for $k = 2$; the general case follows by induction (as the sum of integer polymatroids is again an integer polymatroid, by Theorem 44.6). Choose an integer vector $x \in P_1 + P_2$. Let Q be the contrapolymatroid given by

(46.21) $\qquad Q := x - P_2.$

Then $P_1 \cap Q \neq \emptyset$, since $x = x_1 + x_2$ for some $x_1 \in P_1$ and $x_2 \in P_2$, implying $x_1 \in P_1 \cap Q$. Now Q is integer as x and P_2 are integer. Hence by Corollary 46.2a, $P_1 \cap Q$ contains an integer vector y. Then $x - y \in P_2$, and so x is the sum of $y \in P_1$ and $x - y \in P_2$. ∎

This implies the integer decomposition property for integer polymatroids, proved by Giles [1975] (also by Baum and Trotter [1981]):

Corollary 46.2d. *An integer polymatroid has the integer decomposition property.*

Proof. Directly from Corollary 46.2c, by taking all P_i equal. ∎

This gives the following integer rounding properties (Baum and Trotter [1981]). Let P_f be the integer polymatroid determined by some integer submodular set function f on S. Let $\mathcal{B}$ be the collection of integer base vectors of P_f. Let B be the $\mathcal{B} \times S$ incidence matrix. Then for each $c \in \mathbb{Z}_+^S$, one has

(46.22) $$\begin{aligned}&\min\{y^{\mathsf{T}}\mathbf{1} \mid y \in \mathbb{Z}_+^{\mathcal{B}}, y^{\mathsf{T}}B \geq c^{\mathsf{T}}\}\\ &= \lceil \min\{y^{\mathsf{T}}\mathbf{1} \mid y \in \mathbb{R}_+^{\mathcal{B}}, y^{\mathsf{T}}B \geq c^{\mathsf{T}}\}\rceil.\end{aligned}$$

Indeed, $\geq$ is trivial. To see equality, let k be equal to the right-hand side. Then $c \in k \cdot P_f$, and hence, by Corollary 46.2d, $c \leq b_1 + \cdots + b_k$ for rows $b_1, \ldots, b_k$ of B. This shows equality.

Note that the right-hand side in (46.22) is equal to $\lceil \max\{c^{\mathsf{T}}x \mid x \in A(P_f)\}\rceil$, where $A(P_f)$ is the antiblocking polyhedron of P_f.

Similarly, one has:

(46.23) $$\begin{aligned}&\max\{y^{\mathsf{T}}\mathbf{1} \mid y \in \mathbb{Z}_+^{\mathcal{B}}, y^{\mathsf{T}}B \leq c^{\mathsf{T}}\}\\ &= \lfloor \max\{y^{\mathsf{T}}\mathbf{1} \mid y \in \mathbb{R}_+^{\mathcal{B}}, y^{\mathsf{T}}B \leq c^{\mathsf{T}}\}\rfloor.\end{aligned}$$

Now the right-hand side is equal to $\lfloor \min\{c^{\mathsf{T}}x \mid x \in B(Q)\}\rfloor$, where $B(Q)$ is the blocking polyhedron of $Q := \{x \in \mathbb{R}^S \mid x(U) \geq f(S) - f(S \setminus U)$ for $U \subseteq S\}$.

If f is the rank function of a matroid, then (46.22) describes the minimum number of bases covering S, while (46.23) describes the maximum number of disjoint bases.

46.7. Further results and notes

46.7a. Up and down hull of the common base vectors

Let f_1 and f_2 be nondecreasing submodular set functions on S, with $f_1(\emptyset) = f_2(\emptyset) = 0$ and $f_1(S) = f_2(S)$, and let P_1 and P_2 be the associated polymatroids. Let F_1 and F_2 be the faces of base vectors of P_1 and of P_2, respectively. Suppose that $F_1 \cap F_2 \neq \emptyset$, equivalently that

(46.24) $$f_1(S) = f_2(S) = \max\{x(S) \mid x \in P_1 \cap P_2\} = \min_{U \subseteq S} f_1(U) + f_2(S \setminus U).$$

Consider the polyhedra P and Q defined by

(46.25) $$\begin{aligned} P &:= \{x \in \mathbb{R}^S_+ \mid x \leq y \text{ for some } y \text{ in } F_1 \cap F_2\}, \\ Q &:= \{x \in \mathbb{R}^S_+ \mid x \geq y \text{ for some } y \text{ in } F_1 \cap F_2\}. \end{aligned}$$

So if f_1 and f_2 are the rank functions of matroids on S, then P is just the convex hull of incidence vectors of subsets of S which are contained in a common base.

Note that F_1 and F_2 are the faces of minimal vectors in the contrapolymatroids Q_1 and Q_2 associated with the supermodular set functions g_1 and g_2 on S given by

(46.26) $$g_i(U) := f_i(S) - f_i(S \setminus U)$$

for $U \subseteq S$ and $i = 1, 2$ (cf. Section 44.5). So $P \subseteq P_1 \cap P_2$ and $Q \subseteq Q_1 \cap Q_2$.

Let the set functions f and g on S be defined by

(46.27) $$\begin{aligned} f(U) &:= \max\{x(U) \mid x \in P_1 \cap P_2\} = \min_{T \subseteq U}(f_1(T) + f_2(U \setminus T)), \\ g(U) &:= \min\{x(U) \mid x \in Q_1 \cap Q_2\} = \max_{T \subseteq U}(g_1(T) + g_2(U \setminus T)), \end{aligned}$$

for $U \subseteq S$ (cf. Corollary 46.1c). Then $f(S) = g(S) = f_1(S) = f_2(S) = g_1(S) = g_2(S)$.

It is easy to see that if x belongs to Q, then

(46.28) $$x(U) \geq f(S) - f(S \setminus U) \text{ for each } U \subseteq S$$

(note that $x \geq \mathbf{0}$ follows from (46.28) by taking $U = \{s\}$). Indeed, if $x \geq z$ with $z \in F_1 \cap F_2$, then $x(U) \geq z(U) = f(S) - z(S \setminus U) \geq f(S) - f(S \setminus U)$, as $z \in P_1 \cap P_2$.

Similarly, if x belongs to P, then

(46.29) $$\begin{aligned} &x_s \geq 0 && (s \in S), \\ &x(U) \leq g(S) - g(S \setminus U) && (U \subseteq S). \end{aligned}$$

In fact, the systems (46.28) and (46.29) determine Q and P respectively. This was shown by Cunningham [1977] and McDiarmid [1978], thus proving a conjecture of Fulkerson [1971a] (cf. Weinberger [1976]).

Theorem 46.3. *Polyhedron Q is determined by* (46.28). *Polyhedron P is determined by* (46.29).

Proof. Consider $x \in \mathbb{R}_+^S$ and let P_i' be the polymatroid $P_i' := \{y \in P_i \mid y \leq x\}$ for $i = 1, 2$ (cf. Section 44.1). By (44.8), the submodular function f_i' associated with P_i' is given by

(46.30) $$f_i'(U) = \min_{T \subseteq U}(f_i(T) + x(U \setminus T))$$

for $U \subseteq S$ and $i = 1, 2$. Now x is in Q if and only if there is a vector z in $P_1 \cap P_2$ with $z \leq x$ and $z(S) = f(S)$, i.e., if and only if there is a vector z in $P_1' \cap P_2'$ with $z(S) = f(S)$. By (46.7) such a vector exists if and only if

(46.31) $$\min_{U \subseteq S}(f_1'(U) + f_2'(S \setminus U)) \geq f(S).$$

Substituting (46.30) one finds that (46.31) is equivalent to (46.28).

The second statement of Theorem 46.3 is proved similarly. ∎

This theorem has a self-refining character. If k is a rational number with $k \leq f(S)$ and if $w \in Q$, then

(46.32) $$\begin{aligned}&\{x \in \mathbb{R}_+^S \mid x \geq z \text{ for some } z \text{ in } P_1 \cap P_2 \text{ with } z(S) = k\}\\ &= \{x \in \mathbb{R}_+^S \mid x(U) \geq k - f(S \setminus U) \text{ for all } U \subseteq S\}\end{aligned}$$

and

(46.33) $$\begin{aligned}&\{x \in \mathbb{R}_+^S \mid x \geq z \text{ for some } z \text{ in } F_1 \cap F_2 \text{ with } z \leq w\}\\ &= \{x \in \mathbb{R}_+^S \mid x(S \setminus (T \cup U)) \geq f(S) - w(U) - f(T) \text{ for disjoint}\\ &\qquad T, U \subseteq S\},\end{aligned}$$

as can be seen by taking appropriate subpolymatroids of P_1 and P_2 (cf. also McDiarmid [1976,1978]).

This has the following applications. Let $G = (V, E)$ be a bipartite graph, let $x \in \mathbb{R}_+^E$, and let k be a natural number. Then there exists a vector $z \leq x$ such that z is a convex combination of incidence vectors of matchings in G of size k if and only if

(46.34) $$x(E[U]) \geq k - |V| + |U|$$

for all $U \subseteq V$ (where $E[U]$ denotes the set of edges spanned by U). This can be derived as follows. Let V_1 and V_2 be the colour classes of G. For $F \subseteq E$, let $f_i(F)$ be the number of vertices in V_i covered by F (for $i = 1, 2$). Then $f(F)$ equals the maximum size of a matching in F, which is equal to the minimum number of vertices covering F. Hence the inequalities $x(F) \geq k - f(E \setminus F)$ (for $F \subseteq E$) follow from $x(E[U]) \geq k - |V \setminus U|$ (for $U \subseteq V$).

Another application is Corollary 52.3a on the up hull of the r-arborescence polytope (cf. Section 52.1a).

Gröflin and Hoffman [1981] gave a method to show the following:

Theorem 46.4. (46.28) *and* (46.29) *are box-TDI.*

Proof. We prove that (46.28) is box-TDI. The box-total dual integrality of (46.29) is proved similarly.

Let $\mathcal{R}$ be the collection of all pairs (T, U) of subsets of S with $T \cap U = \emptyset$. Then the system

(46.35) $$x(S \setminus (T \cup U)) \geq f(S) - f_1(T) - f_2(U) \quad ((T, U) \in \mathcal{R})$$

is equivalent to (46.28), in the following sense: by (46.27), (46.35) determines Q, and (46.35) contains all inequalities occurring in (46.28); moreover, all inequalities in (46.35) satisfied with equality by some $x \in Q$, also occur in (46.28). Hence, if (46.35) is box-totally dual integral, also (46.28) is box-totally dual integral. So it suffices to show the box-total dual integrality of (46.35). To this end, let $w \in \mathbb{Z}_+^S$, and consider the dual of minimizing $w^{\mathsf{T}} x$ over (46.35):

(46.36) $$\max\{\sum_{(T,U)\in\mathcal{R}} y(T, U)(f(S) - f_1(T) - f_2(U)) \mid y \in \mathbb{R}_+^{\mathcal{R}}, \sum_{(T,U)\in\mathcal{R}} y(T, U)\chi^{S\setminus(T\cup U)} = w\}.$$

We show that it is attained by an integer vector y if w is integer.

To this end, let y attain the maximum (46.36) such that

(46.37) $$\sum_{(T,U)\in\mathcal{R}} y(T, U)(|T| + |S \setminus U|)(|U| + |S \setminus T|)$$

is as small as possible. Then:

(46.38) if $y(A, B) > 0$ and $y(C, D) > 0$, then either $A \subseteq C$ and $B \supseteq D$, or $A \supseteq C$ and $B \subseteq D$.

Suppose not. Define $\alpha := \min\{y(A, B), y(C, D)\}$. Define $y' : \mathcal{R} \to \mathbb{R}_+$ by

(46.39) $$\begin{aligned} y'(A, B) &:= y(A, B) - \alpha, \\ y'(C, D) &:= y(C, D) - \alpha, \\ y'(A \cap C, B \cup D) &:= y(A \cap C, B \cup D) + \alpha, \\ y'(A \cup C, B \cap D) &:= y(A \cup C, B \cap D) + \alpha, \end{aligned}$$

and let y' coincide with y in the other components. One easily checks that

(46.40) $$\sum_{(T,U)\in\mathcal{R}} y'(T, U)\chi^{S\setminus(T\cup U)} = \sum_{(T,U)\in\mathcal{R}} y(T, U)\chi^{S\setminus(T\cup U)} \text{ and}$$
$$\sum_{(T,U)\in\mathcal{R}} y'(T, U)(f(S) - f_1(T) - f_2(U)) \geq \sum_{(T,U)\in\mathcal{R}} y(T, U)(f(S) - f_1(T) - f_2(U)),$$

by the submodularity of f_1 and f_2. So y' also attains the maximum (46.36). Moreover, one straightforwardly checks that replacing y by y' decreases (46.37).[36] This contradicts our assumption, and therefore proves (46.38).

[36] This can be seen with Theorem 2.1: Make a copy $\widetilde{S}$ of S, and, for any $U \subseteq S$, let $\widetilde{U}$ be the set of copies of elements of U. Define $X_{T,U} := T \cup (\widetilde{S} \setminus \widetilde{U})$. Then $|T| + |S \setminus U| = |X_{T,U}|$ and $|U| + |S \setminus T| = |(S \cup \widetilde{S}) \setminus X_{T,U}|$. Moreover, for (A, B) and (C, D) in $\mathcal{R}$ we have $X_{A\cap C, B\cup D} = X_{A,B} \cap X_{C,D}$ and $X_{A\cup C, B\cap D} = X_{A,B} \cup X_{C,D}$. So the replacements decrease (46.37) by Theorem 2.1, since $X_{A,B} \not\subseteq X_{C,D} \not\subseteq X_{A,B}$.

Let $\mathcal{R}_0 := \{(T,U) \in \mathcal{R} \mid y(T,U) > 0\} = \{(T_1,U_1),\ldots,(T_n,U_n)\}$ with $T_1 \subseteq \cdots \subseteq T_n$ and $U_n \subseteq \cdots \subseteq U_1$ (this is possible by (46.38)). Let M be the $\{0,1\}$ matrix with rows indexed by $\mathcal{R}_0$ and columns indexed by S, such that $M_{(T,U),s} = 1$ if and only if $s \notin T \cup U$. Then for each s in S, the indices i for which $M_{(T_i,U_i),s} = 1$ form a contiguous interval of $\{1,\ldots,n\}$. Hence M is totally unimodular (as it is a network matrix with directed tree being a directed path). So we have the box-total dual integrality of (46.35) by Theorem 5.35. ∎

Frank and Tardos [1984a] indicated a direct derivation of this theorem from the total dual integrality of (46.1).

There are a number of straightforward corollaries. As for the integrality of polyhedra:

Corollary 46.4a. *If f (or, equivalently, g) is integer, then the polyhedra P, Q, and $F_1 \cap F_2$ are integer.*

Proof. This follows directly from Theorem 46.4. Note that $F_1 \cap F_2$ is integer if and only if P is integer. ∎

Also a min-max relation follows:

Corollary 46.4b. *Let $M_1 = (S,\mathcal{I}_1)$ and $M_2 = (S,\mathcal{I}_2)$ be matroids, with rank functions r_1 and r_2 and let k be the maximum size of a common independent set. Then for any subset U of S,*

(46.41) $$\min_I |U \cap I| = \max_{S_1,\ldots,S_t} \sum_{i=1}^{t} (k - r(S \setminus S_i)),$$

where the minimum ranges over all common independent sets I with $|I| = k$, and where the maximum ranges over all partitions of U into sets $S_1,\ldots,S_t$ ($t \geq 0$), and where $r(T)$ denotes the maximum size of a common independent set contained in T.

Proof. Apply Theorem 46.4, taking $c := \chi^U$, $f_i := r_i$, and $f := r$. ∎

It is not necessarily true that if $F_1 \cap F_2$ is integer, then also $P_1 \cap P_2$ (or $Q_1 \cap Q_2$) is integer — i.e., that the converse implication of Corollary 46.4a holds. For instance, if

(46.42) $$\begin{aligned} P_1 &:= \{(x,y,z)^{\mathsf{T}} \mid 0 \leq x \leq 1, 0 \leq y \leq 1, 0 \leq z \leq \tfrac{3}{2}, x+z \leq 2\},\\ P_2 &:= \{(x,y,z)^{\mathsf{T}} \mid 0 \leq x \leq 1, 0 \leq y \leq 1, 0 \leq z \leq \tfrac{3}{2}, y+z \leq 2\}, \end{aligned}$$

then $F_1 \cap F_2 = \{(1,1,1)^{\mathsf{T}}\}$, but $(\frac{1}{2},\frac{1}{2},\frac{3}{2})^{\mathsf{T}}$ is a vertex of $P_1 \cap P_2$.

Related results on integer decomposition of integer polymatroids in McDiarmid [1983].

46.7b. Further notes

Giles [1975] characterized the facets of the intersection of two polymatroids. Ageev [1988] studied the problem of maximizing a concave function over the intersection of polymatroids.

Chapter 47

Polymatroid intersection algorithmically

In this chapter we consider the problem of finding a vector of maximum weight in the intersection of two (extended) polymatroids algorithmically. We describe a strongly polynomial-time algorithm for this problem in four stages (where f_1 and f_2 are submodular set functions on S):

- a strongly polynomial-time algorithm finding a maximum-size vector in $EP_{f_1} \cap EP_{f_2}$ (Section 47.1),
- a strongly polynomial-time algorithm finding a common base vector of f_1 and f_2 maximizing $x(s)$ for some prescribed $s \in S$ (Section 47.2),
- a polynomial-time algorithm finding a maximum-weight common base vector of f_1 and f_2 (Section 47.3),
- a strongly polynomial-time algorithm finding a maximum-weight common base vector of f_1 and f_2 (Section 47.4).

At the base of the algorithms is submodular function minimization, which leads back to the 'consistent breadth-first search' technique proposed in a pioneering paper of Schönsleben [1980] on polymatroid intersection.

47.1. A maximum-size common vector in two polymatroids

We first consider the problem:

(47.1) given: submodular set functions f_1 and f_2 on a set S (by value giving oracles),
find: an $x \in EP_{f_1} \cap EP_{f_2}$ maximizing $x(S)$, and a $T \subseteq S$ with $x(S) = f_1(T) + f_2(S \setminus T)$.

So T certifies that x indeed maximizes $x(S)$ over $EP_{f_1} \cap EP_{f_2}$, since for any $x' \in EP_{f_1} \cap EP_{f_2}$ we have:

(47.2) $$x'(S) = x'(T) + x'(S \setminus T) \leq f_1(T) + f_2(S \setminus T) = x(S).$$

On the other hand, x certifies that T minimizes $f_1(T) + f_2(S \setminus T)$.

Then (Lawler and Martel [1982a], extending a weakly polynomial bound of Schönsleben [1980]):

Theorem 47.1. *Problem* (47.1) *is solvable in strongly polynomial-time.*

Proof. We can assume that $f_1(\emptyset) = 0$ and $f_2(\emptyset) = 0$. Define the submodular set function f on S by

$$f(U) := f_1(U) + f_2(S \setminus U) - f_2(S) \tag{47.3}$$

for $U \subseteq S$. With the submodular function minimization algorithm described in Section 45.4 we find a subset T of S minimizing f. So, by Corollary 46.1b, $f(T) + f_2(S)$ is equal to the maximum of $x(S)$ over $EP_{f_1} \cap EP_{f_2}$.

The submodular function minimization algorithm of Section 45.4 also gives vertices $b_1, \ldots, b_k$ of EP_f and $\lambda_1, \ldots, \lambda_k \geq 0$ with $\lambda_1 + \cdots + \lambda_k = 1$ such that for

$$y := \lambda_1 b_1 + \cdots + \lambda_k b_k \tag{47.4}$$

we have $y(T) = f(T)$, $\mathrm{supp}^-(y) \subseteq T$, and $\mathrm{supp}^+(y) \subseteq S \setminus T$. (Here, as usual, $\mathrm{supp}^+(x) := \{s \in S \mid x(s) > 0\}$ and $\mathrm{supp}^-(x) := \{s \in S \mid x(s) < 0\}$.)

Now for each $i = 1, \ldots, k$, we can find $b'_i \in EP_{f_1}$ and $b''_i \in EP_{f_2}$ with $b_i = b'_i - b''_i$. Indeed, let $u_1, \ldots, u_n$ be a total order of S generating b_i. (That is, $b_i(u_j) = f(\{u_1, \ldots, u_j\}) - f(\{u_1, \ldots, u_{j-1}\})$ for $j = 1, \ldots, n$. These orderings are also implied by the submodular function minimization algorithm.) Let b'_i be the vertex of EP_{f_1} generated by the order $u_1, \ldots, u_n$ (that is, $b'_i(u_j) = f_1(\{u_1, \ldots, u_j\}) - f_1(\{u_1, \ldots, u_{j-1}\})$ for $j = 1, \ldots, n$). Let b''_i be the vertex of EP_{f_2} generated by the order $u_n, u_{n-1}, \ldots, u_1$ (that is, $b''_i(u_j) = f_2(\{u_j, \ldots, u_n\}) - f_2(\{u_{j+1}, \ldots, u_n\})$ for $j = 1, \ldots, n$). Then by definition of f we have $b_i = b'_i - b''_i$, since for each j:

$$\begin{aligned} b_i(u_j) &= f(\{u_1, \ldots, u_j\}) - f(\{u_1, \ldots, u_{j-1}\}) \\ &= f_1(\{u_1, \ldots, u_j\}) + f_2(\{u_{j+1}, \ldots, u_n\}) - f_1(\{u_1, \ldots, u_{j-1}\}) \\ &\quad - f_2(\{u_j, \ldots, u_n\}) = b'_i(u_j) - b''_i(u_j). \end{aligned} \tag{47.5}$$

Define

$$x' := \sum_{i=1}^{k} \lambda_i b'_i,\ x'' := \sum_{i=1}^{k} \lambda_i b''_i, \text{ and } x := x' \wedge x'', \tag{47.6}$$

where $\wedge$ stands for taking coordinatewise minimum. As $x' \in EP_{f_1}$ and $x'' \in EP_{f_2}$, we know $x \in EP_{f_1} \cap EP_{f_2}$. Also, as $y = x' - x''$, we know that if $u \in T$, then $y(u) \leq 0$, hence $x''(u) \geq x'(u)$, and therefore $x(u) = x'(u)$. Similarly, if $u \in S \setminus T$, then $x(u) = x''(u)$. Hence

$$\begin{aligned} x(S) &= x(T) + x(S \setminus T) = x'(T) + x''(S \setminus T) = (x' - x'')(T) + x''(S) \\ &= y(T) + x''(S) = f(T) + f_2(S) = f_1(T) + f_2(S \setminus T), \end{aligned} \tag{47.7}$$

as required. ∎

47.2. Maximizing a coordinate of a common base vector

Theorem 47.1 implies the strong polynomial-time solvability of:

(47.8) given: submodular set functions f_1 and f_2 on a set S (by value giving oracles) and an element $s \in S$,
find: a common base vector x of f_1 and f_2 maximizing $x(s)$, and subsets S_1 and S_2 of S with $S_1 \cap S_2 = \{s\}$, $S_1 \cup S_2 = S$, and $x(S_i) = f_i(S_i)$ for $i = 1, 2$.

This is a result of Frank [1984a]:

Theorem 47.2. *Problem* (47.8) *is solvable in strongly polynomial time.*

Proof. We can assume that $f_1(S) = f_2(S)$ and that f_1 and f_2 have a common base vector (this can be checked by Theorem 47.1). Hence

(47.9) $f_1(S) \leq f_1(U) + f_2(S \setminus U)$

for each $U \subseteq S$. Define $S' := S \setminus \{s\}$.

First determine S_1, S_2 with $S_1 \cap S_2 = \{s\}$ and $S_1 \cup S_2 = S$ and minimizing $f_1(S_1) + f_2(S_2)$. This can be done by minimizing the submodular function $f_1(U + s) + f_2(S \setminus U)$ over $U \subseteq S'$.

Define

(47.10) $\alpha := f_1(S_1) + f_2(S_2) - f_1(S)$.

For $i = 1, 2$ and $U \subseteq S'$, define

(47.11) $g_i(U) := \min\{f_i(U), f_i(U + s) - \alpha\}$.

Then g_1 and g_2 are submodular set functions on S', as is easy to check. Moreover,

(47.12) $g_i(S') = f_i(S) - \alpha$.

To show this, we may assume that $i = 1$. Then we must show:

(47.13) $f_1(S') \geq f_1(S) - \alpha = 2f_1(S) - f_1(S_1) - f_2(S_2)$.

Now $f_1(S_1 \setminus \{s\}) + f_2(S_2) \geq f_1(S)$ (since f_1 and f_2 have a common base vector) and $f_1(S_1) - f_1(S_1 \setminus \{s\}) \geq f_1(S) - f_1(S')$ (by the submodularity of f_1). These two inequalities imply (47.13).

Then

(47.14) g_1 and g_2 have a common base vector.

Otherwise, S' can be partitioned into sets R_1 and R_2 with

(47.15) $g_1(R_1) + g_2(R_2) < g_1(S')$.

If $g_1(R_1) = f_1(R_1)$ and $g_2(R_2) = f_2(R_2)$, then (47.15) implies

(47.16) $$2f_1(S) > f_1(S_1) + f_2(S_2) + f_1(R_1) + f_2(R_2) \\ \geq f_1(S_1 \cap R_1) + f_1(S_1 \cup R_1) + f_2(S_2 \cap R_2) + f_2(S_2 \cup R_2).$$

By symmetry, we can assume that $f_1(S) > f_1(S_1 \cap R_1) + f_2(S_2 \cup R_2)$. However, $S_1 \cap R_1$ and $S_2 \cup R_2$ partition S, contradicting (47.9).

If $g_1(R_1) = f_1(R_1)$ and $g_2(R_2) = f_2(R_2 + s) - \alpha$, then (47.15) implies

(47.17) $$f_1(S) - \alpha > f_1(R_1) + f_2(R_2 + s) - \alpha,$$

and hence $f_1(S) > f_1(R_1) + f_2(R_2 + s)$, contradicting (47.9).

If $g_1(R_1) = f_1(R_1 + s) - \alpha$ and $g_2(R_2) = f_2(R_2 + s) - \alpha$, then (47.15) implies

(47.18) $$f_1(S) - \alpha > f_1(R_1 + s) + f_2(R_2 + s) - 2\alpha,$$

implying $f_1(S_1) + f_2(S_2) > f_1(R_1 + s) + f_2(R_2 + s)$, contradicting the minimality of $f_1(S_1) + f_2(S_2)$. This proves (47.14).

By Theorem 47.1, we can find in strongly polynomial time a common base vector x of g_1 and g_2. So $x(S') = g_1(S')$. Extend x to S by defining $x(s) := \alpha$. Then

(47.19) x is a common base vector of f_1 and f_2.

By symmetry, it suffices to show that x is a base vector of f_1. First, x belongs to EP_{f_1}, since for each $U \subseteq S'$ we have

(47.20) $$x(U) \leq g_1(U) \leq f_1(U) \text{ and} \\ x(U + s) = x(U) + \alpha \leq g_1(U) + \alpha \leq f_1(U + s).$$

Next, x is a base vector of f_1, since

(47.21) $$x(S) = x(S') + \alpha = g_1(S') + \alpha = f_1(S),$$

by (47.12). This proves (47.19).

Moreover,

(47.22) $$x(S_i) = f_i(S_i)$$

for $i = 1, 2$. Indeed (for $i = 1$),

(47.23) $$x(S_1) = x(S) - x(S_2 \setminus \{s\}) \geq f_1(S) - g_2(S_2 \setminus \{s\}) \\ \geq f_1(S) - f_2(S_2) + \alpha = f_1(S_1).$$

This proves (47.22), which implies that x is a common base vector of f_1 and f_2 maximizing $x(s)$, as for any common base vector z of f_1 and f_2 we have

(47.24) $$z(s) = z(S_1) + z(S_2) - z(S) \leq f_1(S_1) + f_2(S_2) - f_1(S) \\ = x(S_1) + x(S_2) - x(S) = x(s).$$

So x, S_1, and S_2 have the required properties. ∎

47.3. Weighted polymatroid intersection in polynomial time

It may be shown with the ellipsoid method that the following problem is solvable in polynomial time:

(47.25) given: submodular functions f_1, f_2 on a set S (by value giving oracles) and a function $w : S \to \mathbb{Z}$,
find: a common base vector x of f_1 and f_2 maximizing $w^{\mathsf{T}}x$, and $w_1, w_2 : S \to \mathbb{Z}$ with $w = w_1 + w_2$ such that, for each $i = 1, 2$, x maximizes $w_i^{\mathsf{T}}x$ over all base vectors of f_i.

Cunningham and Frank [1985] gave, with the help of Theorem 47.2, a combinatorial polynomial-time algorithm (using submodular function minimization).

In order to describe this, we first give an auxiliary result concerning polymatroids. Let f be a submodular set function on S and let F be a face of EP_f. Define

(47.26) $$F^{\downarrow} := F - \mathbb{R}^S_+.$$

Then $F^{\downarrow}$ is an extended polymatroid again. Moreover, algorithmic properties for $F^{\downarrow}$ can be deduced from those for EP_f:

Lemma 47.3α. *Let f be a submodular set function on S, let $w : S \to \mathbb{Z}_+$, and let F be the set of vectors x in EP_f maximizing $w^{\mathsf{T}}x$. Then there is a submodular set function f' on S with $F^{\downarrow} = EP_{f'}$. Moreover, if f is given by a value giving oracle, $f'(U)$ can be computed in strongly polynomial time, for any $U \subseteq S$.*

Proof. We can assume that $f(\emptyset) = 0$. Let $\emptyset \neq T_1 \subset T_2 \subset \cdots \subset T_{k-1} \subset T_k = S$ be the (unique) sets satisfying

(47.27) $$w = \lambda_1 \chi^{T_1} + \cdots + \lambda_k \chi^{T_k},$$

for some $\lambda_1, \ldots, \lambda_{k-1} > 0$ and $\lambda_k \geq 0$. Set $T_0 := \emptyset$, and define f' by:

(47.28) $$f'(U) := \sum_{i=1}^{k} (f((U \cap T_i) \cup T_{i-1}) - f(T_{i-1})),$$

for $U \subseteq S$. Then f' is submodular, as it is the sum of k submodular functions. Also,

(47.29) $$f' \leq f,$$

since for each U we have, by the submodularity of f:

(47.30) $$\begin{aligned} f'(U) &= \sum_{i=1}^{k} (f((U \cap T_i) \cup T_{i-1}) - f(T_{i-1})) \\ &\leq \sum_{i=1}^{k} (f(U \cap T_i) - f(U \cap T_{i-1})) = f(U). \end{aligned}$$

We show:

(47.31) $F^{\downarrow} = EP_{f'}$.

To see $\subseteq$, it suffices to show that $F \subseteq EP_{f'}$. Let $x \in F$. So $x(T_i) = f(T_i)$ for $i = 0, \ldots, k-1$. Hence

$$
\begin{aligned}
(47.32) \qquad x(U) &= \sum_{i=1}^{k} x(U \cap (T_i \setminus T_{i-1})) = \sum_{i=1}^{k} (x((U \cap T_i) \cup T_{i-1}) - x(T_{i-1})) \\
&\leq \sum_{i=1}^{k} (f((U \cap T_i) \cup T_{i-1}) - f(T_{i-1})) = f'(U)
\end{aligned}
$$

for each $U \subseteq S$. This proves that $x \in EP_{f'}$.

To see $\supseteq$ in (47.31), it suffices to show that any $x \in EP_{f'}$ with $x(S) = f'(S)$ belongs to F. As $f' \leq f$ we know that $x \in EP_f$. So it suffices to show that $x(T_j) = f(T_j)$ for $j = 1, \ldots, k$ (as this implies that x maximizes $w^{\mathsf{T}}x$ over EP_f, by the greedy algorithm). Now, as $f'(S) = f(S)$:

$$
\begin{aligned}
(47.33) \qquad x(T_j) &= x(S) - x(S \setminus T_j) \geq f'(S) - f'(S \setminus T_j) \\
&= f(S) - \sum_{i=1}^{k} (f((T_i \setminus T_j) \cup T_{i-1}) - f(T_{i-1})) \\
&= f(S) - \sum_{i=j+1}^{k} (f(T_i) - f(T_{i-1})) = f(T_j).
\end{aligned}
$$

This proves (47.31). ∎

We also will use the following lemma:

Lemma 47.3β. *Let f be a submodular set function on S, let $w : S \to \mathbb{Z}$, and let F be the set of base vectors x of f maximizing $w^{\mathsf{T}}x$. Let $U \subseteq S$ and let x maximize $x(U)$ over F. Then x maximizes $(w + \chi^U)^{\mathsf{T}}x$ over all base vectors of f.*

Proof. Let $w' := w + \chi^U$. As x maximizes $x(U)$ over F, we know that x maximizes ${w'}^{\mathsf{T}}x$ over F. Also, some $z \in F$ maximizes ${w'}^{\mathsf{T}}z$ over EP_f, by the greedy method, as there is an ordering of S in which both w and w' are monotonically nondecreasing, and so EP_f has a vertex z maximizing both $w^{\mathsf{T}}z$ and ${w'}^{\mathsf{T}}z$.

As ${w'}^{\mathsf{T}}x \geq {w'}^{\mathsf{T}}z$, x maximizes ${w'}^{\mathsf{T}}x$ over EP_f. ∎

Now we can derive:

Theorem 47.3. *Problem* (47.25) *is solvable in polynomial time.*

Proof. We give a polynomial-time algorithm to transform a solution of (47.25) for some w to a solution of (47.25) for $w := w + \chi^s$, for any $s \in S$. This implies a polynomial-time algorithm for (47.25), since we can assume that $w \geq \mathbf{0}$, and since any $w \geq \mathbf{0}$ can be obtained from $w = \mathbf{0}$ by a polynomially bounded number of resettings $w := 2w$ and $w := w + \chi^s$ for $s \in S$. Note that for $w = \mathbf{0}$, (47.25) is trivial, and that a solution x, w_1, w_2 for w yields a solution $x, 2w_1, 2w_2$ for $2w$.

Let $s \in S$. Let x, w_1, w_2 be a solution of (47.25) for some w. For $i = 1, 2$, let F_i be the set of all vectors $x \in EP_{f_i}$ maximizing $w_i^{\mathsf{T}} x$ and let f_i' be a submodular function satisfying $F_i^{\downarrow} = EP_{f_i'}$ (Lemma 47.3α). Applying Theorem 47.2 to f_1', f_2', we find a common base vector x' of f_1' and f_2' maximizing $x'(s)$, and subsets S_1, S_2 of S with $S_1 \cap S_2 = \{s\}$, $S_1 \cup S_2 = S$, and $x'(S_1) = f_1'(S_1)$, $x'(S_2) = f_2'(S_2)$. Then x' maximizes $x'(S_1)$ over $EP_{f_1'}$, and x' maximizes $x'(S_2)$ over $EP_{f_2'}$. Hence, by Lemma 47.3β, x' is a base vector of f_1' maximizing $(w_1 + \chi^{S_1})^{\mathsf{T}} x'$, and also, x' is a base vector of f_2' maximizing $(w_2 + \chi^{S_2})^{\mathsf{T}} x'$. So

(47.34) $$x', w_1' := w_1 + \chi^{S_1} - \chi^S, w_2' := w_2 + \chi^{S_2},$$

gives a solution of (47.25) for $w + \chi^s$. ∎

47.4. Weighted polymatroid intersection in strongly polynomial time

A general simultaneous diophantine approximation method of Frank and Tardos [1985,1987] implies that (47.25) is *strongly* polynomial-time solvable. Fujishige, Röck, and Zimmermann [1989] showed that from Theorem 47.3 a combinatorial strongly polynomial-time algorithm can be derived, by extending the method of Tardos [1985a] for the minimum-cost circulation problem.

To prove this, we first show a sensitivity result. Let f_1, f_2 be submodular set functions on S. Call a pair $w_1, w_2 : S \to \mathbb{R}$ *good* if there exists an x that maximizes $w_i^{\mathsf{T}} x$ over EP_{f_i}, for both $i = 1$ and $i = 2$.

Lemma 47.4α. *Let $w : S \to \mathbb{Q}$ and let w_1, w_2 be a good pair with $w = w_1 + w_2$. Then for any $\tilde{w} : S \to \mathbb{Q}$ with $\tilde{w} \geq w$ there exists a good pair $\tilde{w}_1, \tilde{w}_2$ with $\tilde{w} = \tilde{w}_1 + \tilde{w}_2$ and $\|\tilde{w}_i - w_i\|_\infty \leq \|\tilde{w} - w\|_1$ for $i = 1, 2$.*

Proof. We can assume that w and $\tilde{w}$ are integer, and that $\|\tilde{w} - w\|_1 = 1$ (as the general case then follows inductively).

Let F_i be the set of all x maximizing $w_i^{\mathsf{T}} x$ over EP_{f_i}. Let f_i' be a submodular function satisfying $F_i^{\downarrow} = EP_{f_i'}$. Let s be such that $\tilde{w}(s) = w(s) + 1$. By the solvability of problem (47.8), there is a common base vector x of f_1' and f_2' maximizing x_s, and there exist S_1, S_2 with $S_1 \cap S_2 = \{s\}$ and $S_1 \cup S_2 = S$ such that $x(S_1) = f_1'(S_1)$ and $x(S_2) = f_2'(S_2)$. Define

(47.35) $$\tilde{w}_1 := w_1 + \chi^{S_1} - \chi^S, \tilde{w}_2 := w_2 + \chi^{S_2}.$$

So $\tilde{w} = \tilde{w}_1 + \tilde{w}_2$. By Lemma 47.3$\beta$, x maximizes $\tilde{w}_i^{\mathsf{T}}x$ over EP_{f_i} for $i = 1, 2$. Therefore, the pair $\tilde{w}_1, \tilde{w}_2$ is good. As $\|\tilde{w}_i - w_i\|_\infty \leq 1$ for $i = 1, 2$, this proves the lemma. ∎

Theorem 47.4. *Given submodular functions f_1, f_2 on a set S and $w \in \mathbb{Q}^S$, one can find a common base vector x of f_1 and f_2 maximizing $w^{\mathsf{T}}x$, in strongly polynomial time.*

Proof. Let be given submodular functions f_1, f_2 on a set S and a function $w : S \to \mathbb{Q}$. We may assume that f_1 and f_2 have a common base vector. (This can be checked by Theorem 47.1.)

We keep chains $\mathcal{C}_1, \mathcal{C}_2$ of subsets of S such that for $i = 1, 2$ and each $U \in \mathcal{C}_i$:

(47.36) $x(U) = f_i(U)$ for each common base vector x of f_1 and f_2 maximizing $w^{\mathsf{T}}x$,

and such that $S \in \mathcal{C}_1$ and $S \in \mathcal{C}_2$. Initially we set $\mathcal{C}_i := \{S\}$ for $i = 1, 2$. We describe an iteration that either extends $\mathcal{C}_1$ or $\mathcal{C}_2$, or gives a solution x.

We can assume that, for $i = 1, 2$,

(47.37) each base vector x of f_i satisfies $x(U) = f_i(U)$ for each $U \in \mathcal{C}_i$.

Indeed, let F_i be the set of vectors x in EP_{f_i} with $x(U) = f_i(U)$ for each $U \in \mathcal{C}_i$. So F_i is equal to the set of $x \in EP_{f_i}$ maximizing $c_i^{\mathsf{T}}x$, where $c_i := \sum_{U \in \mathcal{C}_i} \chi^U$. By Lemma 47.3$\alpha$, we can find f_i' with $F_i^{\downarrow} = EP_{f_i'}$. By (47.36), replacing the f_i by f_i' does not change the set of optimum solutions x of our problem.

Let

(47.38) $L :=$ linear hull of $\{\chi^U \mid U \in \mathcal{C}_1 \cup \mathcal{C}_2\}$.

Determine $y \in L$ minimizing

(47.39) $\|w - y\|_\infty$.

This can be done in strongly polynomial time as follows. For $i = 1, 2$, let $\mathcal{P}_i$ be the partition of S into nonempty classes such that u and v belong to the same class if and only if there is no set in $\mathcal{C}_i$ containing exactly one of u, v. Let D be the directed graph with vertex set $\mathcal{P}_1 \cup \mathcal{P}_2$ such that for each $v \in S$ there is an arc of length $w(v)$ from $U \in \mathcal{P}_1$ to $W \in \mathcal{P}_2$ with $v \in U \cap W$, and an arc of length $-w(v)$ in the reverse direction. Determine the minimum mean-length α of a directed circuit in D (cf. Section 8.5). It is the minimum α for which there exist $p_i : \mathcal{P}_i \to \mathbb{Q}$ such that

(47.40) $-\alpha \leq w(v) + p_1(U) - p_2(W) \leq \alpha$

for each arc as described. Then

(47.41) $$y := -\sum_{U \in \mathcal{P}_1} p_1(U)\chi^U + \sum_{W \in \mathcal{P}_2} p_2(W)\chi^W$$

minimizes (47.39).

Let α be the value of (47.39). If $\alpha = 0$, then $w \in L$, and so

(47.42) $$w = \sum_{i=1}^{2} \sum_{U \in \mathcal{C}_i} \lambda_i(U)\chi^U$$

for functions $\lambda_i : \mathcal{C}_i \to \mathbb{Q}$. Then for any common base vector x of f_1 and f_2 we have

(47.43) $$w^{\mathsf{T}}x = \sum_{i=1}^{2} \sum_{U \in \mathcal{C}_i} \lambda_i(U)x(U) = \sum_{i=1}^{2} \sum_{U \in \mathcal{C}_i} \lambda_i(U)f_i(U).$$

So each common base vector is optimum. As we can find any common base vector in strongly polynomial time (by Theorem 47.1), we have solved the problem.

So we can assume that $\alpha > 0$. Define $w' : S \to \mathbb{Z}$ by

(47.44) $$w' := \lfloor \frac{5n^2}{\alpha}(w - y) \rfloor,$$

where $n := |S|$. By definition of α, $\|w'\|_\infty = 5n^2$. Hence by Theorem 47.3, we can find in strongly polynomial time a common base vector x' of f_1 and f_2 and $w'_1, w'_2 : S \to \mathbb{Z}$ with $w' = w'_1 + w'_2$ such that x' is a base vector of f_i maximizing ${w'}_i^{\mathsf{T}} x'$, for $i = 1, 2$.

For $i = 1, 2$, we can determine a chain $\mathcal{D}_i$ of subsets of S (with $S \in \mathcal{D}_i$) and a function $\lambda_i : \mathcal{D}_i \to \mathbb{Z}$ such that

(47.45) $$w'_i = \sum_{W \in \mathcal{D}_i} \lambda_i(W)\chi^W$$

and such that $\lambda_i(W) > 0$ if $W \neq S$. We show that

(47.46) there exist $i \in \{1, 2\}$ and $W \in \mathcal{D}_i$ with $\lambda_i(W) > 2n$ and $\chi^W \notin L$.

Suppose not. Let $\mathcal{D}'_i := \{W \in \mathcal{D}_i \mid \chi^W \notin L\}$, and $\mathcal{D}''_i := \mathcal{D}_i \setminus \mathcal{D}'_i$, for $i = 1, 2$. So if $W \in \mathcal{D}'_i$, then $\lambda_i(W) \leq 2n$. This gives the contradiction:

(47.47) $$\begin{aligned} 4n^2 &\geq \|\sum_{i=1}^{2} \sum_{W \in \mathcal{D}'_i} \lambda_i(W)\chi^W\|_\infty = \|w' - \sum_{i=1}^{2} \sum_{W \in \mathcal{D}''_i} \lambda_i(W)\chi^W\|_\infty \\ &> \|\frac{5n^2}{\alpha}(w - y) - \sum_{i=1}^{2} \sum_{W \in \mathcal{D}''_i} \lambda_i(W)\chi^W\|_\infty - 1 \geq 5n^2 - 1. \end{aligned}$$

The last inequality holds as y minimizes $\|w - y\|_\infty$ over $y \in L$.

This shows (47.46). We can assume that $W \in \mathcal{D}'_1$ is such that $\lambda_1(W) > 2n$. Then:

(47.48) each optimum common base vector x of f_1 and f_2 satisfies $x(W) = f_1(W)$.

To see this, let

$$(47.49)\qquad \tilde{w} := \frac{5n^2}{\alpha}(w - y).$$

Replacing w by $\tilde{w}$ does not change the set of optimum common base vectors, since y belongs to L (implying (by our assumption (47.37)) that $y^{\mathsf{T}}x$ is the same for all common base vectors x of f_1 and f_2).

By Lemma 47.4α, there exists a good pair $\tilde{w}_1, \tilde{w}_2$ with $\tilde{w} = \tilde{w}_1 + \tilde{w}_2$ and

$$(47.50)\qquad \|\tilde{w}_i - w'_i\|_\infty \leq \|\tilde{w} - w'\|_1 < n$$

for $i = 1, 2$. Now for any $v \in W$ and $u \in S \setminus W$ we have $w'_1(v) > w'_1(u) + 2n$, as $\lambda_1(W) > 2n$, and as $\lambda_1(W') \geq 0$ for each $W' \in \mathcal{D}_1 \setminus \{S\}$. Hence, by (47.50), $\tilde{w}_1(v) > \tilde{w}_1(u)$. So (by the greedy method) any base vector x of f_1 maximizing $\tilde{w}_1^{\mathsf{T}}x$ satisfies $x(W) = f_1(W)$. This shows (47.48).

Let $\mathcal{C}_1 = \{U_1 \subset U_2 \subset \cdots \subset U_t = S\}$. For $j = 1, \ldots, t$, let $W_j := (W \cap U_j) \cup U_{j-1}$, where $U_0 := \emptyset$. Then $x(W_j) = f(W_j)$ for each optimum common base vector x (since W_j arises by taking unions and intersections from W, U_j, and U_{j-1}).

Moreover, $W_j \notin \mathcal{C}_1$ for at least one $j = 1, \ldots, t$, since

$$(47.51)\qquad \chi^W = \sum_{j=1}^{t}(\chi^{W_j} - \chi^{U_{j-1}})$$

while χ^W does not belong to L, implying that not all χ^{W_j} belong to L, and so some W_j does not belong to $\mathcal{C}_1$. So W_j can be added to $\mathcal{C}_1$, and we can iterate. ∎

From an optimum common base vector x, an optimum 'dual solution' w_1, w_2 can be derived, with a method of Cunningham and Frank [1985]. This gives:

Corollary 47.4a. *Problem* (47.25) *is solvable in strongly polynomial time.*

Proof. By Theorem 47.4, we can find a common base vector x of f_1 and f_2 maximizing $w^{\mathsf{T}}x$, in strongly polynomial time. Define a directed graph $D = (S, A)$ as follows.

For $i = 1, 2$, let A_i consist of all pairs (u, v) with $u, v \in S$ such that for each $U \subseteq V$:

$$(47.52)\qquad \text{if } x(U) = f_i(U) \text{ and } u \in U \text{ then } v \in U.$$

We can find A_i in strongly polynomial time, by finding the minimum of $f_i(U) - x(U)$ over subsets U of S with $u \in U$ and $v \notin U$ (with any strongly polynomial-time submodular function minimization algorithm).

Let D have arc set $A := A_1 \cup A_2^{-1}$ (taking two parallel arcs from u to v in case $(u, v) \in A_1$ and $(v, u) \in A_2$). Define a length function l on A by, for $(u, v) \in A$:

(47.53) $$l(u,v) := \begin{cases} w(v) - w(u) & \text{for } (u,v) \in A_1, \\ 0 & \text{for } (v,u) \in A_2. \end{cases}$$

We claim:

(47.54) D has no negative-length directed circuits.

For suppose that C is a negative-length directed circuit. We take such a C with $|AC|$ smallest. Then two consecutive arcs in C neither both belong to A_1 nor both belong to A_2^{-1}. For suppose that $a = (t,u)$ and $a' = (u,v)$ are in C and that they both belong to A_1. Then $(t,v) \in A_1$ and $l(a)+l(a') = l(t,v)$, contradicting the minimality of $|AC|$. This similarly gives a contradiction if $a, a' \in A_2^{-1}$.

So we can assume that C traverses the vertices $u_0, u_1, \ldots, u_k$ in this order, with $u_0 = u_k$, such that (u_{i-1}, u_i) belongs to A_1 if i is odd, and to A_2^{-1} if i is even. Let $X := \{u_1, u_3, \ldots, u_{k-1}\}$ and $Y := \{u_2, u_4, \ldots, u_k\}$. As C has negative length, we know $l(AC) < 0$, and hence $w(X) < w(Y)$.

By (47.52), for each $i = 1,2$ and for each $U \subseteq V$ with $x(U) = f_i(U)$ we have $|U \cap Y| \geq |U \cap X|$. Hence there exists an $\varepsilon > 0$ such that the vector

(47.55) $$x' := x + \varepsilon(\chi^X - \chi^Y)$$

belongs to EP_{f_1} and to EP_{f_2}. So, since $x'(S) = x(S)$, x' is again a common base vector of f_1 and f_2. However, $w^{\mathsf{T}}x' = w^{\mathsf{T}}x + w(X) - w(Y) > w^{\mathsf{T}}x$, contradicting the fact that x maximizes $w^{\mathsf{T}}x$. This proves (47.54).

By Theorem 8.7, we can find a potential $p : S \to \mathbb{Z}$ for D with respect to l, in strongly polynomial time. Then p satisfies

(47.56) $$\begin{array}{ll} p(v) - p(u) \leq w(v) - w(u) & \text{for each } (u,v) \in A_1, \\ p(v) - p(u) \geq 0 & \text{for each } (u,v) \in A_2. \end{array}$$

Define $w_1 := w - p$ and $w_2 := p$. We show that w_1 and w_2 are as required in (47.25).

(47.56) implies that, for each $i = 1,2$,

(47.57) if $(u,v) \in A_i$ then $w_i(v) \geq w_i(u)$.

We show that (47.57) implies that, for each $i = 1,2$, x is a base vector of f_i maximizing $w_i^{\mathsf{T}}x$, as required. We may assume $i = 1$.

Let μ and ν be the minimum and maximum value (respectively) of the entries in w_1. For $j \in \mathbb{Z}$, let $U_j := \{v \in S \mid w_1(v) \geq \mu + j\}$. Then, taking $k := \nu - \mu$,

(47.58) $$w_1 = \mu \cdot \chi^S + \sum_{j=1}^{k} \chi^{U_j}.$$

Moreover,

(47.59) $x(U_j) = f_1(U_j)$ for each $j = 1, \ldots, k$.

Indeed, for all $s \in U_j$ and $t \in S \setminus U_j$ we have $(s,t) \notin A_1$ (by (47.57), since $w_1(t) < \mu + j \leq w_1(s)$). Hence, by definition of A_1, there is a set $T_{s,t}$ with $s \in T_{s,t}$, $t \notin T_{s,t}$, and $x(T_{s,t}) = f_1(T_{s,t})$. As the collection of sets U with $x(U) = f_1(U)$ is closed under taking unions and intersections, (47.59) follows.

Then for any base vector x' of f_1 we have

$$(47.60) \qquad w_1^{\mathsf{T}} x' = \mu x'(S) + \sum_{j=1}^{k} x'(U_j) \leq \mu f_1(S) + \sum_{j=1}^{k} f_1(U_j).$$

By (47.59), we here have equality throughout for $x' := x$, which proves that x maximizes $w_1^{\mathsf{T}} x$ over all base vectors of f_1. ∎

Theorem 47.4 implies for (nonextended) polymatroids (extending a result of Schönsleben [1980] for integer f_1 and f_2 for which there is a fixed K with $P_{f_1} \cap P_{f_2} \subseteq [0,K]^S$):

Corollary 47.4b. *Given submodular set functions f_1, f_2 on S (by value giving oracles) and a weight function $w \in \mathbb{Q}^S$, we can find a maximum-weight vector $x \in P_{f_1} \cap P_{f_2}$ in strongly polynomial time.*

Proof. We can assume that $f_1(\emptyset) = f_2(\emptyset) = 0$ and that f_1 and f_2 are nondecreasing (as we can replace $f_i(U)$ by $\min_{T \supseteq U} f_i(T)$). Extend S with a new element t to a set $S' := S + t$. Define set functions f_1' and f_2' on S' by:

$$(47.61) \qquad f_i'(U) := f_i(U) \text{ and } f_i'(U+t) := 0$$

for $U \subseteq S$ and $i = 1,2$. Then f_1' and f_2' are submodular (using the nondecreasingness of f_1 and f_2). Moreover, consider any $x' \in \mathbb{R}^{S'}$ with $x'(S') = 0$. Let x be the restriction of x' to S. Then:

$$(47.62) \qquad x' \in EP_{f_i'} \text{ if and only if } x \in P_{f_i}.$$

Indeed, if $x' \in EP_{f_i'}$, then $x'(s) \geq 0$ for each $s \in S$, since $x'(S'-s) \leq f'(S'-s) = 0$ and $x'(S') = 0$, implying that $x(s) = x'(s) \geq 0$. Moreover, for each $U \subseteq S$ one has $x(U) = x'(U) \leq f_i'(U) = f_i(U)$. So $x \in P_{f_i}$.

Conversely, if $x \in P_f$, then for each $U \subseteq S$ one has $x'(U) = x(U) \leq f_i(U) = f_i'(U)$ and $x'(U+t) = x(U) - x(S) = -x(S \setminus U) \leq 0 = f_i'(U+t)$. So $x' \in EP_{f_i'}$. This proves (47.62).

Define $w' \in \mathbb{Q}^{S'}$ by $w'(v) := w(v)$ if $v \in S$, and $w'(t) := 0$. By Theorem 47.4, we can find a common base vector x' of f_1' and f_2' maximizing $w'^{\mathsf{T}} x'$ in strongly polynomial time. Let x be the restriction of x' to S. By (47.62), x maximizes $w^{\mathsf{T}} x$ over $P_{f_1} \cap P_{f_2}$. ∎

Similarly for maximum-weight common base vectors in (nonextended) polymatroids:

Corollary 47.4c. *Given submodular set functions f_1, f_2 on S (by value giving oracles) and a weight function $w \in \mathbb{Q}^S$, we can find a maximum-weight common base vector x of P_{f_1} and P_{f_2} in strongly polynomial time.*

Proof. Again, we can assume that $f_1(\emptyset) = f_2(\emptyset) = 0$ and that f_1 and f_2 are nondecreasing. Then the present corollary follows directly from Theorem 47.4, since

$$(47.63) \qquad P_{f_1} \cap P_{f_2} \cap \{x \mid x(S) = f_1(S)\} = EP_{f_1} \cap EP_{f_2} \cap \{x \mid x(S) = f_1(S)\}.$$

Indeed, if $x \in EP_{f_i}$ and $x(S) = f_i(S)$, then $x \geq \mathbf{0}$, since for any $s \in S$ one has $x_s = x(S) - x(S - s) \geq f_i(S) - f_i(S - s) \geq 0$. ∎

Back to extended polymatroids, Corollary 47.4b yields that we can optimize over the intersection of two extended polymatroids in strongly polynomial time:

Corollary 47.4d. *Given submodular set functions f_1, f_2 on S (by value giving oracles) and a weight function $w \in \mathbb{Q}_+^S$, we can find a maximum-weight vector $x \in EP_{f_1} \cap EP_{f_2}$ in strongly polynomial time.*

Proof. We may assume that $f_1(\emptyset) = f_2(\emptyset) = 0$. Let

$$(47.64) \qquad L := \max_{i=1,2}(|f_i(S)| + \sum_{s \in S} |f_i(\{s\})|).$$

Then $|f_i(U)| \leq L$ for each $i = 1, 2$ and $U \subseteq S$, since

$$(47.65) \qquad f_i(U) \leq \sum_{s \in U} f_i(\{s\}) \leq L$$

and

$$(47.66) \qquad f_i(U) \geq f_i(S) - f_i(S \setminus U) \geq f_i(S) - \sum_{s \in S \setminus U} f_i(\{s\}) \geq -L.$$

Let $K := |S| \cdot L + 1$. Then for any vertex x of $EP_{f_1} \cap EP_{f_2}$ and any $s \in S$:

$$(47.67) \qquad x(s) > -K,$$

since $x = A^{-1}b$ for some totally unimodular matrix A and some vector b whose entries are values of f_1 and f_2 (as in the proof of Theorem 46.1; observe that the entries of A^{-1} belong to $\{0, \pm 1\}$).

Define $f_i'(U) := f_i(U) + K \cdot |U|$. Then

$$(47.68) \qquad EP_{f_i'} = K \cdot \mathbf{1} + EP_{f_i}$$

for $i = 1, 2$. Hence, by (47.67), all vertices of $EP_{f_1'} \cap EP_{f_2'}$ are nonnegative. So any vector x maximizing $w^\mathsf{T} x$ over $P_{f_1'} \cap P_{f_2'}$ also maximizes $w^\mathsf{T} x$ over $EP_{f_1'} \cap EP_{f_2'}$. By Corollary 47.4b, x can be found in strongly polynomial time. ∎

47.5. Contrapolymatroids

Similar results hold for intersections of contrapolymatroids, by reduction to polymatroids. Given supermodular set functions g_1 and g_2 on S (by value giving oracles) and a weight function $w \in \mathbb{Q}^S$, we can find in strongly polynomial time:

(47.69) (i) a minimum-weight vector in $EQ_{g_1} \cap EQ_{g_2}$,
(ii) a minimum-weight common base vector of EQ_{g_1} and EQ_{g_2},
(iii) a minimum-weight vector in $Q_{g_1} \cap Q_{g_2}$, and
(iv) a minimum-weight common base vector of Q_{g_1} and Q_{g_2}.

Here (i) and (ii) follow from Corollary 47.4d and Theorem 47.4 applied to the submodular functions $-g_1$ and $-g_2$. Moreover, (iii) and (iv) follow by application of (i) and (ii) to the supermodular functions $\bar{g}_i$ given by $\bar{g}_i(U) = \max_{T \subseteq U} g_i(T)$ for $U \subseteq S$ and $i = 1, 2$ (assuming without loss of generality $g_1(\emptyset) = g_2(\emptyset) = 0$).

47.6. Intersecting a polymatroid and a contrapolymatroid

Let f be a submodular, and g a supermodular, set function on S. The results on polymatroid intersection also imply that

(47.70) a maximum-weight vector in the intersection of the extended polymatroid EP_f and the extended contrapolymatroid EQ_g can be found in strongly polynomial time,

assuming that we have value giving oracles for f and g.

To see this, we can assume that $f(\emptyset) = g(\emptyset) = 0$ and $g(S) \leq f(S)$. Let t be a new element. Define submodular set functions f_1 and f_2 on $S + t$ by:

(47.71) $f_1(U) := f(U)$, $f_1(U+t) := f(U) - g(S)$, $f_2(U) := f(S) - g(S \setminus U)$, $f_2(U + t) := -g(S \setminus U)$,

for $U \subseteq S$. Reset $f_1(S + t) := 0$. Then for each $x \in \mathbb{R}^S$ and $\lambda \in \mathbb{R}$:

(47.72) (x, λ) is a common base vector of EP_{f_1} and EP_{f_2}
$\iff \lambda = -x(S)$ and $x \in EP_f \cap EQ_g$.

To see necessity, let (x, λ) be a common base vector of EP_{f_1} and EP_{f_2}. As $f_1(S + t) = 0$, we have $\lambda = -x(S)$. Moreover, for any $U \subseteq S$, we have

(47.73) $x(U) \leq f_1(U) = f(U)$ and
$x(U) = x(S) - x(S \setminus U) = -\lambda - x(S \setminus U) \geq -f_2((S \setminus U) + t) = g(U)$.

So $x \in EP_f \cap EQ_g$.

To see sufficiency, assume $\lambda = -x(S)$ and $x \in EP_f \cap EQ_g$. Then for each $U \subseteq S$ we have:

(47.74)
$$\begin{aligned}
&x(U) \leq f(U) = f_1(U),\\
&x(U+t) = x(U) + \lambda = x(U) - x(S) \leq f(U) - g(S) = f_1(U+t),\\
&x(U) = x(S) - x(S \setminus U) \leq f(S) - g(S \setminus U) = f_2(U),\\
&x(U+t) = x(U) + \lambda = x(U) - x(S) = -x(S \setminus U) \leq -g(S \setminus U)\\
&= f_2(U+t).
\end{aligned}$$

So (x, λ) is a common base vector of EP_{f_1} and EP_{f_2}.

This shows (47.72), which implies that finding a minimum-weight vector in $EP_f \cap EQ_g$ amounts to finding a minimum-weight common base vector of EP_{f_1} and EP_{f_2}.

Similarly, we can find a modular function h satisfying $g \leq h \leq f$ in strongly polynomial time, if $g \leq f$ (Frank's discrete sandwich theorem (Corollary 46.2b)). To see this, let f_1 and f_2 be as above, and find an (x, λ) in $EP_{f_1} \cap EP_{f_2}$ maximizing $x(S) + \lambda$. If $x(S) + \lambda \geq 0$, then $x \in EP_f \cap EQ_g$, that is x gives a modular function h with $g \leq h \leq f$.

47.6a. Further notes

Polymatroid intersection is a special case of submodular flow, as discussed in Chapter 60. We therefore refer for further algorithmic work to the notes in Section 60.3e.

A preflow-push algorithm for finding a maximum common vector in the intersection of two polymatroids was presented by Fujishige and Zhang [1992].

Tardos, Tovey, and Trick [1986] gave an improved version of Cunningham and Frank's polynomial-time algorithm for weighted polymatroid intersection. Fujishige [1978a] gave a (non-polynomial-time) algorithm for weighted polymatroid intersection. Optimizing over the intersection of a base polytope and an affine space was considered by Hartvigsen [1996,1998a,2001a].

Frank [1984c] and Fujishige and Iwata [2000] gave surveys.

Chapter 48

Dilworth truncation

If a submodular function f has $f(\emptyset) < 0$, the associated extended polymatroid is empty, as the conditions $x(U) \leq f(U)$ for all U include $x(\emptyset) < f(\emptyset)$. However, by ignoring the condition for $U = \emptyset$, the obtained polyhedron is yet an extended polymatroid, for a different submodular function, denoted by $\hat{f}$. This function $\hat{f}$ is called the *Dilworth truncation* of f.

48.1. If $f(\emptyset) < 0$

Let f be a submodular set function on S. If $f(\emptyset) < 0$, the associated extended polymatroid EP_f is empty. However, by ignoring the empty set, we yet obtain an extended polymatroid. (The interest in this goes back to Dilworth [1944].)

Consider the system

(48.1) $\qquad x(U) \leq f(U)$ for $U \in \mathcal{P}(S) \setminus \{\emptyset\}$,

and the problem dual to maximizing $w^{\mathsf{T}}x$ over (48.1), for $w \in \mathbb{R}^S_+$:

(48.2)
$$\min\{\sum_{U \in \mathcal{P}(S)\setminus\{\emptyset\}} y(U)f(U) \mid y \in \mathbb{R}_+^{\mathcal{P}(S)\setminus\{\emptyset\}}, \sum_{U \in \mathcal{P}(S)\setminus\{\emptyset\}} y(U)\chi^U = w\}.$$

Recall that a collection $\mathcal{F}$ of sets is called *laminar* if

(48.3) $\qquad T \cap U = \emptyset$ or $T \subseteq U$ or $U \subseteq T$ for all $T, U \in \mathcal{F}$.

Then a basic result of Edmonds [1970b] is:

Theorem 48.1. *If f is a submodular set function on S, then* (48.2) *has an optimum solution y with $\mathcal{F} := \{U \in \mathcal{P}(S) \setminus \{\emptyset\} \mid y(U) > 0\}$ laminar.*

Proof. Let $y : \mathcal{P}(S) \setminus \{\emptyset\} \to \mathbb{R}_+$ achieve this minimum, with

(48.4)
$$\sum_{U \in \mathcal{P}(S)\setminus\{\emptyset\}} y(U)|U||S \setminus U|$$

as small as possible. Assume that $\mathcal{F}$ is not laminar, and choose $T, U \in \mathcal{F}$ violating (48.3). Let $\alpha := \min\{y(T), y(U)\}$. Decrease $y(T)$ and $y(U)$ by α, and increase $y(T \cap U)$ and $y(T \cup U)$ by α. Since

(48.5) $$\chi^{T\cap U} + \chi^{T\cup U} = \chi^{T} + \chi^{U},$$

y remains a feasible solution of (48.2). As moreover

(48.6) $$f(T \cap U) + f(T \cup U) \leq f(T) + f(U),$$

f remains optimum. However, by Theorem 2.1, sum (48.4) decreases, contradicting our assumption. ∎

This implies that system (48.1) is TDI. More generally, it implies the box-total dual integrality of (48.1):

Corollary 48.1a. *For any submodular set function f on S, system* (48.1) *is box-totally dual integral.*

Proof. Consider some $w : S \to \mathbb{Z}_+$, and problem (48.2) dual to maximizing $w^{\mathsf{T}}x$ over (48.1). By Theorem 48.1, this minimum is attained by a y with $\mathcal{F} := \{U \in \mathcal{P}(S) \setminus \{\emptyset\} \mid y(U) > 0\}$ laminar. Hence the constraints corresponding to positive entries in y form a totally unimodular matrix (by Theorem 41.11). Therefore, by Theorem 5.35, (48.1) is box-TDI. ∎

Let EP'_f denote the solution set of (48.1). So EP'_f is nonempty for each submodular function f. As for integrality we have:

Corollary 48.1b. *If f is submodular and integer, then EP'_f is integer.*

Proof. Directly from Corollary 48.1a. ∎

In fact, as we shall see in Section 48.2, EP'_f is again an extended polymatroid.

48.2. Dilworth truncation

For each submodular function f, there exists a unique largest submodular function $\hat{f}$ with the property that $\hat{f}(U) \leq f(U)$ for each nonempty $U \subseteq S$, and $\hat{f}(\emptyset) = 0$. This follows from a method of Dilworth [1944].

Let f be a submodular set function on S. The *Dilworth truncation* $\hat{f} : \mathcal{P}(S) \to \mathbb{R}$ of f is given by:

(48.7) $$\hat{f}(U) := \min\{\sum_{P\in\mathcal{P}} f(P) \mid \mathcal{P} \text{ is a partition of } U \text{ into nonempty sets}\}$$

for $U \subseteq S$. So $\hat{f}(\emptyset) = 0$ (as for $U = \emptyset$, only $\mathcal{P} = \emptyset$ qualifies in (48.7)). Dunstan [1976] showed:

Theorem 48.2. *$\hat{f}$ is submodular.*

Proof. Choose $T, U \subseteq S$, and let $\mathcal{P}$ and $\mathcal{Q}$ be partitions of T and U (respectively) into nonempty sets with

$$\hat{f}(T) = \sum_{P \in \mathcal{P}} f(P) \text{ and } \hat{f}(U) = \sum_{Q \in \mathcal{Q}} f(Q). \tag{48.8}$$

Consider the family $\mathcal{F}$ made by $\mathcal{P}$ and $\mathcal{Q}$ (taking a set twice if it occurs in both partitions). We can transform $\mathcal{F}$ iteratively into a laminar family, by replacing any $X, Y \in \mathcal{F}$ with $X \cap Y \neq \emptyset$ and $X \not\subseteq Y \not\subseteq X$ by $X \cap Y, X \cup Y$. In each iteration, the sum

$$\sum_{Z \in \mathcal{F}} f(Z) \tag{48.9}$$

does not increase (as f is submodular). As at each iteration the sum

$$\sum_{Z \in \mathcal{F}} |Z||S \setminus Z| \tag{48.10}$$

decreases (by Theorem 2.1), this process terminates. We end up with a laminar family $\mathcal{F}$.

The inclusionwise maximal sets in $\mathcal{F}$ form a partition $\mathcal{R}$ of $T \cup U$, and the remaining sets form a partition $\mathcal{S}$ of $T \cap U$. Therefore,

$$\begin{aligned} \hat{f}(T \cup U) + \hat{f}(T \cap U) &\leq \sum_{X \in \mathcal{R}} f(X) + \sum_{Y \in \mathcal{S}} f(Y) \\ &\leq \sum_{P \in \mathcal{P}} f(P) + \sum_{Q \in \mathcal{Q}} f(Q) = \hat{f}(T) + \hat{f}(U), \end{aligned} \tag{48.11}$$

showing that $\hat{f}$ is submodular. ∎

Lovász [1983c] observed that $\hat{f}$ is the unique largest among all submodular set functions g on S with $g(\emptyset) = 0$ and $g(U) \leq f(U)$ for $U \neq \emptyset$. Indeed, each subset U of S can be partitioned into nonempty sets $U_1, \ldots, U_t$ such that

$$g(U) \leq \sum_{i=1}^{t} g(U_i) \leq \sum_{i=1}^{t} f(U_i) = \hat{f}(U) \tag{48.12}$$

(the first inequality follows from the submodularity of g, as $g(\emptyset) = 0$).

Trivially, $EP_{\hat{f}} = EP'_f$. In particular, EP'_f is an extended polymatroid. Moreover, by (44.34),

Theorem 48.3.

$$\hat{f}(U) = \max\{x(U) \mid x \in EP'_f\}. \tag{48.13}$$

Proof. By (44.34), since $EP'_f = EP_{\hat{f}}$. ∎

$\hat{f}(U)$ can be computed in strongly polynomial time:

Theorem 48.4. *If a submodular set function f on S is given by a value giving oracle, then for each given $U \subseteq S$, $\hat{f}(U)$ can be computed in strongly polynomial time.*

Proof. We can assume that $U = S$. Order $S = \{s_1, \ldots, s_n\}$ arbitrarily. For $i = 1, \ldots, n$, define $U_i := \{s_1, \ldots, s_i\}$. Set $x := \mathbf{0}$. Iteratively, for $i = 1, \ldots, n$, determine

(48.14) $$\mu := \min\{f(T) - x(T) \mid s_i \in T \subseteq U_i\}$$

(with a submodular function minimization algorithm), and reset $x(s_i) := x(s_i) + \mu$.

We end up with $x \in EP'_f$ and for each $u \in S$ a subset T_u of S with $u \in T_u$ and $x(T_u) = f(T_u)$. As the collection of subsets T of S with $x(T) = f(T)$ is closed under unions and intersections of intersecting sets (cf. Theorem 44.2), we can modify the T_u in such a way that they form a partition $U_1, \ldots, U_k$ of S. Then $\hat{f}(S) = f(U_1) + \cdots + f(U_k)$, as x attains the maximum in (48.13). ∎

As a consequence, given a submodular set function f on S (by a value giving oracle), we can optimize over EP'_f in strongly polynomial time (by Corollary 44.3b, as $EP'_f = EP_{\hat{f}}$ and as we can compute $\hat{f}$).

48.2a. Applications and interpretations

Graphic matroids (Dilworth [1944], also Edmonds [1970b], Dunstan [1976]). Let $G = (V, E)$ be an undirected graph and let for each $F \subseteq E$, $f(F)$ be given by

(48.15) $$f(F) := \left|\bigcup F\right| - 1.$$

It is easily checked that the function f is submodular, and that the function $\hat{f}$ as given by (48.7) satisfies

(48.16) $$\hat{f}(F) = |V| \text{ minus the number of components of the graph } (V, F),$$

i.e., $\hat{f}$ is the rank function of the cycle matroid of G.

Geometric interpretation. The operation of making $\hat{f}$ from f can be interpreted geometrically as follows (Lovász [1977c], Mason [1977,1981]).

Let $\mathcal{F}$ be a collection of flats (subspaces) in a projective space, and define for each subset $\mathcal{F}'$ of $\mathcal{F}$, the rank $r(\mathcal{F}')$ by

(48.17) $$r(\mathcal{F}') := \text{the (projective) dimension of } \bigcup \mathcal{F}'.$$

One easily checks that r is nondecreasing and submodular and that $r(\emptyset) = 0$. Now let

(48.18) $\quad f(\mathcal{F}') := r(\mathcal{F}') - 1$

for $\mathcal{F}' \subseteq \mathcal{F}$, and consider the function $\hat{f}$. Then $\hat{f}$ can be interpreted geometrically as follows. Let H be some hyperplane 'in general position' in the projective space. Then $\hat{f}(\mathcal{F}')$ is equal to the projective dimension of $H \cap \bigcup \mathcal{F}'$, i.e., $\hat{f}$ is as given by (48.17) if we replace $\mathcal{F}$ by $\{F \cap H \mid F \in \mathcal{F}\}$ (see Lovász [1977c] and Mason [1977, 1981]).

Rigidity. Let $M = (S, \mathcal{I})$ be a loopless matroid, with rank function r. Let d be a natural number. Define the set function f on S by

(48.19) $\quad f(U) := d \cdot r(U) - d + 1,$

for $U \subseteq S$. Again, f is submodular and nondecreasing. Moreover, the function $\hat{f}$ is the rank function of a loopless matroid, as $\hat{f}(\{s\}) = f(\{s\}) = 1$ for all s in S.

Let $M_d = (S, \mathcal{I}_d)$ be this matroid. Since $EP'_f = EP_{\hat{f}}$, a subset I of S is independent in M_d if and only if

(48.20) $\quad |U| \leq d \cdot r(U) - d + 1$

for all $U \subseteq I$.

In case M is the cycle matroid of a connected graph $G = (V, E)$, this relates to the following (cf. Crapo [1979] and Crapo and Whiteley [1978]). Let the vertices of G be placed 'in general position' in the d-dimensional Euclidean space. Make the edges 'rigid bars'. Suppose now that the whole graph G is rigid (which only depends on G and not on the embedding, since the vertices are 'in general position'). Then G is called *rigid (in d dimensions)*. It is not difficult to see that the minimal sets F of edges of G for which the subgraph (V, F) is rigid, form the bases of a matroid. For $d = 1$ this matroid is just the cycle matroid of G, as can be checked easily. Laman [1970] (cf. Asimow and Roth [1978,1979]) showed that for $d = 2$, a graph $G = (V, E)$ is a base (i.e., a minimal rigid graph), if and only if

(48.21) $\quad$ (i) $|E| = 2|V| - 3$,
$\quad$ (ii) $|E[U]| \leq 2|U| - 3$, for each $U \subseteq V$.

Now if M is the cycle matroid of a rigid graph G, with rank function r, then (48.21)(ii) is equivalent to

(48.22) $\quad |F| \leq 2r(F) - 1$, for each subset F of E,

that is, by (48.20), to: E is independent in the matroid M_2, as given above. Condition (48.21)(i) implies that M_2 has rank $2r(E) - 1$. Hence, if G is rigid in 2 dimensions, then the bases of M_2 are the minimally rigid subgraphs of G in 2 dimensions.

In general, the matroid of rigid subgraphs of a graph $G = (V, E)$ (in d dimensions) has rank $d|V| - \binom{d+1}{2}$. However, it is not necessarily true that G is minimally rigid in d dimensions if and only if G has $d|V| - \binom{d+1}{2}$ edges and each subgraph (U, F) of G has at most $d|U| - \binom{d+1}{2}$ edges. For instance, if G arises from glueing two copies of the complete graph K_5 together in two vertices, and deleting the edge connecting these two vertices, then G is not rigid in 3 dimensions, but it satisfies the conditions given above for $d = 3$. (These conditions are easily seen to be necessary.)

More on the relation between rigidity and matroid union can be found in Whiteley [1988].

48.3. Intersection

Corollaries 48.1a and 48.1b on submodular functions f not necessarily satisfying $f(\emptyset) \geq 0$, can be extended to pairs of functions. Let f_1 and f_2 be submodular set functions on S, and consider the system

(48.23) $\quad x(U) \leq f_i(U)$ for $U \in \mathcal{P}(S) \setminus \{\emptyset\}$ and $i = 1, 2$.

Then:

Theorem 48.5. *System* (48.23) *is box-totally dual integral.*

Proof. Choose $w \in \mathbb{Z}^S$, and consider the problem dual to maximizing $w^{\mathsf{T}} x$ over (48.23):

(48.24)
$$\min\{\sum_{U \in \mathcal{P}(S) \setminus \{\emptyset\}} (y_1(U) f_1(U) + y_2(U) f_2(U)) \mid y_1, y_2 \in \mathbb{R}_+^{\mathcal{P}(S) \setminus \{\emptyset\}}, \sum_{U \in \mathcal{P}(S) \setminus \{\emptyset\}} (y_1(U) + y_2(U)) \chi^U = w\}.$$

Let y_1, y_2 attain the minimum.

For $i \in \{1, 2\}$, define

(48.25)
$$w_i := \sum_{U \in \mathcal{P}(S) \setminus \{\emptyset\}} y_i(U) \chi^U.$$

By Theorem 48.1, for each $i = 1, 2$,

(48.26)
$$\min\{\sum_{U \in \mathcal{P}(S) \setminus \{\emptyset\}} y_i(U) f_i(U) \mid y_i \in \mathbb{R}_+^{\mathcal{P}(S) \setminus \{\emptyset\}}, \sum_{U \in \mathcal{P}(S) \setminus \{\emptyset\}} y_i(U) \chi^U = w_i\}$$

has an optimum solution y_i with $\mathcal{F}_i := \{U \mid y_i(U) > 0\}$ laminar.

These (modified) y_1, y_2 again are optimum in (48.24). As the constraints corresponding to positive components of y_1, y_2 give a totally unimodular matrix (by Theorem 41.11), Theorem 5.35 implies that system (48.23) is box-TDI. ∎

Theorem 48.5 implies primal integrality:

Corollary 48.5a. *If f_1 and f_2 are submodular and integer, then $EP'_{f_1} \cap EP'_{f_2}$ is box-integer.*

Proof. Directly from Theorem 48.5. ∎

Given submodular functions f_1 and f_2 (by value giving oracles), we can optimize over $EP'_{f_1} \cap EP'_{f_2}$ in strongly polynomial time (by Corollary 47.4d, as $EP'_{f_1} = EP_{\hat{f}_1}$ and $EP'_{f_2} = EP_{\hat{f}_2}$).

Chapter 49

Submodularity more generally

We now discuss a number of generalizations of submodular functions, namely those defined on a subcollection $\mathcal{C}$ of the collection of all subsets of a set S. The results are similar to those for submodular functions defined on all subsets on S. Often, the corresponding polyhedra form a polymatroid for some derived submodular function defined on all subsets of S.
We consider three kinds of collections, in order of increasing generality: lattice families, intersecting families, and crossing families.

49.1. Submodular functions on a lattice family

We first consider the generalization of submodular functions to those defined on a 'lattice family'.

Let S be a finite set. A family $\mathcal{C}$ of sets is called a *lattice family* if

(49.1) $\quad T \cap U, T \cup U \in \mathcal{C}$ for all $T, U \in \mathcal{C}$.

For a lattice family $\mathcal{C}$, a function $f : \mathcal{C} \to \mathbb{R}$ is called *submodular* if

(49.2) $\quad f(T \cap U) + f(T \cup U) \leq f(T) + f(U)$

for all $T, U \in \mathcal{C}$. Consider the system

(49.3) $\quad x(U) \leq f(U)$ for $U \in \mathcal{C}$,

and the problem dual to maximizing $w^{\mathsf{T}}x$ over (49.3), for $w \in \mathbb{R}^S$:

(49.4) $$\min\{\sum_{U \in \mathcal{C}} y(U)f(U) \mid y \in \mathbb{R}_+^{\mathcal{C}}, \sum_{U \in \mathcal{C}} y(U)\chi^U = w\}.$$

Theorem 49.1. *Let $\mathcal{C}$ be a lattice family, $f : \mathcal{C} \to \mathbb{R}$ a submodular function, and $w \in \mathbb{R}^S$. Then* (49.4) *has an optimum solution y with $\mathcal{F} := \{U \in \mathcal{C} \mid y(U) > 0\}$ a chain.*

Proof. Let $y : \mathcal{C} \to \mathbb{R}_+$ achieve this minimum, with

(49.5) $$\sum_{U \in \mathcal{C}} y(U)|U||S \setminus U|$$

as small as possible. Assume that $\mathcal{F}$ is not a chain, and choose $T, U \in \mathcal{F}$ with $T \not\subseteq U$ and $U \not\subseteq T$. Let $\alpha := \min\{y(T), y(U)\}$. Decrease $y(T)$ and $y(U)$ by α, and increase $y(T \cap U)$ and $y(T \cup U)$ by α. Since

$$\chi^{T\cap U} + \chi^{T\cup U} = \chi^T + \chi^U, \tag{49.6}$$

y remains a feasible solution of (49.4). As moreover

$$f(T \cap U) + f(T \cup U) \leq f(T) + f(U), \tag{49.7}$$

f remains optimum. However, by Theorem 2.1, sum (49.5) decreases, contradicting our assumption. ∎

This implies the box-total dual integrality of (49.3):

Corollary 49.1a. *If $\mathcal{C}$ is a lattice family and $f : \mathcal{C} \to \mathbb{R}$ is submodular, then system* (49.3) *is box-TDI.*

Proof. Consider some $w : \mathcal{C} \to \mathbb{Z}$, and problem (49.4) dual to maximizing $w^{\mathsf{T}}x$ over (49.3). By Theorem 49.1, this minimum is attained by a y with $\mathcal{F} := \{U \in \mathcal{C} \mid y(U) > 0\}$ a chain. So the constraints corresponding to positive components of y form a totally unimodular matrix (by Theorem 41.11). Hence by Theorem 5.35, (49.3) is box-TDI. ∎

For any $\mathcal{C} \subseteq \mathcal{P}(S)$ and $f : \mathcal{C} \to \mathbb{R}$, define:

$$\begin{aligned} P_f &:= \{x \in \mathbb{R}^S \mid x \geq \mathbf{0}, x(U) \leq f(U) \text{ for each } U \in \mathcal{C}\}, \\ EP_f &:= \{x \in \mathbb{R}^S \mid x(U) \leq f(U) \text{ for each } U \in \mathcal{C}\}. \end{aligned} \tag{49.8}$$

Then Corollary 49.1a implies:

Corollary 49.1b. *If $\mathcal{C}$ is a lattice family and $f : \mathcal{C} \to \mathbb{R}$ is submodular and integer, then EP_f is box-integer.*

Proof. Directly from Corollary 49.1a. ∎

Another consequence of Theorem 49.1 is that a submodular function f on a lattice family is uniquely determined by EP_f (given the lattice family):

Corollary 49.1c. *If $\mathcal{C}$ is a lattice family and $f : \mathcal{C} \to \mathbb{R}$ is submodular, then*

$$f(U) = \max\{x(U) \mid x \in EP_f\} \tag{49.9}$$

for each $U \in \mathcal{C}$.

Proof. Let $w := \chi^U$ and let y attain minimum (49.4), with $\mathcal{F} := \{T \in \mathcal{C} \mid y(T) > 0\}$ a chain. Since

$$\chi^U = w = \sum_{T\in\mathcal{F}} y(T)\chi^T, \tag{49.10}$$

we know that $\mathcal{F} = \{U\}$ and $y(U) = 1$. So the maximum in (49.9) is equal to $\sum_{T\in\mathcal{C}} y(T)f(T) = y(U)f(U) = f(U)$. ∎

We note that for any lattice family $\mathcal{C} \subseteq \mathcal{P}(S)$ with $\bigcup\mathcal{C} = S$, and any submodular function $f : \mathcal{C} \to \mathbb{R}$, the polytope P_f is a polymatroid. Indeed, define

$$(49.11) \qquad f'(U) := \min\{f(T) \mid T \in \mathcal{C}, T \supseteq U\}.$$

for $U \subseteq S$. Then f' is submodular, and $P_{f'} = P_f$.

49.2. Intersection

Also the intersection of two of the polyhedra EP_f is tractable. Let S be a finite set. For $i = 1, 2$, let $\mathcal{C}_i$ be a lattice family on S and let $f_i : \mathcal{C}_i \to \mathbb{R}$ be submodular. Consider the system

$$(49.12) \qquad \begin{aligned} x(U) &\leq f_1(U) \text{ for } U \in \mathcal{C}_1,\\ x(U) &\leq f_2(U) \text{ for } U \in \mathcal{C}_2. \end{aligned}$$

Then:

Corollary 49.1d. *System* (49.12) *is box-TDI.*

Proof. Choose $w \in \mathbb{R}^S$, and consider the problem dual to maximizing $w^{\mathsf{T}}x$ over (49.12):

$$(49.13) \qquad \begin{aligned} \min\{&\sum_{U\in\mathcal{C}_1} y_1(U)f_1(U) + \sum_{U\in\mathcal{C}_2} y_2(U)f_2(U) \mid \\ &y_1 \in \mathbb{R}_+^{\mathcal{C}_1}, y_2 \in \mathbb{R}_+^{\mathcal{C}_2}, \sum_{U\in\mathcal{C}_1} y_1(U)\chi^U + \sum_{U\in\mathcal{C}_2} y_2(U)\chi^U = w\}. \end{aligned}$$

Let y_1, y_2 attain the minimum.

For $i \in \{1, 2\}$, define

$$(49.14) \qquad w_i := \sum_{U\in\mathcal{C}_i} y_i(U)\chi^U.$$

By Theorem 49.1, for each $i = 1, 2$,

$$(49.15) \qquad \min\{\sum_{U\in\mathcal{C}_i} y_i(U)f_i(U) \mid y_i \in \mathbb{R}_+^{\mathcal{C}_i}, \sum_{U\in\mathcal{C}_i} y_i(U)\chi^U = w_i\}$$

has an optimum solution y_i with $\mathcal{F}_i := \{U \in \mathcal{C}_i \mid y_i(U) > 0\}$ a chain.

These y_1, y_2 again are optimum in (49.13). So, by Theorem 41.11, the constraints corresponding to positive components of y form a totally unimodular matrix. Hence by Theorem 5.35, (49.12) is box-TDI. ∎

This implies primal integrality:

Corollary 49.1e. *If f_1 and f_2 are submodular and integer, then $EP_{f_1} \cap EP_{f_2}$ is box-integer.*

Proof. Directly from Corollary 49.1d. ∎

49.3. Complexity

To find the minimum of a submodular function f defined on a lattice family $\mathcal{C}$ in polynomial time, just an oracle telling if a set U belongs to $\mathcal{C}$, and if so, giving $f(U)$, is not sufficient: if $\mathcal{C} = \{\emptyset, T, S\}$ for some $T \subseteq S$, with $f(\emptyset) = f(S) = 0$ and $f(T) = -1$, we cannot find T by a polynomially bounded number of oracle calls. So we need to have more information on $\mathcal{C}$.

A lattice family $\mathcal{C}$ is fully characterized by the smallest set M and the largest set L in $\mathcal{C}$, together with the pre-order $\preceq$ on S defined by:

(49.16) $\quad u \preceq v \iff$ each $U \in \mathcal{C}$ containing v also contains u.

Then $\preceq$ is a pre-order (that is, it is reflexive and transitive). A subset U of S belongs to $\mathcal{C}$ if and only if $M \subseteq U \subseteq L$ and U is a lower ideal in $\preceq$ (that is, if $v \in U$ and $u \preceq v$, then $u \in U$).

Hence $\mathcal{C}$ has a description of size $O(|S|^2)$, such that for given $U \subseteq S$ one can test in polynomial time if U belongs to $\mathcal{C}$.

For $U \subseteq S$, define

(49.17) $\quad U^{\downarrow} := \{s \in S \mid \exists t \in U : s \preceq t\}$ and
$\quad U^{\uparrow} := \{s \in S \mid \exists t \in U : t \preceq s\}$.

Set

(49.18) $\quad v^{\uparrow} := \{v\}^{\uparrow}$, $v^{\downarrow} := \{v\}^{\downarrow}$, $\tilde{v} := v^{\uparrow} \cap v^{\downarrow}$.

For any $U \subseteq S$, let $\overline{U}$ be the (unique) smallest set in $\mathcal{C}$ containing $U \cap L$; that is,

(49.19) $\quad \overline{U} = (U \cap L)^{\downarrow} \cup M$.

So having L, M, and $\preceq$, the set $\overline{U}$ can be determined in polynomial time.

Determine a number $\alpha > 0$ such that

(49.20) $\quad \alpha \geq f(S \setminus v^{\uparrow}) - f((S \setminus v^{\uparrow}) \cup \tilde{v})$ and $\alpha \geq f(v^{\downarrow}) - f(v^{\downarrow} \setminus \tilde{v})$

for all $v \in L \setminus M$. Such an α can be found by at most $4|S|$ oracle calls.

Then α satisfies, for any $X, Y \in \mathcal{C}$ with $X \subseteq Y$:

(49.21) $\quad |f(Y) - f(X)| \leq \alpha |Y \setminus X|$.

To show this, we can assume that $Y \setminus X = \tilde{v}$ for some $v \in L \setminus M$. Then $f(Y) - f(X) \leq f(v^{\downarrow}) - f(v^{\downarrow} \setminus \tilde{v}) \leq \alpha$ and $f(Y) - f(X) \geq f((S \setminus v^{\uparrow}) \cup \tilde{v}) - f(S \setminus v^{\uparrow}) \geq -\alpha$, implying (49.21).

Now define a function $\bar{f} : \mathcal{P}(S) \to \mathbb{R}$ by:

(49.22) $\quad \bar{f}(U) := f(\overline{U}) + \alpha|\overline{U} \triangle U|$

for $U \subseteq S$.

Then:

Theorem 49.2. *For any $\alpha > 0$ satisfying (49.20) for all $v \in L \setminus M$, the function $\bar{f}$ is submodular.*

Proof. First consider $T, U \subseteq L$. Then $T \subseteq \overline{T}$ and $U \subseteq \overline{U}$, and hence:

(49.23)
$$\begin{aligned}\bar{f}(T) + \bar{f}(U) &= f(\overline{T}) + \alpha|\overline{T} \setminus T| + f(\overline{U}) + \alpha|\overline{U} \setminus U| \\ &\geq f(\overline{T} \cap \overline{U}) + \alpha|(\overline{T} \cap \overline{U}) \setminus (T \cap U)| + f(\overline{T} \cup \overline{U}) + \alpha|(\overline{T} \cup \overline{U}) \setminus (T \cup U)| \\ &\geq f(\overline{T \cap U}) + \alpha|\overline{T \cap U} \setminus (T \cap U)| + f(\overline{T \cup U}) + \alpha|\overline{T \cup U} \setminus (T \cup U)| \\ &= \bar{f}(T \cap U) + \bar{f}(T \cup U).\end{aligned}$$

(The last inequality uses (49.21), since $\overline{T} \cap \overline{U} \supseteq \overline{T \cap U}$ (while $\overline{T} \cup \overline{U} = \overline{T \cup U}$).) Hence, for $T, U \subseteq S$ one has:

(49.24)
$$\begin{aligned}\bar{f}(T) + \bar{f}(U) &= \bar{f}(T \cap L) + \alpha|T \setminus L| + \bar{f}(U \cap L) + \alpha|U \setminus L| \\ &\geq \bar{f}((T \cap L) \cap (U \cap L)) + \bar{f}((T \cap L) \cup (U \cap L)) + \alpha|T \setminus L| + \alpha|U \setminus L| \\ &= \bar{f}((T \cap U) \cap L) + \bar{f}((T \cup U) \cap L) + \alpha|(T \cap U) \setminus L| + \alpha|(T \cup U) \setminus L| \\ &= \bar{f}(T \cap U) + \bar{f}(T \cup U).\end{aligned}$$

So $\bar{f}$ is submodular. ∎

The function $\bar{f}$ enables us to reduce optimization problems on submodular functions defined on a lattice family, to those defined on all subsets.

Minimization. By Theorem 45.1, the minimum of $\bar{f}$ can be found in strongly polynomial time. Hence

(49.25) if $\mathcal{C}$ is given by L, M, and $\preceq$, and a submodular function $f : \mathcal{C} \to \mathbb{R}$ is given by a value giving oracle, we can find a $U \in \mathcal{C}$ minimizing $f(U)$ in strongly polynomial time.

Indeed, if $\bar{f}$ attains its minimum at U, then $U \in \mathcal{C}$, since otherwise $\overline{U} \neq U$ and hence $\bar{f}(U) > \bar{f}(\overline{U})$ (as $\alpha > 0$), contradicting the fact that $\bar{f}$ attains its minimum at U. This shows (49.25).

Maximization over EP_f. Given a lattice family $\mathcal{C}$ of subsets of a set S, a submodular function $f : \mathcal{C} \to \mathbb{R}$, and a weight function $w \in \mathbb{Q}^S$, we can maximize $w^{\mathsf{T}}x$ over EP_f, by adapting the greedy algorithm as follows.

Note that $\max\{w^{\mathsf{T}}x \mid x \in EP_f\}$ is finite if and only if $w \geq \mathbf{0}$, $w(s) = 0$ for each $s \in S \setminus L$, and

(49.26) $\quad u \preceq v$ implies $w(u) \geq w(v)$

for all $u, v \in S$. If (49.26) is not the case, the maximum value is infinite, since if $u \preceq v$, then for any $x \in EP_f$, the vector $x + \lambda(\chi^v - \chi^u)$ belongs to EP_f for all $\lambda \geq 0$. Now, if $w(v) > w(u)$, the weight increases to infinity along this line, and therefore the maximum value is ∞.

So we can check in strongly polynomial time if $\max\{w^{\mathsf{T}}x \mid x \in EP_f\}$ is finite, and therefore we can assume that it is finite. Moreover, we can assume that $L = S$, since $w(s) = 0$ for each $s \in S \setminus L$, and hence we can delete $S \setminus L$. Similarly, we can assume that $\emptyset \in \mathcal{C}$ and $f(\emptyset) = 0$. For if $\emptyset \in \mathcal{C}$ and $f(\emptyset) < 0$, then $EP_f = \emptyset$, and if $f(\emptyset) > 0$, we can reset $f(\emptyset) := 0$, without violating the submodularity and without modifying EP_f. If $\emptyset \notin \mathcal{C}$, then we can add $\emptyset$ to $\mathcal{C}$ and set $f(\emptyset) := 0$, again maintaining submodularity and EP_f. Finally, we can assume that $\preceq$ is a partial order, since if $u \preceq v \preceq u$, then by (49.26), $w(u) = w(v)$, and each set in $\mathcal{C}$ either contains both u and v, or neither of them. So we can merge u and v; and in fact we can merge any set $\tilde{v}$ to one element.

Now let $\leq$ be a linear order such that for any u, v, if $u \preceq v$ or $w(u) > w(v)$, then $u \leq v$. By (49.26), the latter defines a partial order. So $\leq$ is a linear extension of it, and hence can be found in strongly polynomial time.

Let $S = \{s_1, \ldots, s_n\}$ with $s_1 < s_2 < \cdots < s_n$. For $i = 0, \ldots, n$, define $U_i := \{s_1, \ldots, s_i\}$. As $\leq$ is a linear extension of $\preceq$, each U_i is a lower ideal of $\preceq$, and hence each U_i belongs to $\mathcal{C}$. Define $x(s_i) := f(U_i) - f(U_{i-1})$ for $i = 1, \ldots, n$. Then x maximizes $w^{\mathsf{T}}x$ over EP_f.

To see this, let $\bar{f}$ be defined as above. Then by Theorem 44.3, x belongs to $EP_{\bar{f}}$ (as f and $\bar{f}$ coincide on each U_i), and hence x belongs to EP_f. To see that x is optimum, we have for any $z \in EP_f$:

$$(49.27)\qquad \begin{aligned} w^{\mathsf{T}}z &= \sum_{i=1}^{n-1} z(U_i)(w(s_i) - w(s_{i+1})) + z(S)w(s_n) \\ &\leq \sum_{i=1}^{n-1} f(U_i)(w(s_i) - w(s_{i+1})) + f(S)w(s_n) \\ &= \sum_{i=1}^{n} w(s_i)(f(U_i) - f(U_{i-1})) = \sum_{i=1}^{n} w(s_i)x(s_i) = w^{\mathsf{T}}x. \end{aligned}$$

This also gives a dual solution to the corresponding LP-formulation of the problem.

Maximization over intersections. Let $\mathcal{C}_1$ and $\mathcal{C}_2$ be lattice families of subsets of S and let f_1 and f_2 be submodular functions on $\mathcal{C}_1$ and $\mathcal{C}_2$ respectively. Let $\mathcal{C}_i$ be specified by L_i, M_i, and $\preceq_i$.

Find a number $\alpha > 0$ satisfying (49.20) for both $f = f_1$ and $f = f_2$. So by (49.21), $\alpha|S| + \max_{i=1,2} |f_i(L_i)|$ is an upper bound on $|f_i(U)|$ for each $i \in \{1, 2\}$ and each $U \in \mathcal{C}_i$. Define

$$(49.28)\qquad K := |S|(\alpha|S| + \max_{i=1,2} |f_i(L_i)|).$$

Now for $i = 1, 2$ and $U \subseteq S$, let $\bar{f}_i(U) := f_i(\overline{U}) + K|\overline{U} \triangle U|$ (where $\overline{U}$ is taken with respect to $\mathcal{C}_i$). So $\bar{f}_1$ and $\bar{f}_2$ are submodular (by Theorem 49.2). Then:

$$(49.29)\qquad \max\{w^{\mathsf{T}}x \mid x \in EP_{f_1} \cap EP_{f_2}\} = \max\{w^{\mathsf{T}}x \mid x \in EP_{\bar{f}_1} \cap EP_{\bar{f}_2}\},$$

if the first maximum is finite. Clearly $\geq$ holds in (49.29), since $EP_{\bar{f}_i} \subseteq EP_{f_i}$ for $i = 1, 2$. To see equality, each face of $EP_{f_1} \cap EP_{f_2}$ is determined by equations $x(U) = f_i(U)$ for $i = 1, 2$ and $U \in \mathcal{D}_i$, where $\mathcal{D}_i$ is a chain of sets in $\mathcal{C}_i$. So it is determined by a system of linear equations with totally unimodular constraint set and right-hand sides determined by function values of f_1 and f_2. So each face contains a vector x with $|x_s| \leq K$ for all $s \in S$ (by (49.28), since the inverse of a nonsingular totally unimodular matrix has all its entries in $\{0, \pm 1\}$). But any such x belongs to $EP_{\bar{f}_1} \cap EP_{\bar{f}_2}$, since for $i = 1, 2$ and $U \subseteq S$, we have:

(49.30) $$x(U) \leq x(\overline{U}) + K|\overline{U} \triangle U| \leq f_i(\overline{U}) + K|\overline{U} \triangle U| = \bar{f}_i(U)$$

(where $\overline{U}$ is taken with respect to $\mathcal{C}_i$). So we have (49.29).

Therefore, by Corollary 47.4d, we can maximize $w^{\mathsf{T}} x$ over $EP_{f_1} \cap EP_{f_2}$ in strongly polynomial time. Note that for any $w \in \mathbb{Q}^S$, we can decide in strongly polynomial time if the first maximum in (49.29) is finite. For this, we should decide if there exist $w_1, w_2 \in \mathbb{Q}^S_+$ such that $w = w_1 + w_2$ and such that for $i = 1, 2$: $w_i(s) = 0$ for $s \in S \setminus L_i$ and $u \preceq_i v$ implies $w_i(u) \geq w_i(v)$ for all u, v. This can be reduced to checking if a certain digraph with lengths has no negative-length directed circuit.

49.4. Submodular functions on an intersecting family

We next consider functions defined on a broader class of collections, the intersecting families, where the function satisfies a restricted form of submodularity. It yields an extension of the *Dilworth truncation* studied in Chapter 48.

A family $\mathcal{C}$ of sets is called an *intersecting family* if for all $T, U \in \mathcal{C}$ one has:

(49.31) if $T \cap U \neq \emptyset$, then $T \cap U, T \cup U \in \mathcal{C}$.

Let $\mathcal{C}$ be an intersecting family. A function $f : \mathcal{C} \to \mathbb{R}$ is called *submodular on intersecting pairs*, or *intersecting submodular*, if

(49.32) $$f(T) + f(U) \geq f(T \cap U) + f(T \cup U)$$

for all $T, U \in \mathcal{C}$ with $T \cap U \neq \emptyset$.

Consider the system

(49.33) $x(U) \leq f(U)$ for $U \in \mathcal{C}$,

and the problem dual to maximizing $w^{\mathsf{T}} x$ over (49.33), for $w \in \mathbb{R}^S$:

(49.34) $$\min\{\sum_{U \in \mathcal{C}} y(U) f(U) \mid y \in \mathbb{R}^{\mathcal{C}}_+, \sum_{U \in \mathcal{C}} y(U) \chi^U = w\}.$$

Recall that a collection $\mathcal{F}$ of sets is called *laminar* if

(49.35) $T \cap U = \emptyset$ or $T \subseteq U$ or $U \subseteq T$, for all $T, U \in \mathcal{F}$.

A basic result (proved with a method due to Edmonds [1970b]) is:

Theorem 49.3. *Let $\mathcal{C}$ be an intersecting family of subsets of a set S, let $f : \mathcal{C} \to \mathbb{R}$ be intersecting submodular and let $w \in \mathbb{R}^S$. Then* (49.34) *has an optimum solution y with $\mathcal{F} := \{U \in \mathcal{C} \mid y(U) > 0\}$ laminar.*

Proof. Let $y : \mathcal{C} \to \mathbb{R}_+$ achieve this minimum, with

(49.36) $$\sum_{U \in \mathcal{C}} y(U)|U||S \setminus U|$$

as small as possible. Assume that $\mathcal{F}$ is not laminar, and choose $T, U \in \mathcal{F}$ violating (49.35). Let $\alpha := \min\{y(T), y(U)\}$. Decrease $y(T)$ and $y(U)$ by α, and increase $y(T \cap U)$ and $y(T \cup U)$ by α. Since

(49.37) $$\chi^{T \cap U} + \chi^{T \cup U} = \chi^T + \chi^U,$$

y remains a feasible solution of (49.34). As moreover

(49.38) $$f(T \cap U) + f(T \cup U) \leq f(T) + f(U),$$

f remains optimum. However, by Theorem 2.1, sum (49.36) decreases, contradicting our assumption. ∎

It gives the box-total dual integrality of (49.33):

Corollary 49.3a. *Let $\mathcal{C}$ be an intersecting family of subsets of a set S and let $f : \mathcal{C} \to \mathbb{R}$ be intersecting submodular. Then system* (49.33) *is box-TDI.*

Proof. Consider problem (49.34) dual to maximizing $w^{\mathsf{T}}x$ over (49.33). By Theorem 49.3, this minimum is attained by a y with $\mathcal{F} := \{U \in \mathcal{C} \mid y(U) > 0\}$ laminar. As the matrix of constraints corresponding to $\mathcal{F}$ is totally unimodular (Theorem 41.11), Theorem 5.35 gives the corollary. ∎

49.5. Intersection

Again, these results can be extended in a natural way to pairs of functions, by derivation from Theorem 49.3.

Corollary 49.3b. *For $i = 1, 2$, let $\mathcal{C}_i$ be an intersecting family of subsets of a set S and let $f_i : \mathcal{C}_i \to \mathbb{R}$ be intersecting submodular. Then the system*

(49.39) $$\begin{aligned} x(U) &\leq f_1(U) \text{ for } U \in \mathcal{C}_1, \\ x(U) &\leq f_2(U) \text{ for } U \in \mathcal{C}_2, \end{aligned}$$

is box-TDI.

Proof. Choose $w \in \mathbb{R}^S$, and consider the problem dual to maximizing $w^\mathsf{T} x$ over (49.39):

(49.40) $$\min\{\sum_{U\in\mathcal{C}_1} y_1(U)f_1(U) + \sum_{U\in\mathcal{C}_2} y_2(U)f_2(U) \mid y_1 \in \mathbb{R}_+^{\mathcal{C}_1}, y_2 \in \mathbb{R}_+^{\mathcal{C}_2}, \sum_{U\in\mathcal{C}_1} y_1(U)\chi^U + \sum_{U\in\mathcal{C}_2} y_2(U)\chi^U = w\}.$$

Let y_1, y_2 attain the minimum. For $i \in \{1,2\}$, define

(49.41) $$w_i := \sum_{U\in\mathcal{C}_i} y_i(U)\chi^U.$$

By Theorem 49.3,

(49.42) $$\min\{\sum_{U\in\mathcal{C}_i} y_i(U)f_i(U) \mid y_i \in \mathbb{R}_+^{\mathcal{C}_i}, \sum_{U\in\mathcal{C}_i} y_i(U)\chi^U = w_i\}$$

has an optimum solution y_i with $\mathcal{F}_i := \{U \in \mathcal{C}_i \mid y_i(U) > 0\}$ laminar.

As $\mathcal{F}_1 \cup \mathcal{F}_2$ determine a totally unimodular matrix (by Theorem 41.11), Theorem 5.35 implies that system (49.39) is box-TDI. ∎

This implies the integrality of polyhedra:

Corollary 49.3c. *If f_1 and f_2 are integer, then $EP_{f_1} \cap EP_{f_2}$ is box-integer.*

Proof. Directly from Corollary 49.3b. ∎

49.6. From an intersecting family to a lattice family

Let $\mathcal{C}$ be an intersecting family of subsets of a set S and let $f : \mathcal{C} \to \mathbb{R}$ be submodular on intersecting pairs. Let $\check{\mathcal{C}}$ be the collection of all unions of sets in $\mathcal{C}$. Since $\mathcal{C}$ is closed under unions of intersecting sets, $\check{\mathcal{C}}$ is equal to the collection of *disjoint* unions of nonempty sets in $\mathcal{C}$. It is not difficult to show that $\check{\mathcal{C}}$ is a lattice family and that $\emptyset \in \check{\mathcal{C}}$.

Call a partition *proper* if its classes are nonempty. Define $\check{f} : \check{\mathcal{C}} \to \mathbb{R}$ by:

(49.43) $$\check{f}(U) := \min\{\sum_{P\in\mathcal{P}} f(P) \mid \mathcal{P} \subseteq \mathcal{C} \text{ is a proper partition of } U\}.$$

for $U \in \check{\mathcal{C}}$. So $\check{f}(\emptyset) = 0$. Then (Dunstan [1976]):

Theorem 49.4. *$\check{f}$ is submodular.*

Proof. Choose $T, U \in \check{\mathcal{C}}$, and let $\mathcal{P}$ and $\mathcal{Q}$ be partitions of T and U (respectively) into nonempty sets in $\mathcal{C}$ with

(49.44) $$\check{f}(T) = \sum_{P \in \mathcal{P}} f(P) \text{ and } \check{f}(U) = \sum_{Q \in \mathcal{Q}} f(Q).$$

Consider the family $\mathcal{F}$ made by the union of $\mathcal{P}$ and $\mathcal{Q}$ (taking a set twice if it occurs in both partitions). We can transform $\mathcal{F}$ iteratively into a laminar family, by replacing any $X, Y \in \mathcal{F}$ with $X \cap Y \neq \emptyset$ and $X \not\subseteq Y \not\subseteq X$ by $X \cap Y, X \cup Y$. In each iteration, the sum

(49.45) $$\sum_{Z \in \mathcal{F}} f(Z)$$

does not increase (as f is submodular on intersecting pairs). As at each iteration the sum

(49.46) $$\sum_{Z \in \mathcal{F}} |Z||S \setminus Z|$$

decreases (by Theorem 2.1), this process terminates. We end up with a laminar family $\mathcal{F}$.

The inclusionwise maximal sets in $\mathcal{F}$ form a partition $\mathcal{R}$ of $T \cup U$, and the remaining sets form a partition $\mathcal{S}$ of $T \cap U$. Therefore,

(49.47) $$\check{f}(T \cup U) + \check{f}(T \cap U) \leq \sum_{X \in \mathcal{R}} f(X) + \sum_{Y \in \mathcal{S}} f(Y)$$
$$\leq \sum_{P \in \mathcal{P}} f(P) + \sum_{Q \in \mathcal{Q}} f(Q) = \check{f}(T) + \check{f}(U),$$

showing that $\check{f}$ is submodular. ∎

Trivially, if $\emptyset \notin \mathcal{C}$ or if $f(\emptyset) \geq 0$, then $EP_{\check{f}} = EP_f$. Hence, by (49.9),

(49.48) $$\check{f}(U) = \max\{x(U) \mid U \in EP_f\}.$$

As we shall see in Section 49.7, this enables us to calculate $\check{f}$ from a value giving oracle, using the greedy algorithm.

49.7. Complexity

The results of the previous section enable us to reduce algorithmic problems on intersecting submodular functions, to those on submodular functions on lattice families.

If $\mathcal{C}$ is an intersecting family on S, then for each $s \in S$, the collection $\mathcal{C}_s := \{U \in \mathcal{C} \mid s \in U\}$ is a lattice family. So (like in Section 49.3) we can assume that $\mathcal{C}$ is given by a representation of $\mathcal{C}_s$ for each $s \in S$, in terms of the pre-order $\preceq_s$ given by: $u \preceq_s v$ if and only if each set in $\mathcal{C}$ containing s and v also contains u, and by $M_s := \bigcap \mathcal{C}_s$ and $L_s := \bigcup \mathcal{C}_s$; next to that we should know if $\emptyset$ belongs to $\mathcal{C}$.

We can derive the information on $\check{\mathcal{C}}$ as follows:

(49.49) $$\bigcap \check{\mathcal{C}} = \emptyset, \bigcup \check{\mathcal{C}} = \bigcup_{s\in S} L_s;\ u \preceq v \text{ if and only if } u \in M_v.$$

So we can decide in polynomial time if a set U belongs to $\check{\mathcal{C}}$.

For any intersecting submodular function f on $\mathcal{C}$, the restriction f_s of f to $\mathcal{C}_s$ is submodular. So by the results of Section 49.3, we can find a set minimizing f in strongly polynomial time.

For any $U \in \check{\mathcal{C}}$, we can calculate $\check{f}(U)$, as defined in (49.43), in strongly polynomial time, having a value giving oracle for f. To see this, we use (49.48). We can assume that $\emptyset \notin \mathcal{C}$.

Order the elements of U as $t_1, \ldots, t_k$ such that if $L_{t_j} \subset L_{t_i}$, then $j < i$. For $i = 0, \ldots, k$, let $U_i := L_{t_1} \cup \cdots \cup L_{t_i}$. So $U_k = U$.

Initially, set $x(t) := 0$ for each $t \in U$. Next, for $i = 1, \ldots, k$, calculate

(49.50) $$\mu := \min\{f(T) - x(T) \mid T \in \mathcal{C}, t_i \in T \subseteq U_i\},$$

and reset $x(t_i) := x(t_i)+\mu$. We prove, by induction on i, that for $i = 0, 1, \ldots, k$ we have, after processing $t_1, \ldots, t_i$:

(49.51)
(i) $x(T) \le f(T)$ for each $T \in \mathcal{C}$ with $T \subseteq U_i$,
(ii) for each $j = 1, \ldots, i$ there exists a $T \in \mathcal{C}$ with $t_j \in T \subseteq U_i$ and $x(T) = f(T)$.

For $i = 0$ this is trivial. Let $i \ge 1$. Consider any $T \in \mathcal{C}$ with $T \subseteq U_i$. If $t_i \in T$, then $x(T) \le f(T)$, as at processing t_i we have added μ to $x(t_i)$. If $t_i \notin T$, then $T \subseteq U_{i-1}$. For suppose that there exists a $t_j \in T$ with $t_j \notin U_{i-1}$. So $j > i$ and $t_j \in L_{t_i}$, and therefore $L_{t_j} \subseteq L_{t_i}$, implying $L_{t_j} = L_{t_i}$ (since if $L_{t_j} \subset L_{t_i}$, then $j < i$). But then $t_i \in L_{t_j} \subseteq T$, contradicting the fact that $t_i \notin T$. So $T \subseteq U_{i-1}$. As $t_i \notin T$, $x(T)$ did not change at processing t_i, and hence we know $x(T) \le f(T)$ by induction. This proves (49.51)(i).

To see (49.51)(ii), choose $j \le i$. If $j = i$, there exists after processing t_i a T as required, as we have added μ to $x(t_i)$. If $j < i$, by induction there exists a $T \in \mathcal{C}$ with $t_j \in T \subseteq U_{i-1}$ and $x(T) = f(T)$ before processing t_i. If $t_i \notin T$, $x(T) = f(T)$ is maintained at processing t_i. If $t_i \in T$, then $t_i \in U_{i-1}$, and so $t_i \in L_{t_j}$ for some $j < i$. Hence $L_{t_i} \subseteq L_{t_j}$. So, by the choice of the order of U, $L_{t_i} = L_{t_j}$. Hence before processing t_i we have $x(T') \le f(T')$ for each $T' \subseteq U_i$. So, as $x(T) = f(T)$ and $t_i \in T$, $x(t_i)$ is not modified at processing t_i. Therefore, $x(T) = f(T)$ holds also after processing t_i. This proves (49.51)(ii).

This shows (49.51), which gives, taking $i = k$, that $x(T) \le f(T)$ for each $T \in \mathcal{C}$ with $T \subseteq U$, and that for each $t \in U$, we have a T containing t with $x(T) = f(T)$. We can replace any two T and T' with $T \cap T' \ne \emptyset$ by $T \cup T'$. We end up with a partition $\mathcal{T}$ of U with $x(U) = \sum_{T\in\mathcal{T}} f(T)$. Hence we know

(49.52) $$\check{f}(U) \ge x(U) = \sum_{T\in\mathcal{T}} x(T) = \sum_{T\in\mathcal{T}} f(T) \ge \check{f}(U),$$

and therefore we have equality throughout.

Having this, we can reduce the problem of maximizing $w^{\mathsf{T}}x$ over EP_f, where f is intersecting submodular, to that of maximizing $w^{\mathsf{T}}x$ over $EP_{\check{f}}$, which can be done in strongly polynomial time by the results of Section 49.3. Similarly for intersections of two such polyhedra EP_{f_1} and EP_{f_2}.

49.8. Intersecting a polymatroid and a contrapolymatroid

For an intersecting family $\mathcal{C}$, a function $g : \mathcal{C} \to \mathbb{R}$ is called *supermodular on intersecting pairs*, or *intersecting supermodular*, if $-g$ is intersecting submodular.

Let S be a finite set. Let $\mathcal{C}$ and $\mathcal{D}$ be collections of subsets of S and let $f : \mathcal{C} \to \mathbb{R}$ and $g : \mathcal{D} \to \mathbb{R}$. Consider the system

$$\text{(49.53)} \qquad \begin{aligned} x(U) &\leq f(U) \quad \text{for } U \in \mathcal{C}, \\ x(U) &\geq g(U) \quad \text{for } U \in \mathcal{D}. \end{aligned}$$

Theorem 49.5. *If $\mathcal{C}$ and $\mathcal{D}$ are intersecting families, $f : \mathcal{C} \to \mathbb{R}$ is intersecting submodular, and $g : \mathcal{D} \to \mathbb{R}$ is intersecting supermodular, then system* (49.53) *is box-TDI.*

Proof. Choose $w \in \mathbb{Z}^S$, and consider the dual problem of maximizing $w^\mathsf{T} x$ over (49.53):

$$\text{(49.54)} \qquad \begin{aligned} \min\{\sum_{U \in \mathcal{C}} y(U) f(U) - \sum_{U \in \mathcal{D}} z(U) g(U) \mid \\ y \in \mathbb{R}_+^{\mathcal{C}}, z \in \mathbb{R}_+^{\mathcal{D}}, \sum_{U \in \mathcal{C}} y(U)\chi^U - \sum_{U \in \mathcal{D}} z(U)\chi^U = w\}. \end{aligned}$$

Let y, z attain this minimum. Define

$$\text{(49.55)} \qquad u := \sum_{U \in \mathcal{C}} y(U)\chi^U \text{ and } v := \sum_{U \in \mathcal{D}} z(U)\chi^U.$$

So y attains

$$\text{(49.56)} \qquad \min\{\sum_{U \in \mathcal{C}} y(U) f(U) \mid y \in \mathbb{R}_+^{\mathcal{C}}, \sum_{U \in \mathcal{C}} y(U)\chi^U = u\}$$

and z attains

$$\text{(49.57)} \qquad \max\{\sum_{U \in \mathcal{D}} z(U) g(U) \mid z \in \mathbb{R}_+^{\mathcal{D}}, \sum_{U \in \mathcal{D}} z(U)\chi^U = v\}.$$

By Theorem 49.3, (49.56) has an optimum solution y with $\mathcal{F} := \{U \in \mathcal{C} \mid y(U) > 0\}$ laminar. Similarly, (49.57) has an optimum solution z with $\mathcal{G} := \{U \in \mathcal{D} \mid z(U) > 0\}$ laminar. Now $\mathcal{F}$ and $\mathcal{G}$ determine a totally unimodular submatrix (by Theorem 41.11), and hence by Theorem 5.35, (49.53) is box-TDI. ∎

49.9. Submodular functions on a crossing family

Finally, we consider submodular functions defined on a crossing family. The results discussed above for submodular functions on intersecting families do not all transfer to crossing families. But certain restricted versions still hold.

A family $\mathcal{C}$ of subsets of a set S is called a *crossing family* if for all $T, U \in \mathcal{C}$ one has:

(49.58) if $T \cap U \neq \emptyset$ and $T \cup U \neq S$, then $T \cap U, T \cup U \in \mathcal{C}$.

A function $f : \mathcal{C} \to \mathbb{R}$, defined on a crossing family $\mathcal{C}$, is called *submodular on crossing pairs*, or *crossing submodular*, if for all $T, U \in \mathcal{C}$ with $T \cap U \neq \emptyset$ and $T \cup U \neq S$:

(49.59) $f(T) + f(U) \geq f(T \cap U) + f(T \cup U)$.

In general, the system

(49.60) $x(U) \leq f(U)$ for $U \in \mathcal{C}$

is *not* TDI. For instance, if $S = \{1, 2, 3\}$, $\mathcal{C} = \{\{1, 2\}, \{1, 3\}, \{2, 3\}\}$, from S, and $f(U) := 1$ for each $U \in \mathcal{C}$, then (49.60) not even determines an integer polyhedron (as $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})^{\mathsf{T}}$ is a vertex of it).

However, for any $k \in \mathbb{R}$, the system

(49.61) $x(U) \leq f(U)$ for $U \in \mathcal{C}$,
$x(S) = k$

is box-TDI. This can be done by reduction to Corollary 49.3a. Similarly for pairs of such functions. This was shown by Frank [1982b,1984a] and Fujishige [1984e].

Let $\mathcal{C}$ be a crossing family of subsets of a set S. Let $\hat{\mathcal{C}}$ be the collection of all nonempty intersections of sets in $\mathcal{C}$ (we allow the intersection of 0 sets, so $S \in \hat{\mathcal{C}}$). Since $\mathcal{C}$ is a crossing family, we know

(49.62) $\hat{\mathcal{C}} = \{U \mid U \neq \emptyset; \exists \mathcal{P} \subseteq \mathcal{C} : \mathcal{P}$ is a copartition of $S \setminus U\}$,

where a *copartition* of U is a collection $\mathcal{P}$ of subsets of S such that the collection $\{S \setminus T \mid T \in \mathcal{P}\}$ is a partition of U. We call the copartition *proper* if $T \neq S$ for each $T \in \mathcal{P}$.

Note that, in (49.62), restricting $\mathcal{P}$ to proper copartitions of $S \setminus U$, does not modify $\hat{\mathcal{C}}$. We allow $\mathcal{P} = \emptyset$, so $S \in \hat{\mathcal{C}}$.

Define $\hat{f} : \hat{\mathcal{C}} \to \mathbb{R}$ by:

(49.63) $\hat{f}(U) := \min\{\sum_{P \in \mathcal{P}} f(P) \mid \mathcal{P} \subseteq \mathcal{C}$ is a proper copartition of $S \setminus U\}$

for $U \in \hat{\mathcal{C}}$. So $\hat{f}(S) = 0$. Then:

Theorem 49.6. *$\hat{\mathcal{C}}$ is an intersecting family and $\hat{f}$ is submodular on intersecting pairs.*

Proof. Define, for $s \in S$,

(49.64) $\qquad \hat{\mathcal{C}}_s := \{U \in \hat{\mathcal{C}} \mid s \in U\}$ and $\mathcal{D} := \{S \setminus U \mid s \in U \in \mathcal{C}\}$.

As $\mathcal{C}$ is crossing, $\mathcal{D}$ is intersecting. Hence $\check{\mathcal{D}}$ is a lattice family. As $\hat{\mathcal{C}}_s = \{S \setminus U \mid U \in \check{\mathcal{D}}\}$, also $\hat{\mathcal{C}}_s$ is a lattice family. As this is true for each $s \in S$, $\hat{\mathcal{C}}$ is intersecting.

To prove that $\hat{f}$ is intersecting submodular, it suffices to show that for each $s \in S$, the restriction $\hat{f}_s$ of $\hat{f}$ to $\hat{\mathcal{C}}_s$ is submodular. Define $g : \mathcal{D} \to \mathbb{R}$ by $g(U) := f(S \setminus U)$ for $U \in \mathcal{D}$. Then g is intersecting submodular (as f is crossing submodular). Hence, by Theorem 49.4, $\check{g}$ is submodular on $\check{\mathcal{D}}$. As $\hat{f}_s(U) = \check{g}(S \setminus U)$ for $U \in \hat{\mathcal{C}}_s$, $\hat{f}_s$ is submodular. ∎

Fujishige [1984e] showed that the following box-TDI result can be derived from Corollary 49.3a:

Theorem 49.7. *Let $\mathcal{C}$ be a crossing family of subsets of S, let $f : \mathcal{C} \to \mathbb{R}$ be crossing submodular, and let $k \in \mathbb{R}$. Then system* (49.61) *is box-TDI and determines the polyhedron of maximal vectors of $EP_{f'}$ for some submodular function f' defined on a lattice family.*

Proof. We can assume that $k = 0$, since, choosing any $t \in S$ and resetting $f(U) := f(U) - k$ for all $U \in \mathcal{C}$ with $t \in U$, does not change the box-total dual integrality of (49.61). We can also assume that $\emptyset \notin \mathcal{C}$.

The box-total dual integrality of (49.61) follows from that of

(49.65)
$$\begin{aligned} &x(U) \le \hat{f}(U) \quad \text{for } U \in \hat{\mathcal{C}},\\ &x(S) = 0, \end{aligned}$$

as (49.65) and (49.61) have the same solution set, and as each constraint in (49.65) is a nonnegative integer combination of constraints in (49.61). The box-total dual integrality of (49.65) follows from Corollary 49.3a (using Theorem 5.25). It also shows that the solution set of (49.61) is the set of maximal vectors of $EP_{f'}$ for some submodular function f' defined on a lattice family. ∎

Frank and Tardos [1984b] observed that this implies a relation with matroids:

Corollary 49.7a. *If $\mathcal{C}$ is a crossing family of subsets of a set S, $f : \mathcal{C} \to \mathbb{Z}$ is crossing submodular, and $k \in \mathbb{Z}$, then the collection*

(49.66) $\qquad \{B \subseteq S \bigm| |B| = k, |B \cap U| \le f(U) \text{ for each } U \in \mathcal{C}\}$

forms the collection of bases of a matroid (if nonempty).

Proof. Directly from Theorem 49.7, using the observations on (44.43) and (49.11). ∎

Similarly, the box-total dual integrality of pairs of such systems follows:

Theorem 49.8. *For $i = 1, 2$, let $\mathcal{C}_i$ be a crossing family of subsets of a set S, let $f_i : \mathcal{C}_i \to \mathbb{R}$ be crossing submodular, and let $k \in \mathbb{R}$. Then the system*

(49.67)
$$\begin{aligned} &x(U) \leq f_1(U) \text{ for } U \in \mathcal{C}_1,\\ &x(U) \leq f_2(U) \text{ for } U \in \mathcal{C}_2,\\ &x(S) = k, \end{aligned}$$

is box-TDI.

Proof. Similar to the proof of the previous theorem, by reduction to Corollary 49.3b. ∎

This implies the integrality of polyhedra:

Corollary 49.8a. *For $i = 1, 2$, let $\mathcal{C}_i$ be a crossing family of subsets of a set S, let $f_i : \mathcal{C}_i \to \mathbb{R}$ be crossing submodular, and let $k \in \mathbb{R}$. If f_1, f_2, and k are integer, system* (49.67) *determines a box-integer polyhedron.*

Proof. Directly from Theorem 49.8. ∎

49.10. Complexity

The reduction given in the proof of Theorem 49.6 also enables us to calculate $\hat{f}(U)$ from a value giving oracle for f, similar to the proof in Section 49.7. We assume that $\mathcal{C}$ is given by descriptions of the lattice families $\mathcal{C}_{s,t} := \{U \in \mathcal{C} \mid s \in U, t \notin U\}$ as in Section 49.3.

Note that

(49.68)
$$EP_{\hat{f}} \cap \{x \mid x(S) = 0\} = EP_f \cap \{x \mid x(S) = 0\}.$$

This follows from the fact that if $x \in EP_f$ and $x(S) = 0$, then for any $U \in \hat{\mathcal{C}}$ and any proper copartition $\mathcal{P} = \{U_1, \ldots, U_p\}$ of $S \setminus U$ with $f(U) = \sum_{P \in \mathcal{P}} f(P)$, one has:

(49.69)
$$\begin{aligned} x(U) &= -x(S \setminus U) = -\sum_{P \in \mathcal{P}} x(S \setminus P) = \sum_{P \in \mathcal{P}} x(P) \leq \sum_{P \in \mathcal{P}} f(P)\\ &= f(U). \end{aligned}$$

Having this, the problem of maximizing $w^{\mathsf{T}}x$ over $EP_f \cap \{x \mid x(S) = 0\}$, where f is crossing submodular, is reduced to the problem of maximizing $w^{\mathsf{T}}x$ over $EP_{\hat{f}} \cap \{x \mid x(S) = 0\}$. The latter problem can be solved in strongly polynomial time by the results of Section 49.7. Similar results hold for intersections of two such polyhedra:

Theorem 49.9. *For crossing families $\mathcal{C}_1, \mathcal{C}_2$ of subsets of a set S, crossing submodular functions $f_1 : \mathcal{C}_1 \to \mathbb{Q}$ and $f_2 : \mathcal{C}_2 \to \mathbb{Q}$, $k \in \mathbb{Q}$, and $w \in \mathbb{Q}^S$, one* *can find an* $x \in EP_{f_1} \cap EP_{f_2}$ *with* $x(S) = k$ *and maximizing* $w^{\mathsf{T}}x$ *in strongly polynomial time.*

Proof. From the above. ∎

If $\mathcal{C}$ is a crossing family and $f : \mathcal{C} \to \mathbb{Q}$ is crossing submodular, then we can find its minimum value in polynomial time, as, for each $s, t \in S$, we can minimize f over the lattice family $\{U \in \mathcal{C} \mid s \in U, t \notin U\}$, and take the minimum of all these minima, and of the values in $\emptyset$ and S (if in $\mathcal{C}$).

Hence we can decide in polynomial time if a given vector $x \in \mathbb{Q}^S$ belongs to EP_f, by testing if the minimum value of the crossing submodular function $g : \mathcal{C} \to \mathbb{Q}$ defined by

$$g(U) := f(U) - x(U) \tag{49.70}$$

for $U \in \mathcal{C}$, is nonnegative.

49.10a. Nonemptiness of the base polyhedron

Let $\mathcal{C}$ be a crossing family of subsets of a set S and let $f : \mathcal{C} \to \mathbb{R}$ be crossing submodular. We give a theorem of Fujishige [1984e] characterizing when EP_f contains a vector x with $x(S) = 0$. If $S \in \mathcal{C}$ and $f(S) = 0$, then the set $EP_f \cap \{x \mid x(S) = 0\}$ is called the *base polyhedron* of f.

To give the characterization, again call a collection $\mathcal{P} \subseteq \mathcal{C}$ a *copartition* of S if the collection $\{S \setminus U \mid U \in \mathcal{P}\}$ is a partition of S.

Theorem 49.10. *EP_f contains a vector x satisfying $x(S) = 0$ if and only if*

$$\sum_{U \in \mathcal{P}} f(U) \geq 0 \tag{49.71}$$

for each partition or copartition $\mathcal{P} \subseteq \mathcal{C}$ of S. If moreover f is integer, there exists an integer such vector x.

Proof. The condition is necessary, since if $x \in EP_f$ satisfies $x(S) = 0$ and $\mathcal{P} \subseteq \mathcal{C}$ is a partition of S, then

$$\sum_{U \in \mathcal{P}} f(U) \geq \sum_{U \in \mathcal{P}} x(U) = x(S) = 0. \tag{49.72}$$

Similarly, if $\mathcal{P} \subseteq \mathcal{C}$ is a copartition of S, then

$$\sum_{U \in \mathcal{P}} f(U) \geq \sum_{U \in \mathcal{P}} x(U) = \sum_{U \in \mathcal{P}} (x(S) - x(S \setminus U)) = |\mathcal{P}|x(S) - x(S) = 0. \tag{49.73}$$

To see sufficiency, let $\mathcal{D} := \hat{\mathcal{C}}$ and $g := \hat{f}$ (cf. (49.62)). By Theorem 49.6, $\mathcal{D}$ is an intersecting family and g is intersecting submodular. Moreover, $S \in \mathcal{D}$. Let $\mathcal{E} := \check{\mathcal{D}}$ and $h := \check{g}$. By Theorem 49.4, $\mathcal{E}$ is a lattice family and h is submodular.

Now if EP_h contains a vector x with $x(S) = 0$, then $x \in EP_g$, and hence $x \in EP_f$ (using $x(S) = 0$). So it suffices to show that EP_h contains a vector x with $x(S) = 0$.

By Corollary 49.1c, in order to show this, it suffices to show that $h(S) \geq 0$. The solution can be taken integer if f (hence h) is integer.

Suppose $h(S) < 0$. Since $h = \check{g}$, $\mathcal{D}$ contains a proper partition $\mathcal{P}$ of S with

(49.74) $$h(S) = \sum_{U \in \mathcal{P}} g(U).$$

Since $g = \hat{f}$, for each $U \in \mathcal{P}$, $\mathcal{C}$ contains a proper copartition $\mathcal{Q}_U$ of $S \setminus U$ such that

(49.75) $$g(U) = \sum_{T \in \mathcal{Q}_U} f(T).$$

Let $\mathcal{F}$ be the family consisting of the union of the $\mathcal{Q}_U$ over $U \in \mathcal{P}$, taking multiplicities into account. Then

(49.76) (i) all elements of S are contained in the same number of sets in $\mathcal{F}$;
(ii) $\sum_{T \in \mathcal{F}} f(T) < 0$.

Now apply the following operation as often as possible to $\mathcal{F}$: if $T, W \in \mathcal{F}$ with $T \cap W \neq \emptyset$, $T \cup W \neq S$, and $T \not\subseteq W \not\subseteq T$, replace T and W by $T \cap W$ and $T \cup W$. This maintains (49.76) and decreases $\sum_{T \in \mathcal{F}} |T||S \setminus T|$ (by Theorem 2.1). So the process terminates, and we end up with a *cross-free family*: for all $T, W \in \mathcal{F}$ we have $T \subseteq W$ or $W \subseteq T$ or $T \cap W = \emptyset$ or $T \cup W = S$.

We show that $\mathcal{F}$ contains a partition or copartition $\mathcal{P}$ of S. By (49.71), $\mathcal{F} \setminus \mathcal{P}$ again satisfies (49.76), and hence we can repeat. We end up with $\mathcal{F}$ empty, a contradiction.

To show that $\mathcal{F}$ contains a partition or copartition of S, choose $U \in \mathcal{F}$. If $U = \emptyset$ or $U = S$ we are done (taking $\mathcal{P} := \{U\}$). So we can assume that $\emptyset \neq U \neq S$. Let $\mathcal{X}$ be the collection of inclusionwise maximal subsets of $S \setminus U$ that belong to $\mathcal{F}$. Let $\mathcal{Y}$ be the collection of inclusionwise minimal supersets of $S \setminus U$ that belong to $\mathcal{F}$. Since $\mathcal{F}$ is cross-free and $U \neq \emptyset$, the sets in $\mathcal{X}$ are pairwise disjoint. Similarly, the complements of the sets in $\mathcal{Y}$ are pairwise disjoint.

If $\bigcup \mathcal{X} = S \setminus U$, then $\mathcal{X} \cup \{U\}$ is a partition of S as required. If $\bigcap \mathcal{Y} = S \setminus U$, then $\mathcal{Y} \cup \{U\}$ is a copartition of S as required. So we can assume that there exist $s \in (S \setminus U) \setminus \bigcup \mathcal{X}$ and $t \in U \cap \bigcap \mathcal{Y}$. Since each element of S is contained in the same number of sets in $\mathcal{F}$, and since $s \notin U$, and $t \in U$, there exists a $T \in \mathcal{F}$ with $s \in T$ and $t \notin T$. So $T \not\subseteq U \not\subseteq T$.

Hence $T \cap U = \emptyset$ or $T \cup U = S$. However, if $T \cap U = \emptyset$, then T is contained in some set in $\mathcal{X}$, and hence $s \in T \subseteq \bigcup \mathcal{X}$, a contradiction. If $T \cup U = S$, then T contains some set in $\mathcal{Y}$, and hence $t \notin T \supseteq \bigcap \mathcal{Y}$, again a contradiction. ∎

This theorem will be used in proving Theorem 61.8.

Fujishige and Tomizawa [1983] characterized the vertices of the base polyhedron of a submodular function defined on a lattice family.

49.11. Further results and notes

49.11a. Minimizing a submodular function over a subcollection of a lattice family

In Section 45.7 we saw that the minimum of a submodular function over the odd subsets can be found in strongly polynomial time. A generalization of minimizing a submodular function over the odd subsets (cf. Section 45.7), was given by Grötschel, Lovász, and Schrijver [1981,1984a] (the latter paper corrects a serious flaw in the first paper found by A. Frank). This was extended by Goemans and Ramakrishnan [1995] to the following.

Let $\mathcal{C}$ be a lattice family and let $\mathcal{D}$ be a subcollection of $\mathcal{C}$ with the following property:

(49.77) for all $X, Y \in \mathcal{C} \setminus \mathcal{D}$: $X \cap Y \in \mathcal{D} \iff X \cup Y \in \mathcal{D}$.

Examples are: $\mathcal{D} := \{X \in \mathcal{C} \bigm| |X| \not\equiv q (\mathrm{mod}\ p)\}$ for some natural numbers p, q, and $\mathcal{D} := \mathcal{C} \setminus \mathcal{A}$ for some antichain or some sublattice $\mathcal{A} \subseteq \mathcal{C}$.

To prove that for a submodular function on $\mathcal{C}$, the minimum over $\mathcal{D}$ can be found in strongly polynomial time, Goemans and Ramakrishnan gave the following interesting lemma:

Lemma 49.11α. *Let $\mathcal{C}$ be a lattice family, let f be a submodular function on $\mathcal{C}$, let $\mathcal{D} \subseteq \mathcal{C}$ satisfy (49.77), and let U minimize $f(U)$ over $U \in \mathcal{D}$. If $U \neq \emptyset$, then there exists a $u \in U$ such that $f(W) \geq f(U)$ for each subset W of U with $W \in \mathcal{C}$ and $u \in W$.*

Proof. Suppose not. Then for each $u \in U$ there exists a $W_u \in \mathcal{C}$ satisfying $u \in W_u \subseteq U$ and $f(W_u) < f(U)$. Choose each W_u inclusionwise maximal with this property. Then

(49.78) $$f(\bigcap_{u \in T} W_u) < f(U)$$

for each nonempty $T \subseteq U$. To prove this, choose a counterexample T with $|T|$ minimal. Then $|T| > 1$, since $f(W_u) < f(U)$ for each $u \in U$. Choose $t \in T$. Since $\bigcap_{u \in T} W_u \neq \bigcap_{u \in T-t} W_u$ by the minimality of T, we know that $\bigcap_{u \in T-t} W_u \not\subseteq W_t$, and hence W_t is a proper subset of $(\bigcap_{u \in T-t} W_u) \cup W_t$. So by the maximality of W_t, $f((\bigcap_{u \in T-t} W_u) \cup W_t) \geq f(U)$. Hence

(49.79) $$\begin{aligned} f(U) &\leq f(\bigcap_{u \in T} W_u) = f((\bigcap_{u \in T-t} W_u) \cap W_t) \\ &\leq f(\bigcap_{u \in T-t} W_u) + f(W_t) - f((\bigcap_{u \in T-t} W_u) \cup W_t) \\ &< f(U) + f(U) - f(U) = f(U), \end{aligned}$$

a contradiction.

This shows (49.78), which implies

(49.80) $$\bigcap_{u \in T} W_u \notin \mathcal{D}$$

for each nonempty $T \subseteq U$.

This can be extended to:

(49.81) $$X := (\bigcap_{u \in T} W_u) \cap (\bigcup_{u \in V} W_u) \notin \mathcal{D}$$

for all disjoint $T, V \subseteq U$ with V nonempty. Suppose to the contrary that $X \in \mathcal{D}$. Choose such X with $|V|$ minimal. By (49.80), $|V| \geq 2$. Choose $v \in V$. The minimality of V gives

$$(49.82)\qquad (\bigcap_{u\in T} W_u)\cap W_v \notin \mathcal{D} \text{ and } (\bigcap_{u\in T} W_u)\cap (\bigcup_{u\in V\setminus\{v\}} W_u)\notin \mathcal{D}.$$

By assumption, the union of these sets belongs to $\mathcal{D}$. Hence, by (49.77), also their intersection belongs to $\mathcal{D}$; that is

$$(49.83)\qquad (\bigcap_{u\in T\cup\{v\}} W_u)\cap (\bigcup_{u\in V\setminus\{v\}} W_u)\in \mathcal{D}$$

This contradicts the minimality of $|V|$.

This proves (49.81), which gives for $T := \emptyset$ and $V := U$ a contradiction, since then $X = U \in \mathcal{D}$. ∎

This lemma is used in proving the following theorem, where we assume that $\mathcal{C}$ is given as in Section 49.3, f is given by a value giving oracle, and $\mathcal{D}$ is given by an oracle telling if any given set in $\mathcal{C}$ belongs to $\mathcal{D}$:

Theorem 49.11. *Given a submodular function f on a lattice family $\mathcal{C}$, and a subcollection $\mathcal{D}$ of $\mathcal{C}$ satisfying* (49.77)*, a set U minimizing $f(U)$ over $U \in \mathcal{D}$ can be found in strongly polynomial time.*

Proof. We describe the algorithm. For all distinct $s,t \in S$ define

$$(49.84)\qquad \mathcal{C}_{s,t} := \{U \in \mathcal{C} \mid s \in U, t \notin U\}.$$

Let $U_{s,t}$ be the inclusionwise minimal set minimizing f over $\mathcal{C}_{s,t}$. ($U_{s,t}$ can be found by minimizing a slight perturbation of f.) Choose in

$$(49.85)\qquad \{\emptyset, S\}\cup\{U_{s,t} \mid s,t\in S\}$$

a $U \in \mathcal{D}$ minimizing f. Then U minimizes f over $\mathcal{D}$.

To see this, we must show that set (49.85) contains a set minimizing f over $\mathcal{D}$. Let W be a set minimizing f over $\mathcal{D}$, with $|W|$ minimal. If $W \in \{\emptyset, S\}$ we are done. So we can assume that $W \notin \{\emptyset, S\}$. By Lemma 49.11$\alpha$ (applied to the function $\tilde{f}(X) := f(S \setminus X)$ for $X \subseteq S$), there exists an element $t \in S \setminus W$ such that each $T \supseteq W$ with $t \notin T$ satisfies $f(T) \geq f(W)$.

The lemma also gives the existence of an $s \in W$ such that each $T \subset W$ with $s \in T$ satisfies $f(T) > f(W)$. Indeed, for small enough $\varepsilon > 0$, W minimizes $f(X)+\varepsilon|X|$ over $X \in \mathcal{D}$. Hence, by Lemma 49.11α, there exists an $s \in W$ such that each $T \subseteq W$ with $s \in T$ satisfies $f(T)+\varepsilon|T| \geq f(W)+\varepsilon|W|$. This implies $f(T) > f(W)$ if $T \neq W$.

We show that $W = U_{s,t}$. Indeed, W minimizes f over $\mathcal{C}_{s,t}$, since

$$(49.86)\qquad f(U_{s,t}) \geq f(W\cap U_{s,t}) + f(W\cup U_{s,t}) - f(W) \geq f(W)+f(W)-f(W) = f(W).$$

Moreover, $W \subseteq U_{s,t}$, as otherwise $W \cap U_{s,t} \subset W$, implying that the second inequality in (49.86) would be strict.

So $f(W) = f(U_{s,t})$, and hence, by the minimality of $U_{s,t}$, we have $W = U_{s,t}$. ∎

It is interesting to note that this algorithm implies that the set $\{\emptyset, S\}\cup\{U_{s,t} \mid s,t \in S\}$ contains a set minimizing f over $\mathcal{D}$, for any nonempty subcollection $\mathcal{D}$ of $\mathcal{C}$ satisfying (49.77).

Goemans and Ramakrishnan showed that if $\mathcal{C}$ and $\mathcal{D}$ are *symmetric* (that is, $U \in \mathcal{C} \iff S \setminus U \in \mathcal{C}$, and similarly for $\mathcal{D}$) and $\emptyset \notin \mathcal{D}$, then (49.77) is equivalent to: if $X, Y \in \mathcal{C} \setminus \mathcal{D}$ are disjoint, then $X \cup Y \in \mathcal{C} \setminus \mathcal{D}$.

Related work was reported by Benczúr and Fülöp [2000].

49.11b. Generalized polymatroids

We now describe a generalization, given by Frank [1984b], that comprises sub- and supermodular functions, and (extended) polymatroids and contrapolymatroids. (Hassin [1978,1982] described the case $\mathcal{C} = \mathcal{D} = \mathcal{P}(S)$.)

Let $\mathcal{C}$ and $\mathcal{D}$ be intersecting families of subsets of a finite set S and let $f : \mathcal{C} \to \mathbb{R}$ and $g : \mathcal{D} \to \mathbb{R}$. We say that the pair (f, g) is *paramodular* if

(49.87)
(i) f is submodular on intersecting pairs,
(ii) g is supermodular on intersecting pairs,
(iii) if $T \in \mathcal{C}$ and $U \in \mathcal{D}$ with $T \setminus U \neq \emptyset$ and $U \setminus T \neq \emptyset$, then $T \setminus U \in \mathcal{C}$ and $U \setminus T \in \mathcal{D}$, and

$$f(T \setminus U) - g(U \setminus T) \leq f(T) - g(U).$$

If (f, g) is paramodular, the solution set P of the system (for $x \in \mathbb{R}^S$):

(49.88)
$$\begin{aligned} x(U) &\leq f(U) \quad \text{for } U \in \mathcal{C},\\ x(U) &\geq g(U) \quad \text{for } U \in \mathcal{D}, \end{aligned}$$

is called a *generalized polymatroid* (*determined by* (f, g)).

Generalized polymatroids generalize polymatroids (where $g(U) = 0$ for each $U \subseteq S$), extended polymatroids (where $\mathcal{D} = \emptyset$), contrapolymatroids (where $\mathcal{C} = \emptyset$ and $g(\{s\}) \geq 0$ for each $s \in S$), and extended contrapolymatroids (where $\mathcal{C} = \emptyset$).

The intersection of a generalized polymatroid with a 'box' $\{x \mid d \leq x \leq c\}$ (for $d, c \in \mathbb{R}^S$) is again a generalized polymatroid: we can add $\{s\}$ to $\mathcal{C}$ and to $\mathcal{D}$ if necessary, and (re)define $f(\{s\}) := w(s)$ and $g(\{s\}) := d(s)$, if necessary. This transformation does not violate the paramodularity of (f, g).

Another transformation is as follows. Let $P \subseteq \mathbb{R}^S$ be a generalized polymatroid and let $\kappa, \lambda \in \mathbb{R}$. Let t be a new element and let $S' := S \cup \{t\}$. Let P' be the polyhedron in $\mathbb{R}^{S'}$ given by

(49.89) $P' := \{(x, \eta) \mid x \in P, \lambda \leq x(S) + \eta \leq \kappa\}$.

Then P' again is a generalized polymatroid, determined by the functions obtained by extending $\mathcal{C}$ and $\mathcal{D}$ with S' and extending f, g with the values $f(S') := \kappa$ and $g(S') := \lambda$.

The class of generalized polymatroids is closed under projections. That is, for any generalized polymatroid $P \subseteq \mathbb{R}^S$ and any $t \in S$, the set

(49.90) $P' := \{x \in \mathbb{R}^{S-t} \mid \exists \eta : (x, \eta) \in P\}$

is again a generalized polymatroid. This will be shown as Corollary 49.13c.

The following theorem will imply that system (49.88) is TDI. Hence, if f and g are integer, then P is integer.

Theorem 49.12. *System* (49.88) *is box-TDI.*

Proof. Let t be a new element. Define

$$(49.91) \qquad \mathcal{B} := \mathcal{C} \cup \{(S \setminus D) \cup \{t\} \mid D \in \mathcal{D}\}.$$

Then $\mathcal{B}$ is a crossing family of subsets of $S \cup \{t\}$. Define $e : \mathcal{B} \to \mathbb{R}$ by: $e(C) := f(C)$ for $C \in \mathcal{C}$ and $e((S \setminus D) \cup \{t\}) := -g(D)$ for $D \in \mathcal{D}$. Then e is crossing submodular. Hence, by Theorem 49.7, system

$$(49.92) \qquad \begin{aligned} &x(U) \leq e(U) \qquad \text{for } U \in \mathcal{B}, \\ &x(S \cup \{t\}) = 0, \end{aligned}$$

is box-TDI. Therefore, by Theorem 5.27, system (49.88) is box-TDI. ∎

This gives for the integrality of generalized polymatroids:

Corollary 49.12a. *If (f, g) is paramodular and f and g are integer, the generalized polymatroid is box-integer.*

Proof. Directly from Theorem 49.12. ∎

More generally one has the box-total dual integrality of the system

$$(49.93) \qquad \begin{aligned} x(U) &\leq f_1(U) \quad \text{for } U \in \mathcal{C}_1, \\ x(U) &\geq g_1(U) \quad \text{for } U \in \mathcal{D}_1, \\ x(U) &\leq f_2(U) \quad \text{for } U \in \mathcal{C}_2, \\ x(U) &\geq g_2(U) \quad \text{for } U \in \mathcal{D}_2, \end{aligned}$$

for pairs of paramodular pairs (f_i, g_i):

Corollary 49.12b. *For $i = 1, 2$, let $\mathcal{C}_i$ and $\mathcal{D}_i$ be intersecting families and let $f_i : \mathcal{C}_i \to \mathbb{R}$, $g_i : \mathcal{D}_i \to \mathbb{R}$ form a paramodular pair. Then system (49.93) is box-TDI.*

Proof. Similar to the proof of Theorem 49.12, by reduction to Theorem 49.8. ∎

This gives for primal integrality:

Corollary 49.12c. *If f_1, g_1, f_2 and g_2 are integer, the intersection of the associated generalized polymatroids is box-integer.*

Proof. Directly from Corollary 49.12b. ∎

Another consequence is the following box-TDI result of McDiarmid [1978]:

Corollary 49.12d. *Let f_1 and f_2 be submodular set functions on a set S and let $\lambda, \kappa \in \mathbb{R}$. Then the system*

$$(49.94) \qquad \begin{aligned} &x(U) \leq f_1(U) \quad \text{for } U \subseteq S, \\ &x(U) \leq f_2(U) \quad \text{for } U \subseteq S, \\ &\lambda \leq x(S) \leq \kappa, \end{aligned}$$

is box-TDI.

Proof. Redefine $f_1(S) := \min\{f_1(S), \kappa\}$, and define $g_1 : \{S\} \to \mathbb{R}$ by $g_1(S) := \lambda$, and $g_2 : \emptyset \to \mathbb{R}$. Then (f_1, g_1) and (f_2, g_2) are paramodular pairs, and the box-total dual integrality of (49.94) is equivalent to the box-total dual integrality of (49.93). ∎

From Corollary 49.12c one can derive that the intersection of two integer generalized polymatroids is integer again. To prove this, we show that for any integer generalized polymatroid P there exists a paramodular pair (f, g) determining P, with f and g integer.

Let P be a generalized polymatroid, determined by the paramodular pair (f, g) of functions $f : \mathcal{C} \to \mathbb{R}$ and $g : \mathcal{D} \to \mathbb{R}$, where $\mathcal{C}$ and $\mathcal{D}$ are intersecting families. For any $U \subseteq S$, define

(49.95) $$\tilde{f}(U) := \max\{x(U) \mid x \in P\} \text{ and } \tilde{g}(U) := \min\{x(U) \mid x \in P\}.$$

So $\tilde{f}$ and $\tilde{g}$ are integer if P is integer.

Let

(49.96) $$\widetilde{\mathcal{C}} := \{U \in \mathcal{C} \mid \tilde{f}(U) < \infty\} \text{ and } \widetilde{\mathcal{D}} := \{U \in \mathcal{D} \mid \tilde{g}(U) > -\infty\}.$$

We restrict $\tilde{f}$ and $\tilde{g}$ to $\widetilde{\mathcal{C}}$ and $\widetilde{\mathcal{D}}$ respectively. We show that $(\tilde{f}, \tilde{g})$ is a paramodular pair determining P.

It is convenient to note that if $w \in \mathbb{R}^S$ with $w = w_1 + w_2$, then

(49.97) $$\max\{w^{\mathsf{T}}x \mid x \in P\} \leq \max\{w_1^{\mathsf{T}}x \mid x \in P\} + \max\{w_2^{\mathsf{T}}x \mid x \in P\}.$$

Theorem 49.13. *For any generalized polymatroid P, $\tilde{\mathcal{C}}$ and $\tilde{\mathcal{D}}$ are intersecting families, and the pair $(\tilde{f}, \tilde{g})$ is paramodular and determines P.*

Proof. We first show the following. Let $w \in \mathbb{Z}^S$ and let $\lambda > 0$ be such that $w_s \leq \lambda$ for each $s \in S$. Let $U := \{s \in S \mid w(s) = \lambda\}$ and $w' := w - \chi^U$. Then

(49.98) $$\max\{w^{\mathsf{T}}x \mid x \in P\} = \max\{w'^{\mathsf{T}}x \mid x \in P\} + \tilde{f}(U).$$

Here $\leq$ follows from (49.97), by definition of $\tilde{f}$. Equality is proved by induction on $|U|$, the case $U = \emptyset$ being trivial; so let $U \neq \emptyset$.

Let y, z be an optimum solution to the dual of $\max\{w^{\mathsf{T}}x \mid x \in P\}$:

(49.99) $$\min\{\sum_{T\in\mathcal{C}} y_T f(T) - \sum_{T\in\mathcal{D}} z_T g(T) \mid y \in \mathbb{R}_+^{\mathcal{C}}, z \in \mathbb{R}_+^{\mathcal{D}}, \sum_{T\in\mathcal{C}} y_T \chi^T - \sum_{T\in\mathcal{D}} z_T \chi^T = w\}.$$

Define $\mathcal{F} := \{T \in \mathcal{C} \mid y_T > 0\}$ and $\mathcal{G} := \{T \in \mathcal{D} \mid z_T > 0\}$. Similarly to Theorem 49.3, we can assume that $\mathcal{F} \cup \mathcal{G}$ is laminar.

Choose $u \in U$, and let W be an inclusionwise minimal set in $\mathcal{F}$ containing u. (Such a set exists, as $w(s) = \lambda > 0$.) Let $\mathcal{H}$ be the collection of inclusionwise maximal sets in $\mathcal{G}$ contained in $W - u$. As $\mathcal{G}$ is laminar, the sets in $\mathcal{H}$ are disjoint. Moreover, each $t \in W \setminus U$ is contained in some set in $\mathcal{H}$: since $w(t) < w(u)$ and since every set in $\mathcal{F}$ containing u also contains t (as $t \in W$), there exists an $X \in \mathcal{G}$ with $t \in X$ and $u \notin X$; as $\mathcal{F} \cup \mathcal{G}$ is laminar, we know that $X \subseteq W - u$.

Now let $Y := W \setminus \bigcup \mathcal{H}$. So Y is a nonempty subset of U. Define $w'' := w - \chi^Y$, let y' be obtained from y by decreasing $y(W)$ by 1, and let z' be obtained from z by decreasing $y(H)$ by 1 for each $H \in \mathcal{H}$. So (since $\chi^Y = \chi^W - \sum_{H\in\mathcal{H}} \chi^H$)

(49.100) $$\sum_{T\in\mathcal{C}} y'(T)\chi^T - \sum_{T\in\mathcal{D}} z'(T)\chi^T = w''$$

and

(49.101) $$\tilde{f}(Y) \leq f(W) - \sum_{H\in\mathcal{H}} g(H).$$

Moreover, setting $U' := U \setminus Y$, we have (by (49.97))

(49.102) $$\tilde{f}(U) \leq \tilde{f}(Y) + \tilde{f}(U'),$$

and by our induction hypothesis, as $|U'| < |U|$,

(49.103) $$\max\{w''^{\mathsf{T}}x \mid x \in P\} = \max\{w'^{\mathsf{T}}x \mid x \in P\} + \tilde{f}(U').$$

Hence

(49.104)
$$\begin{aligned}\max\{w^{\mathsf{T}}x \mid x \in P\} &= \sum_{T\in\mathcal{C}} y(T)f(T) - \sum_{T\in\mathcal{D}} z(T)g(T)\\ &= \sum_{T\in\mathcal{C}} y'(T)f(T) - \sum_{T\in\mathcal{D}} z'(T)g(T) + f(W) - \sum_{H\in\mathcal{H}} g(H)\\ &\geq \max\{w''^{\mathsf{T}}x \mid x \in P\} + \tilde{f}(Y) = \max\{w'^{\mathsf{T}}x \mid x \in P\} + \tilde{f}(U') + \tilde{f}(Y)\\ &\geq \max\{w'^{\mathsf{T}}x \mid x \in P\} + \tilde{f}(U),\end{aligned}$$

thus proving (49.98).

We next derive that $\tilde{f}$ is submodular on intersecting pairs. Choose $X, Y \in \widetilde{\mathcal{C}}$ with $X \cap Y \neq \emptyset$. Define $w := \chi^X + \chi^Y$. Then by (49.98) and (49.97),

(49.105) $$\tilde{f}(X\cap Y) + \tilde{f}(X\cup Y) = \max\{w^{\mathsf{T}}x \mid x \in P\} \leq \tilde{f}(X) + \tilde{f}(Y).$$

So $\tilde{\mathcal{C}}$ is an intersecting family and $\tilde{f}$ is submodular on intersecting pairs. By symmetry, it follows that $\tilde{\mathcal{D}}$ is an intersecting family and $\tilde{g}$ is supermodular on intersecting pairs.

Finally, to see that (f,g) is paramodular, let $X \in \mathcal{C}$ and $Y \in \mathcal{D}$. Define $w := \chi^X - \chi^Y$. Again, by (49.98) and (49.97),

(49.106) $$\tilde{f}(X\setminus Y) - \tilde{g}(Y\setminus X) = \max\{w^{\mathsf{T}}x \mid x \in P\} \leq \tilde{f}(X) - \tilde{g}(Y).$$

So $\tilde{\mathcal{C}}$ and $\tilde{\mathcal{D}}$ are intersecting families, and the pair $(\tilde{f},\tilde{g})$ is paramodular. It determines P, since P is determined by upper and lower bounds on $x(U)$ for subsets U of S. ∎

Corollary 49.12a implies:

Corollary 49.13a. *A generalized polymatroid P is integer if and only if there is a paramodular pair (f,g) defining P with f and g integer.*

Proof. Sufficiency follows from Corollary 49.12a. Necessity follows from Theorem 49.13, as P is determined by $(\tilde{f},\tilde{g})$, where $\tilde{f}$ and $\tilde{g}$ are integer if P is integer. ∎

A second consequence is:

Corollary 49.13b. *The intersection of two integer generalized polymatroids is integer.*

Proof. Directly by combining Corollaries 49.12c and 49.13a. ∎

We should note that the collections $\tilde{\mathcal{C}}$ and $\tilde{\mathcal{D}}$ found in the proof of Theorem 49.13 are lattice families and that $\tilde{f}$ and $\tilde{g}$ are sub- and supermodular respectively. Moreover, $\tilde{f}(T \setminus U) - \tilde{g}(U \setminus T) \leq \tilde{f}(T) - \tilde{g}(U)$ for each pair $T \in \tilde{\mathcal{C}}$, $U \in \tilde{\mathcal{D}}$.

This implies that projections of generalized polymatroids are again generalized polymatroids (Frank [1984b]):

Corollary 49.13c. *Let $P \subseteq \mathbb{R}^S$ be a generalized polymatroid and let $t \in S$. Define $S' := S - t$. Then the projection*

(49.107) $$P' := \{x \in \mathbb{R}^{S'} \mid \exists \eta : (x, \eta) \in P\}$$

is again a generalized polymatroid.

Proof. We can assume that P is nonempty, that $\mathcal{C}$ and $\mathcal{D}$ are lattice families, and that P is determined by a paramodular pair $(f, g) = (\tilde{f}, \tilde{g})$ as above. Let $\mathcal{C}'$ and $\mathcal{D}'$ be the collections of sets in $\mathcal{C}$ and $\mathcal{D}$ respectively not containing t. Let $f' := f|\mathcal{C}'$ and $g' := g|\mathcal{D}'$.

Trivially, (f', g') is a paramodular pair. We claim that P' is equal to the generalized polymatroid Q determined by (f', g'). Trivially, $P' \subseteq Q$. To see the reverse inclusion, let $x \in Q$. Let η' be the largest real such that $x(T - t) + \eta' \leq f(T)$ for each $T \in \mathcal{C} \setminus \mathcal{C}'$. Let η'' be the smallest real such that $x(U - t) + \eta'' \geq g(U)$ for each $U \in \mathcal{D} \setminus \mathcal{D}'$.

If $x \notin P'$, then $\eta' < \eta''$, and hence there exist $T \in \mathcal{C}$ and $U \in \mathcal{D}$ with $t \in T \cap U$ and $f(T) - x(T - t) < g(U) - x(U - t)$. Hence

(49.108) $$\begin{aligned} x(T \setminus U) - x(U \setminus T) &= x(T - t) - x(U - t) > f(T) - g(U) \\ &\geq f(T \setminus U) - g(U \setminus T). \end{aligned}$$

This contradicts the fact that $x(T \setminus U) \leq f(T \setminus U)$ and $x(U \setminus T) \geq g(U \setminus T)$, as $x \in Q$. ∎

For results on the dimension of generalized polymatroids, see Frank and Tardos [1988], which paper surveys generalized polymatroids and submodular flows. More results on generalized polymatroids are reported by Fujishige [1984b], Nakamura [1988b], Naitoh and Fujishige [1992], and Tamir [1995].

49.11c. Supermodular colourings

A colouring-type of result on supermodular functions was shown by Schrijver [1985]. We give the proof based on generalized polymatroids found by Tardos [1985b].

Theorem 49.14. *Let $\mathcal{C}_1$ and $\mathcal{C}_2$ be intersecting families of subsets of a set S, let $g_1 : \mathcal{C}_1 \to \mathbb{Z}$ and $g_2 : \mathcal{C}_2 \to \mathbb{Z}$ be intersecting supermodular, and let $k \in \mathbb{Z}_+$ with $k \geq 1$. Then S can be partitioned into classes $L_1, \ldots, L_k$ such that*

(49.109) $$g_i(U) \leq |\{j \in \{1, \ldots, k\} \mid L_j \cap U \neq \emptyset\}|$$

for each $i = 1, 2$ and each $U \in \mathcal{C}_i$ if and only if

(49.110) $$g_i(U) \leq \min\{k, |U|\}$$

for each $i = 1, 2$ *and each* $U \in \mathcal{C}_i$.

Proof. Necessity is easy. Sufficiency is shown by induction on k, the case $k = 0$ being trivial. By induction, it suffices to find a subset L of S such that

(49.111) $\quad |U \setminus L| \geq g_i(U) - 1$ and, if $g_i(U) = k$, then $U \cap L \neq \emptyset$.

Indeed, in that case we can apply induction to the functions $g_i' : \mathcal{C}_i' \to \mathbb{Z}$ on $\mathcal{C}_i' := \{U \setminus L \mid U \in \mathcal{C}\}$, defined by

(49.112) $$g_i'(U \setminus L) := \begin{cases} g_i(U) - 1 & \text{if } U \cap L \neq \emptyset, \\ g_i(U) & \text{if } U \cap L = \emptyset, \end{cases}$$

for $U \in \mathcal{C}_i$.

For $i = 1, 2$, consider the system:

(49.113)
$$\begin{array}{rll} \text{(i)} & 0 \leq x_s \leq 1 & \text{for } s \in S, \\ \text{(ii)} & x(U) \leq |U| - g_i(U) + 1 & \text{for } U \in \mathcal{C}_i, \\ \text{(iii)} & x(U) \geq 1 & \text{for } U \in \mathcal{C}_i \text{ with } g_i(U) = k. \end{array}$$

This system determines an integer generalized polymatroid. This can be seen as follows. Let $\mathcal{D}_i$ be the collection of inclusionwise minimal sets in $\{U \in \mathcal{C}_i \mid g_i(U) = k\}$. So $\mathcal{D}_i$ consists of disjoint sets (as $\mathcal{C}_i$ is intersecting and as $g_i(U) \leq k$ for each $U \in \mathcal{C}_i$). Let

(49.114) $\quad \mathcal{C}_i' := \{U \in \mathcal{C}_i \mid \forall T \in \mathcal{D}_i : U \subseteq T \text{ or } T \cap U = \emptyset\}$.

Then (49.113) has the same solution set as:

(49.115)
$$\begin{array}{rll} \text{(i)} & 0 \leq x_s \leq 1 & \text{for } s \in S, \\ \text{(ii)} & x(U) \leq |U| - g_i(U) + 1 & \text{for } U \in \mathcal{C}_i', \\ \text{(iii)} & x(U) \geq 1 & \text{for } U \in \mathcal{D}_i. \end{array}$$

Indeed, (49.115)(iii) implies (49.113)(iii) (as $x \geq \mathbf{0}$). Moreover, for any $U \in \mathcal{C}_i$ with $T \cap U \neq \emptyset$ for some $T \in \mathcal{D}_i$, one has

(49.116) $\quad g_i(T \cap U) \geq g_i(T) + g_i(U) - g_i(T \cup U) \geq g_i(U)$

(as $g_i(T \cup U) \leq k = g_i(T)$). So with (49.115)(iii) we have:

(49.117)
$$\begin{aligned} & x(U) \leq x(T \cap U) + |U \setminus T| \leq |T \cap U| - g_i(T \cap U) + 1 + |U \setminus T| \\ & \leq |U| - g_i(U) + 1 \end{aligned}$$

(as $x_s \leq 1$ for all $x \in U \setminus T$). Hence (49.113) and (49.115) have the same solution set.

Now (49.115) is a system defining a generalized polymatroid, as one easily checks (condition (49.87)(iii) follows, since if $T \in \mathcal{C}_i'$ and $U \in \mathcal{D}_i$ with $T \setminus U \neq \emptyset$ and $U \setminus T \neq \emptyset$, then, by definition of $\mathcal{C}_i'$, T and U are disjoint, and then the inequality in (49.87)(iii) is trivial). It is integer, as the right-hand sides in (49.115) are integer.

Also, the intersection of these generalized polymatroids for $i = 1$ and $i = 2$ is nonempty, since the vector $x := k^{-1} \cdot \mathbf{1}$ belongs to it. (49.115)(i) and (iii) hold trivially. To see (ii), we have

(49.118)
$$\begin{aligned} & x(U) = \tfrac{1}{k}|U| = |U| - \tfrac{k-1}{k}|U| \leq |U| - \tfrac{k-1}{k} g_i(U) = |U| - g_i(U) + \tfrac{1}{k} g_i(U) \\ & \leq |U| - g_i(U) + 1. \end{aligned}$$

Therefore, the intersection contains an integer vector x, which is, by (49.115)(i), the incidence vector of some subset L of S satisfying (49.111), as required. ∎

This theorem generalizes edge-colouring theorems for bipartite graphs $G = (V, E)$. Let V_1 and V_2 be the colour classes of G. Let $\mathcal{C}_i := \{\delta(v) \mid v \in V_i\}$ for $i = 1, 2$. If we define $g_i(\delta(v)) := |\delta(v)|$ for $v \in V_i$ $(i = 1, 2)$, Theorem 49.14 reduces to Kőnig's edge-colouring theorem (Theorem 20.1). If $g_i(\delta(v))$ is set to the minimum degree of G, we obtain Theorem 20.5, and if it is set to the minimum of k and $|\delta(v)|$, we obtain Theorem 20.6.

Theorem 49.14 can also be used in proving the 'disjoint bibranchings theorem' (Theorem 54.11 — see Section 54.7a). Szigeti [1999] gave a generalization of Theorem 49.14.

49.11d. Further notes

Let S and T be disjoint sets. A function $f : \mathcal{P}(S) \times \mathcal{P}(T) \to \mathbb{R}$ is called *bisubmodular* if

(49.119) $$f(X_1 \cap X_2, Y_1 \cup Y_2) + f(X_1 \cup X_2, Y_1 \cap Y_2) \leq f(X_1, Y_1) + f(X_2, Y_2)$$

for all $X_1, X_2 \subseteq S$ and $Y_1, Y_2 \subseteq T$.

Bisubmodular functions were studied by Kung [1978b] and Schrijver [1978, 1979c]. Most of the results can be obtained from those for submodular functions, by considering the submodular set function f' on $S \cup T$ defined by $f'(X \cup Y) := f((S \setminus X) \cup Y)$ for $X \subseteq S$ and $Y \subseteq T$. Similarly for *bisupermodular* functions, where the inequality sign in (49.119) is reversed.

For an interesting related result of Frank and Jordán [1995b] yielding Győri's theorem, see Section 60.3d.

Fujishige [1984c] gave a framework that includes Theorem 46.2 on the total dual integrality of the intersection of a polymatroid and a contrapolymatroid system, Corollary 46.2b on the existence of a modular function between a sub- and a supermodular function, and Theorem 49.13 on the total dual integrality of the generalized polymatroid constraints (but not the total dual integrality of the intersection of two polymatroids). Fujishige [1984b] described generalized polymatroids as projections of base polyhedra of submodular functions.

Chandrasekaran and Kabadi [1988] introduced the concept of a *generalized submodular function* as a function $f : \mathcal{R} \to \mathbb{R}$, where $\mathcal{R} := \{(T, U) \mid T, U \subseteq S, T \cap U = \emptyset\}$ for some set S, satisfying

(49.120) $$\begin{aligned} &f(A, B) + f(C, D) \\ &\geq f(A \cap C, B \cap D) + f((A \setminus D) \cup (C \setminus B), (B \setminus C) \cup (D \setminus A)) \end{aligned}$$

for all $(A, B), (C, D) \in \mathcal{R}$. They showed that the system

(49.121) $$x(T) - x(U) \leq f(T, U) \text{ for } (T, U) \in \mathcal{R}$$

is box-TDI, and that for any $w \in \mathbb{R}^S$, an x maximizing $w^{\mathsf{T}} x$ over (49.121) can be found by a variant of the greedy method. Unions of two such systems need not define an integer polyhedron if the functions are integer, as is shown by an example with $|S| = 2$. A similar framework was considered by Nakamura [1990]. More results can be found in Dress and Havel [1986], Bouchet [1987a,1995], Bouchet, Dress, and

Havel [1992], Ando and Fujishige [1996], Fujishige [1997], and Fujishige and Iwata [2001].

It is direct to represent a lattice family on a set S of size n in $O(n^2)$ space (just by giving all pairs (u, v) for which each set in the family containing u also contains v). Gabow [1993b,1995c] gave an $O(n^2)$ representation for intersecting and crossing families. Related results were found by Fleiner and Jordán [1999].

Tardos [1985b] also studied *generalized matroids*, which form the special case of generalized polymatroids with $0, 1$ vertices. An instance of it we saw in the proof of Theorem 49.14.

More results on submodularity are given by Fujishige [1980b,1984f,1984g,1988], Nakamura [1988b,1988c,1993], Kabadi and Chandrasekaran [1990], Iwata [1995], Iwata, Murota, and Shigeno [1997], and Murota [1998]. Generalizations were studied by Qi [1988b] and Kashiwabara, Nakamura, and Takabatake [1999].

Part V

Trees, Branchings, and Connectors

Part V: Trees, Branchings, and Connectors

This part focuses on structures that are defined by connecting several pairs of vertices simultaneously, with most basic structure that of a *spanning tree*. A spanning tree can be characterized as a minimal set of edges that connects each pair of vertices by at least one path — that is, a minimal *connector*. Alternatively, it can be characterized as a maximal set of edge that connects each pair of vertices by at most one path — that is, a maximal *forest*.

Finding a shortest spanning tree belongs to classical combinatorial optimization, with lots of applications in planning road, energy, and communication networks, in chip design, and in clustering data in areas like biology, taxonomy, archeology, and, more generally, in any large data base. Spanning trees are well under control polyhedrally and algorithmically, both as to *shortest* and as to *disjoint* spanning trees. They form a prime area of application of matroid theory.

There are several variations and generalizations of the notion of spanning tree that are also well under control, like arborescences, branchings, biconnectors, bibranchings, directed cut covers, and matching forests.

An illustrious variant that is worse under control is the Hamiltonian circuit — in other words, the traveling salesman tour — which (in the directed case) can be considered as a smallest strongly connected subgraph. The traveling salesman problem is NP-complete and no complete polyhedral characterization is known. It implies that more general optimization problems like finding a shortest strong connector or a cheapest connectivity augmentation also are NP-complete. In this part we will however come across some special cases that *are* well-solvable and well-characterized.

In this part we also discuss the powerful framework designed by Edmonds and Giles, based on defining the concept of a *submodular flow* in a directed graph with a submodular function on its vertex set. It unifies several of the results and techniques of the present part and of the previous part on matroids and submodular functions.

Chapters:

Chapter 50

Shortest spanning trees

In this chapter we consider shortest spanning trees in undirected graphs. We show that the greedy algorithm finds a shortest spanning tree in a graph, and moreover yields min-max relations and polyhedral characterizations. These are special cases of results on matroids discussed in Chapter 40, but deserve special consideration since the graph framework allows a number of additional viewpoints and opportunities.

We recall some terminology and elementary facts. A graph $G = (V, E)$ is called a *tree* if G is connected and contains no circuit. For any graph $G = (V, E)$, a subset F of E is called:

- a *spanning tree* if (V, F) is a tree,
- a *forest* if F contains no circuit,
- a *maximal forest* if F is an inclusionwise maximal forest,
- a *connector* if (V, F) is connected.

A graph G has a spanning tree if and only if G is connected. For any connected graph $G = (V, E)$, each of the following characterizes a subset F of E as a spanning tree:

- F is a maximal forest;
- F is an inclusionwise minimal connector;
- F is a forest with $|F| = |V| - 1$;
- F is a connector with $|F| = |V| - 1$.

In any graph $G = (V, E)$, a maximal forest has $|V| - k$ edges, where k is the number of components of G; it forms a spanning tree in each of the components of G. So each inclusionwise maximal forest is a maximum-size forest; that is, each forest is contained in a maximum-size forest. Similarly, each connector contains a minimum-size connector.

50.1. Shortest spanning trees

Let $G = (V, E)$ be a connected graph and let $l : E \to \mathbb{R}$ be a function, called the *length* function. For any subset F of E, the *length* $l(F)$ of F is, by definition:

(50.1) $$l(F) := \sum_{e \in F} l(e).$$

In this section we consider the problem of finding a shortest spanning tree in G — that is, one of minimum length.

While this is a special case of finding a minimum-weight base in a matroid, and hence can be solved with the greedy algorithm (Section 40.1), spanning trees allow some variation on the method, essentially because we can exploit the presence of the vertex set (graphic matroids are defined on the edge set only).

Also these variants of the greedy method will be called greedy. Such methods go back to Borůvka [1926a]. The correctness of each of the variants follows from the following basic phenomenon.

Call a forest F *good* if there exists a shortest spanning tree T of G that contains F. (So we are out for a good spanning tree.) Then:

Theorem 50.1. *Let F be a good forest and let e be an edge not in F. Then $F \cup \{e\}$ is a good forest if and only if*

(50.2) *there exists a cut C disjoint from F such that e is shortest among the edges in C.*

Proof. To see necessity, let T be a shortest spanning tree containing $F \cup \{e\}$. Let C be the unique cut disjoint from $T \setminus \{e\}$. Then e is shortest in C, since if $f \in C$, then $T' := (T \setminus \{e\}) \cup \{f\}$ is again a spanning tree. As $l(T') \geq l(T)$ we have $l(f) \geq l(e)$.

To see sufficiency, let T be a shortest spanning tree containing F. Let P be the path in T between the ends of e. Then P contains at least one edge f that belongs to C. Then $T' := (T \setminus \{f\}) \cup \{e\}$ is a spanning tree again. By assumption, $l(e) \leq l(f)$ and hence $l(T') \leq l(T)$. Hence T' is a shortest spanning tree again. As $F \cup \{e\}$ is contained in T', it is a good forest. ∎

(The idea of this proof is in Jarník [1930].)

This theorem offers us a framework for an algorithm: starting with $F := \emptyset$, iteratively extend F by an edge e satisfying (50.2). We end up with a shortest spanning tree.

Rule (50.2) was formulated by Tarjan [1983], and is the most liberal rule in obtaining greedily a shortest spanning tree. The variants of the greedy method are obtained by specifying how to choose edge e.

The first variant, the *tree-growing method*, was given by Jarník [1930] (and by Kruskal [1956], Prim [1957], Dijkstra [1959]). It is also called the *Jarník-Prim method* or *Prim's method* (Prim was the first giving an $O(n^2)$ implementation):

(50.3) Fix a vertex r. Set $F := \emptyset$. As long as F is not a spanning tree, let K be the component of F containing r, let e be a shortest edge leaving K, and reset $F := F \cup \{e\}$.

Corollary 50.1a. *Prim's method yields a shortest spanning tree.*

Proof. Directly from Theorem 50.1, by taking $C := \delta(K)$. ∎

A second variant, the *forest-merging method* or *Kruskal's method*, is due to Kruskal [1956] (and to Loberman and Weinberger [1957] and Prim [1957]):

(50.4) Set $F := \emptyset$. As long as F is not a spanning tree, choose a shortest edge e for which $F \cup \{e\}$ is a forest, and reset $F := F \cup \{e\}$.

(So this version is the true specialization of the greedy algorithm for matroids to graphs.)

Corollary 50.1b. *Kruskal's method yields a shortest spanning tree.*

Proof. Again directly from Theorem 50.1, as e is shortest in the cut $\delta(K)$ for each of the two components K of F incident with e. ∎

Prim [1957] and Loberman and Weinberger [1957] observed that the optimality of the greedy method implies that each length function which gives the same order of the edges (like the logarithm or square of the lengths), has the same collection of shortest spanning trees. Similarly, the shortest spanning tree minimizes the *product* of the lengths (if nonnegative).

In a similar way one finds a *longest* spanning tree. The maximum length of a forest and the minimum length of a connector can also be found with the greedy method.

Note that the greedy method is flexible: We can change our rule of choosing the new edge e at any time throughout the algorithm, as long as at any choice of e, (50.2) is satisfied.

As Prim [1957] and Dijkstra [1959] remark, the value of any variant of the greedy method depends on its implementation. One should have efficient ways to store and update information on the components of F, and on finding an edge satisfying (50.2). We now consider such implementations for Prim's and for Kruskal's method.

50.2. Implementing Prim's method

Prim [1957] and Dijkstra [1959] described implementations of Prim's method that run in time $O(n^2)$. (Here we assume without loss of generality that the graph is simple.)

To this end, we indicate at any vertex v, whether or not v belongs to the component K containing r of the current forest F, and in case $v \notin K$, we store at v a shortest edge e_v connecting v with K (void if there is no such edge). Then at each iteration, we scan all vertices, and select one, v say, for which $v \notin K$ and e_v is shortest. We add e_v to F, and v to K, and for each edge vu incident with v, we replace e_u by vu if $u \notin K$ and vu is shorter than e_u (or if e_u is void).

As each iteration takes $O(n)$ time and as there are $n-1$ iterations we have the result stated by Dijkstra [1959]:

Theorem 50.2. *A shortest spanning tree can be found in time $O(n^2)$.*

Proof. See above. ∎

In fact, by applying 2-heaps (Section 7.3) one can obtain a running time bound of $O(m \log n)$ (E.L. Johnson, cf. Kershenbaum and Van Slyke [1972]), and with Fibonacci heaps (Section 7.4) one obtains (Fredman and Tarjan [1984,1987]):

Theorem 50.3. *A shortest spanning tree can be found in time $O(m + n \log n)$.*

Proof. Directly by applying Fibonacci heaps as described in Section 7.4. ∎

50.3. Implementing Kruskal's method

Bottleneck in implementing Kruskal's method is the necessity to scan the edges sorted by length. As the best bound for sorting is $O(m \log n)$, we cannot hope for implementations of Kruskal's method faster than that.

However, the bound $O(m \log n)$ is easy to achieve. In fact, as was noticed by Kershenbaum and Van Slyke [1972] (using ideas of Van Slyke and Frank [1972]), it is easy to implement Kruskal's method such that the time *after sorting* is $O(m + n \log n)$. This can be done with elementary data-structures like lists; no heaps are needed.

Indeed, it is not hard to design a simple data structure that tests in constant time if the ends of any edge belong to different components of the current forest F, and that merges components in time linear in the size of the smaller component[1].

Then the iterations take $O(m + n \log n)$ time, since checking if the ends of an edge belong to different components takes $O(m)$ time overall, while merging takes $O(n \log n)$ time overall: any vertex v belongs at most $\log_2 n$ times to the smaller component when merging, as, at any such event, the component containing v at least doubles in size.

---

[1] Consider any forest F. Represent each component K by a (singly) linked list. For any vertex v, let $r(v)$ be the first vertex of the list L_v containing v.

Initially, for each vertex v, $r(v) = v$, as $L_v = \{v\}$. At any iteration, the edge $e = uv$ considered connects different components of F if and only if $r(u) \neq r(v)$. Checking this takes constant time.

If $r(u) \neq r(v)$, we can determine which of the lists L_u, L_v is smallest in time $O(\min\{|L_u|, |L_v|\})$ (by scanning them in parallel, starting at $r(u)$ and $r(v)$). Assume without loss of generality that $|L_u| \leq |L_v|$. Then we reset $r(u') := r(v)$ for all u' in L_u, and we insert L_u into L_v directly after v. This can be done in time $O(|L_u|)$.

Tarjan [1983] showed that if the edges are presorted, a minimum spanning tree can be found in time $O(m\alpha(m,n))$ (where $\alpha(m,n)$ is the 'inverse Ackermann function — see Section 50.6a).

50.3a. Parallel forest-merging

A variant that suggests parallel implementation was given by Borůvka [1926a,1926b] — the *parallel forest-merging method* or *Borůvka's method*. (This method was also given by Choquet [1938] (without proof) and Florek, Łukaszewicz, Perkal, Steinhaus, and Zubrzycki [1951a].) It assumes that all edge lengths are different:

(50.5) Set $F := \emptyset$. As long as F is not a spanning tree do the following: choose for each component K of F the shortest edge leaving K, and add all chosen edges to F.

Theorem 50.4. *Assuming that all edge lengths are different, the parallel forest-merging variant yields a shortest spanning tree.*

Proof. We show that F remains a good forest throughout the iterations. Consider some iteration, and let F be the good forest at the start of the iteration. Let $e_1, \ldots, e_k$ be the edges added in the iteration, indexed such that $l(e_1) < l(e_2) < \cdots < l(e_k)$. By the selection rule (50.5), for each $i = 1, \ldots, k$, e_i is the shortest edge leaving some component K of F. Then K is also a component of $F \cup \{e_1, \ldots, e_{i-1}\}$, as none of $e_1, \ldots, e_{i-1}$ leave K (since e_i is shortest leaving K). Hence for each $i = 1, \ldots, k$, $F \cup \{e_1, \ldots, e_i\}$ is a good forest (by induction on i). Concluding, the iteration yields a good forest. ∎

50.3b. A dual greedy algorithm

We can consider a dual approach by iteratively decreasing a connector, instead of iteratively growing a forest. The analogy can be exhibited as follows.

Let $G = (V, E)$ be a connected graph and let $l : E \to\in \mathbb{R}$ be a length function. Call a connector $K \subseteq E$ *good* if K contains a shortest spanning tree. Then we have:

Theorem 50.5. *Let K be a good connector and let $e \in K$. Then $K \setminus \{e\}$ is a good connector if and only if*

(50.6) *K contains a circuit C such that e is a longest edge in C.*

Proof. To see necessity, let T be a shortest spanning tree contained in $K \setminus \{e\}$. Let C be the unique circuit contained in $T \cup \{e\}$. Then e is longest in C, since if $f \in C$, then $T' := (T \setminus \{f\}) \cup \{e\}$ is again a spanning tree. As $l(T') \geq l(T)$ we have $l(e) \geq l(f)$.

To see sufficiency, let T be a shortest spanning tree contained in K. If $e \notin T$, then also $K \setminus \{e\}$ contains T, and hence $K \setminus \{e\}$ is a good connector. So we can assume that $e \in T$. Let D be the cut determined by $T - e$. Then the circuit C contains at least one edge $f \neq e$ that belongs to D. So $T' := (T \setminus \{e\}) \cup \{f\}$ is a spanning tree again. By assumption, $l(e) \geq l(f)$ and hence $l(T') \leq l(T)$. Hence T'

is a shortest spanning tree again. It is contained in $K \setminus \{e\}$, which therefore is a good connector. ∎

So we can formulate the *dual greedy algorithm*: starting with $K := E$, iteratively remove from K an edge e satisfying (50.6). We end up with a shortest spanning tree.

A special case is the following algorithm, proposed by Kruskal [1956]: iteratively delete a longest edge e that is not a bridge. We end up with a shortest spanning tree.

50.4. The longest forest and the forest polytope

The greedy algorithm can be easily adapted so as to give:

Theorem 50.6. *A longest forest can be found in strongly polynomial time.*

Proof. It suffices to find a longest spanning tree in any component. This can be done with the greedy method. ∎

As Edmonds [1971] noticed, it is easy to derive with the greedy method a min-max relation for the maximum length of a forest in a graph $G = (V, E)$. This is similar to the results of Section 40.2.

Theorem 50.7. *Let $G = (V, E)$ be a graph and let $l \in \mathbb{Z}_+^E$. Then the maximum length of a forest is equal to the minimum value of*

$$(50.7)\qquad \sum_{U \in \mathcal{P}(V)\setminus\{\emptyset\}} y_U(|U| - 1),$$

where $y \in \mathbb{Z}_+^{\mathcal{P}(V)\setminus\{\emptyset\}}$ satisfies

$$(50.8)\qquad \sum_{U \in \mathcal{P}(V)\setminus\{\emptyset\}} y_U \chi^{E[U]} \geq l.$$

Proof. The maximum cannot be larger than the minimum, since for any forest F and any $y \in \mathbb{Z}_+^{\mathcal{P}(V)\setminus\{\emptyset\}}$ satisfying (50.8) one has:

$$(50.9)\qquad l(F) \leq \sum_{U \in \mathcal{P}(V)\setminus\{\emptyset\}} y_U |E[U] \cap F| \leq \sum_{U \in \mathcal{P}(V)\setminus\{\emptyset\}} y_U(|U| - 1).$$

To see equality, let $k := \max\{l(e) \mid e \in E\}$, and let E_i be the set of edges e with $l(e) \geq i$, for $i = 0, 1, \ldots, k$. For each $U \in \mathcal{P}(V) \setminus \{\emptyset\}$, let y_U be the number of $i \in \{1, \ldots, k\}$ such that U is a component of the graph (V, E_i). Then it is easy to see that y satisfies (50.8).

We can find a sequence of forests $F_k \subseteq \cdots \subseteq F_1 \subseteq F_0$, where for $i = 0, 1, \ldots, k$, F_i is a maximal forest in (V, E_i) containing F_{i+1}, setting $F_{k+1} := \emptyset$.

Then for $F := F_0$ we have:

$$(50.10) \qquad l(F) = \sum_{i=0}^{k} i|F_i \setminus F_{i+1}| = \sum_{i=1}^{k} |F_i| = \sum_{i=1}^{k} (|V| - \kappa(V, E_i)) = \sum_{U \in \mathcal{P}(V) \setminus \{\emptyset\}} y_U(|U| - 1),$$

where $\kappa(V, E_i)$ denotes the number of components of the graph (V, E_i). ∎

(The series of forests $F_k \subseteq F_{k-1} \subseteq \cdots \subseteq F_1 \subseteq F_0$, corresponds to the greedy method.)

Note that this theorem gives, if G is connected, a min-max relation for the maximum length of a spanning tree.

For any graph $G = (V, E)$, let the *forest polytope* of G, denoted by $P_{\text{forest}}(G)$, be the convex hull of the incidence vectors (in $\mathbb{R}^E$) of the forests of G. The following characterization of the forest polytope is (in matroid terms) due to Edmonds [1971] (announced in Edmonds [1967a]):

Corollary 50.7a. *The forest polytope of a graph G is determined by*

$$(50.11) \qquad \begin{array}{lll} \text{(i)} & x_e \geq 0 & \text{for } e \in E, \\ \text{(ii)} & x(E[U]) \leq |U| - 1 & \text{for nonempty } U \subseteq V. \end{array}$$

Proof. Trivially, the incidence vector of any forest satisfies (50.11), and hence the forest polytope is contained in the polytope determined by (50.11). Suppose now that the latter polytope is larger. Then (since both polytopes are rational and down-monotone in $\mathbb{R}^E_+$) there exists a vector $l \in \mathbb{Q}^E_+$ such that the maximum value of $l^{\mathsf{T}}x$ over (50.11) is larger than the maximum of $l(F)$ over forests F. We can assume that l is integer. However, by Theorem 50.7, the maximum of $l(F)$ is at least the minimum value of the problem dual to maximizing $l^{\mathsf{T}}x$ over (50.11), a contradiction. ∎

Theorem 50.7 can be stated equivalently in TDI terms as follows:

Corollary 50.7b. *System* (50.11) *is totally dual integral.*

Proof. This follows from Theorem 50.7, by the definition of total dual integrality. ∎

Having a description of the forest polytope, we can derive a description of the *spanning tree polytope* $P_{\text{spanning tree}}(G)$ of a graph $G = (V, E)$, which is the convex hull of the incidence vectors of the spanning trees in G.

Corollary 50.7c. *The spanning tree polytope of a graph $G = (V, E)$ is determined by*

(50.12)
$$\begin{array}{rll} \text{(i)} & x_e \geq 0 & \text{for } e \in E, \\ \text{(ii)} & x(E[U]) \leq |U| - 1 & \text{for nonempty } U \subseteq V, \\ \text{(iii)} & x(E) = |V| - 1. & \end{array}$$

Proof. Directly from Corollary 50.7a, since the spanning trees are exactly the forests of size $|V|-1$, and since there exist no forests larger than that. ∎

One also directly has a TDI result:

Corollary 50.7d. *System* (50.12) *is totally dual integral.*

Proof. Directly from Corollary 50.7b, since (50.12) arises from (50.11) by setting an inequality to equality (cf. Theorem 5.25). ∎

Theorem 40.5 implies that (if G is loopless) an inequality (50.12)(ii) is facet-inducing if and only if $|U| \geq 2$ and U induces a 2-connected subgraph of G (cf. Grötschel [1977a]).

In Section 51.4 we consider the problem of testing membership of the forest polytope.

50.5. The shortest connector and the connector polytope

The greedy method also provides a min-max relation for the minimum length of a connector in a graph $G = (V, E)$. Let Π denote the collection of partitions of V into nonempty subsets. For any partition $\mathcal{P}$ of V, let $\delta(\mathcal{P})$ denote the set of edges connecting two different classes of $\mathcal{P}$. So any connector contains at least $|\mathcal{P}| - 1$ edges in $\delta(\mathcal{P})$.

Theorem 50.8. *Let $G = (V, E)$ be a connected graph and let $l \in \mathbb{Z}_+^E$. Then the minimum length of a spanning tree is equal to the maximum value of*

(50.13)
$$\sum_{\mathcal{P} \in \Pi} y_{\mathcal{P}}(|\mathcal{P}| - 1),$$

where $y \in \mathbb{Z}_+^{\Pi}$ such that

(50.14)
$$\sum_{\mathcal{P} \in \Pi} y_{\mathcal{P}} \chi^{\delta(\mathcal{P})} \leq l.$$

Proof. The minimum cannot be smaller than the maximum, since for any spanning tree T and any $y \in \mathbb{Z}_+^{\Pi}$ satisfying (50.14) one has:

(50.15)
$$l(T) \geq \sum_{\mathcal{P} \in \Pi} y_{\mathcal{P}} \chi^{\delta(\mathcal{P})}(T) = \sum_{\mathcal{P} \in \Pi} y_{\mathcal{P}} |\delta(\mathcal{P}) \cap T| \geq \sum_{\mathcal{P} \in \Pi} y_{\mathcal{P}}(|\mathcal{P}| - 1).$$

To see equality, define $k := \max\{l(e) \mid e \in E\}$ and for $i = 0, 1, \ldots, k$, let E_i be the set of edges e with $l(e) \leq i$. For each $\mathcal{P} \in \Pi$, let $y_{\mathcal{P}}$ be the number of

$i \in \{1, \ldots, k\}$ such that $\mathcal{P}$ is the collection of components of (V, E_i). Then it is easy to see that y satisfies (50.14).

We can find a sequence of forests $F_0 \subseteq F_1 \subseteq \cdots F_{k-1} \subseteq F_k$, where F_0 is a maximal forest in (V, E_0), and where for $i = 0, \ldots, k$, F_i is a maximal forest in (V, E_i) containing F_{i-1}, setting $F_{-1} := \emptyset$.

Then for $T := F_k$ we have:

$$\text{(50.16)} \qquad \begin{aligned} l(T) &= \sum_{i=0}^{k} i|F_i \setminus F_{i-1}| = k|T| - \sum_{i=0}^{k-1} |F_i| = \sum_{i=0}^{k-1}(|V| - 1 - |F_i|) \\ &= \sum_{i=1}^{k-1}(\kappa(V, E_i) - 1) = \sum_{\mathcal{P} \in \Pi} y_{\mathcal{P}}(|\mathcal{P}| - 1), \end{aligned}$$

where $\kappa(V, E_i)$ denotes the number of components of the graph (V, E_i). ∎

For any graph $G = (V, E)$, let the *connector polytope* of G, denoted by $P_{\text{connector}}(G)$, be the convex hull of the incidence vectors (in $\mathbb{R}^E$) of the connectors of G. The following characterization can be derived from Edmonds [1970b], and was stated explicitly by Fulkerson [1970b]:

Corollary 50.8a. *The connector polytope of a graph G is determined by*

$$\text{(50.17)} \qquad \begin{array}{lll} \text{(i)} & 0 \leq x_e \leq 1 & \text{for } e \in E, \\ \text{(ii)} & x(\delta(\mathcal{P})) \geq |\mathcal{P}| - 1 & \text{for } \mathcal{P} \in \Pi. \end{array}$$

Proof. Trivially, the incidence vector of any connector satisfies (50.17), and hence the connector polytope is contained in the polytope determined by (50.17). Suppose now that the latter polytope is larger. Then (since both polytopes are rational and up-monotone in $[0,1]^E$) there exists a vector $l \in \mathbb{Q}_+^E$ such that the minimum value of $l^{\mathsf{T}}x$ over (50.17) is smaller than the minimum of $l(C)$ over connectors C. We can assume that l is integer. However, by Theorem 50.8, the minimum of $l(C)$ is at most the maximum value of the problem dual to minimizing $l^{\mathsf{T}}x$ over (50.17), a contradiction. ∎

Theorem 50.8 can be stated equivalently in TDI terms as follows:

Corollary 50.8b. *System* (50.17) *is totally dual integral.*

Proof. This follows from Theorem 50.8, by the definition of total dual integrality. ∎

Chopra [1989] described the facets of the connector polytope. In Section 51.4 we consider the problem of testing membership of the connector polytope.

50.6. Further results and notes

50.6a. Complexity survey for shortest spanning tree

	$O(nm)$	Jarník [1930]
	$O(n^2)$	Prim [1957], Dijkstra [1959]
	$O(m \log n)$	Kershenbaum and Van Slyke [1972], E.L. Johnson (cf. Kershenbaum and Van Slyke [1972])
	$O(m \log_{m/n} n)$	D.B. Johnson [1975b]
	$O(m\sqrt{\log n})$	R.E. Tarjan (cf. Yao [1975])
	$O(m \log \log n)$	Yao [1975]
	$O(m \log \log_{m/n} n)$	Cheriton and Tarjan [1976], Tarjan [1983]
*	$O((m + n \log L) \log \log L)$	D.B. Johnson [1977b]
	$O(m + n \log n)$	Fredman and Tarjan [1984,1987]
	$O(m\beta(m, n))$	Fredman and Tarjan [1984,1987]
	$O(m \log \beta(m, n))$	Gabow, Galil, Spencer, and Tarjan [1986] (cf. Gabow, Galil, and Spencer [1984])
	$O(m(\log_n L + \alpha(m, n)))$	Gabow [1983b,1985b]
	$O(m\alpha(m, n) \log \alpha(m, n))$	Chazelle [1997]
*	$O(m\alpha(m, n))$	Chazelle [2000]

As before, $*$ indicates an asymptotically best bound in the table. Moreover, $\beta(m, n) := \min\{i \mid \log_2^{(i)} n \leq m/n\}$ and $L := \max\{l(e) \mid e \in E\}$ (assuming l nonnegative integer). The function $\alpha(m, n)$ is the *inverse Ackermann function*, defined as follows. For $i, j \geq 1$, the *Ackermann function* $A(i, j)$ is defined recursively by:

$$\begin{aligned} A(1, j) &= 2^j && \text{for } j \geq 1, \\ A(i, 1) &= A(i-1, 2) && \text{for } i \geq 2, \\ A(i, j) &= A(i-1, A(i, j-1)) && \text{for } i, j \geq 2. \end{aligned} \tag{50.18}$$

Next, for $m \geq n \geq 1$,

$$\alpha(m, n) := \min\{i \geq 1 \mid A(i, \lfloor m/n \rfloor) > \log_2 n\}. \tag{50.19}$$

The function $\alpha(m, n)$ is extremely slowly growing.

Fredman and Willard [1990,1994] gave a 'strongly trans-dichotomous' linear-time minimum spanning tree algorithm (where capabilities of random access machines, like addressing, can be used). Based on sampling, Karger [1993,1998] found a simple linear-time approximative spanning tree algorithm, and an $O(m+n \log n)$-time minimum spanning tree algorithm not using Fibonacci heaps.

Katoh, Ibaraki, and Mine [1981] gave an algorithm to find the Kth shortest spanning tree in time $O(Km + \min\{n^2, m \log \log n\})$ (improving slightly Gabow

[1977]). They also gave an algorithm to find the second shortest spanning tree in time $O(\min\{n^2, m\alpha(m,n)\})$.

Pettie and Ramachandran [2000,2002a] showed that a shortest spanning tree can be found in time $O(\mathcal{T}^*(m,n))$, where $\mathcal{T}^*(m,n)$ is the minimum number of edge length comparisons needed to determine the solution.

Frederickson [1983a,1985] gave an $O(\sqrt{m})$-time algorithm to update a shortest spanning tree (and the data-structure) if one edge changes length. Spira and Pan [1973,1975] and Chin and Houck [1978] gave fast algorithms to update a shortest spanning tree if vertices are added or removed. More on sensitivity and most vital edges can be found in Tarjan [1982], Hsu, Jan, Lee, Hung, and Chern [1991], Dixon, Rauch, and Tarjan [1992], Iwano and Katoh [1993], Lin and Chern [1993], and Frederickson and Solis-Oba [1996,1999].

Tarjan [1979] showed that the minimality of a given spanning tree can be checked in time $O(m\alpha(m,n))$ (cf. Dixon, Rauch, and Tarjan [1992]). Komlós [1984, 1985] showed that the minimality of a given spanning tree can be checked by $O(m)$ comparisons of edge lengths. King [1997] gave a linear-time implementation in the unit-cost RAM model. A randomized linear-time algorithm was given by Klein and Tarjan [1994], and Karger, Klein, and Tarjan [1995].

Gabow and Tarjan [1984] (cf. Gabow and Tarjan [1979]) showed that the problem of finding a shortest spanning tree with a prescribed number of edges incident with a (one) given vertex r, is linear-time equivalent to the (unconstrained) shortest spanning tree problem. They also showed that if the edges of a graph are coloured red and blue, a shortest spanning tree having exactly k red edges (for given k) can be found in time $O(m \log\log_{2+\frac{m}{n}} n + n\log n)$.

Brezovec, Cornuéjols, and Glover [1988] gave an efficient algorithm to find a shortest spanning tree in a coloured graph with, for each colour, an upper and a lower bound on the number of edges in the tree of that colour.

Camerini [1978] showed that a spanning tree minimizing $\max_{e\in T} l(e)$ can be found in $O(m)$ time.

Geometric spanning trees (on vertices in Euclidean space, with Euclidean distance as length function) were considered by Bentley, Weide, and Yao [1980], Yao [1982], Supowit [1983], Clarkson [1984,1989], and Agarwal, Edelsbrunner, Schwarzkopf, and Welzl [1991].

50.6b. Characterization of shortest spanning trees

The following theorem is implicit in Kalaba [1960]:

Theorem 50.9. *Let $G = (V,E)$ be a graph, let $l \in \mathbb{R}^E$ be a length function, and let T be a spanning tree in G. Then T is a shortest spanning tree if and only if $l(f) \geq l(e)$ for all $e \in T$ and $f \in E \setminus T$ with $T - e + f$ a spanning tree.*

Proof. Necessity being trivial, we show sufficiency. Let the condition be satisfied, and suppose that T is not a shortest spanning tree. Choose a shorter spanning tree T' with $|T' \setminus T|$ minimal. Let $f \in T' \setminus T$. Let e be an edge on the circuit in $T \cup \{f\}$ with $e \neq f$, such that e connects the two components of $T' \setminus \{f\}$. Then $(T\setminus\{e\})\cup\{f\}$ is a spanning tree, and hence $l(f) \geq l(e)$. Define $T'' := (T'\setminus\{f\})\cup\{e\}$. Then $l(T'') \leq l(T') < l(T)$ and $|T'' \setminus T| < |T' \setminus T|$, contradicting our minimality assumption. ∎

This theorem gives a good characterization of the minimum length of a spanning tree. (As Kalaba [1960] pointed out, it also gives an algorithm to find a shortest spanning tree (by iteratively exchanging one edge for another if it makes the tree shorter), but it is not polynomial-time.)

Recall that a forest is called *good* if it is contained in a shortest spanning tree.

Corollary 50.9a. *Let $G = (V, E)$ be a connected graph, let $l \in \mathbb{R}^E$ be a length function, and let F be a forest. Then F is good if and only if for each $e \in F$ there exists a cut C with $C \cap F = \{e\}$ and with e shortest in C.*

Proof. To see necessity, let F be good and let $e \in F$. So there exists a shortest spanning tree T containing F. By Theorem 50.9, e is a shortest edge connecting the two components of $T - e$. This gives the required cut C.

Sufficiency is shown by induction on $|F|$, the case $F = \emptyset$ being trivial. Choose $e \in F$. By induction, $F \setminus \{e\}$ is good (as the condition is maintained for $F \setminus \{e\}$). The condition implies that (50.2) is satisfied, and hence F is good by Theorem 50.1. ∎

50.6c. The maximum reliability problem

Often, in designing a network, one is not primarily interested in minimizing the total length, but rather in maximizing 'reliability' (for instance when designing energy or communication networks).

Let $G = (V, E)$ be a connected graph and let $r : E \to \mathbb{R}_+$ be a function. Let us call $r(e)$ the *reliability* of edge e. For any path P in G, the *reliability* of P is, by definition, the minimum reliability of the edges occurring in P. The *reliability* $r_G(s, t)$ of two vertices s and t is equal to the maximum reliability of P where P ranges over all $s - t$ paths. That is,

$$r_G(s,t) := \max_{P} \min_{e \in EP} r(e), \tag{50.20}$$

where the maximum ranges over all $s - t$ paths P. (The value of $r_G(s, t)$ can be found with the method described in Section 8.6e.)

The problem now is to find a minimal subgraph H of G having the same reliability as G; that is, with $r_H = r_G$. Hu [1961] observed that there is a spanning tree carrying the reliability of G. More precisely, Hu showed that any spanning tree T of maximum total reliability is such a tree (also shown by Kalaba [1964]):

Corollary 50.9b. *Let $G = (V, E)$ be a graph, let $r \in \mathbb{R}^E$, and let T be any spanning tree. Then $r_T(s, t) = r_G(s, t)$ for all s, t if and only if T is a spanning tree in G maximizing $r(T)$.*

Proof. To see sufficiency, let T maximize $r(T)$. Choose $s, t \in V$, and let P be a path in G attaining maximum (50.20). Let e be an edge on the $s - t$ path in T with minimum $r(e)$. Then P contains an edge f connecting the two components of $T - e$. As T maximizes $r(T)$ we have $r(f) \leq r(e)$. Hence

$$r_T(s,t) = r(e) \geq r(f) \geq r_G(s,t). \tag{50.21}$$

Since trivially $r_T(s,t) \leq r_G(s,t)$, this shows sufficiency.

To see necessity, we apply Theorem 50.9. Choose $e \in T$, and suppose that there is an edge f connecting the components of $T - e$, with $r(f) > r(e)$. Then for the ends s, t of f we have

(50.22) $$r_G(s,t) \geq r(f) > r(e) \geq r_T(s,t),$$

a contradiction. ∎

Corollary 50.9b implies:

Corollary 50.9c. *Let $G = (V, E)$ be a complete graph and let $l : E \to \mathbb{R}_+$ be a length function satisfying*

(50.23) $$l(uw) \geq \min\{l(uv), l(vw)\}$$

for all distinct $u, v, w \in V$. Let T be a longest spanning tree in G. Then for all $u, w \in V$, $l(uw)$ is equal to the minimum length of the edges in the $u - w$ path in T.

Proof. Note that (50.23) implies that $l(uw)$ is equal to the reliability $r_G(u,w)$ of u and w, taking $r := l$. So the corollary follows from Corollary 50.9b. ∎

This implies the following. Let $G = (V, E)$ be a graph and let $c : E \to \mathbb{R}_+$ be a capacity function. Let K be the complete graph on V. For each edge st of K, let the length $l(st)$ be the minimum capacity of any $s - t$ cut in G. (An $s - t$ cut is any subset $\delta(W)$ with $s \in W, t \notin W$.)

Let T be a longest spanning tree in K. Then for all $s, t \in V$, $l(st)$ is equal to the minimum length of the edges of T in the $s - t$ path in T.

(This tree need not be a Gomory-Hu tree, as is shown by the complete graph on vertices $1, 2, 3$ and $c(12) = 1$ and $c(13) = c(23) = 2$. Then edges 12 and 13 form a tree as above, but it is not a Gomory-Hu tree.)

50.6d. Exchange properties of forests

The following fundamental property of forests in fact is the basis of most theorems in this chapter. It is the 'exchange property' that makes the collection of forests into a matroid.

Theorem 50.10. *Let $G = (V, E)$ be a graph and let F and F' be forests with $|F| < |F'|$. Then $F \cup \{e\}$ is a forest for some $e \in F' \setminus F$.*

Proof. We can assume that $E = F \cup F'$. If no such edge e exists, then F is a maximal forest in G. This however implies that $|F| \geq |F'|$, a contradiction. ∎

Call a forest F *extreme* if $l(F') \geq l(F)$ for each forest F' satisfying $|F'| = |F|$. The forests made iteratively in Kruskal's method all are extreme, since:

Corollary 50.10a. *Let F be an extreme forest and let e be a shortest edge with $e \notin F$ and $F \cup \{e\}$ a forest. Then $F \cup \{e\}$ is extreme again.*

Proof. Let F' be an extreme forest with $|F'| = |F| + 1$. By Theorem 50.10, there exists an $e' \in F' \setminus F$ such that $F \cup \{e'\}$ is a forest. As F is extreme we have $l(F' \setminus \{e'\}) \geq l(F)$. Hence $l(F \cup \{e'\}) \leq l(F')$. Also, by the choice of e, $l(e) \leq l(e')$. So $l(F \cup \{e\}) \leq l(F')$. Concluding, $F \cup \{e\}$ is extreme (as F' is extreme). ∎

The following corollary is due to Florek, Łukaszewicz, Perkal, Steinhaus, and Zubrzycki [1951a]. Recall that a forest is called *good* if it is contained in a shortest spanning tree.

Corollary 50.10b. *Each extreme forest is good.*

Proof. Directly from Corollary 50.10a, since it implies that each extreme forest is contained in an extreme maximal forest, and hence in a shortest maximal forest; so it is good. ∎

We also can derive a 'slice-integrality' result:

Corollary 50.10c. *Let $G = (V, E)$ be a graph and let $k, l \in \mathbb{Z}_+$. Then the convex hull of the incidence vectors of forests F with $k \leq |F| \leq l$ is equal to the intersection of the forest polytope of G with $\{x \in \mathbb{R}^E \mid k \leq x(E) \leq l\}$.*

Proof. Let x be in the forest polytope with $k \leq x(E) \leq l$. Let $x = \sum_F \lambda_F \chi^F$, where F ranges over all forests and where the λ_F are nonnegative reals with $\sum_F \lambda_F = 1$. Choose the λ_F with

$$(50.24) \qquad \sum_F \lambda_F |F|^2$$

minimal. Then

$$(50.25) \qquad |F'| \leq |F| + 1 \text{ for all } F, F' \text{ with } \lambda_F > 0 \text{ and } \lambda_{F'} > 0.$$

Otherwise we can choose $e \in F' \setminus F$ such that $F \cup \{e\}$ is a forest (by Theorem 50.10). Let $\alpha := \min\{\lambda_F, \lambda_{F'}\}$. Then decreasing λ_F and $\lambda_{F'}$ by α and increasing $\lambda_{F \cup \{e\}}$ and $\lambda_{F' \setminus \{e\}}$ by α, decreases sum (50.24). This contradicts our assumption, and proves (50.25).

It implies that $k \leq |F| \leq l$ for each F with $\lambda_F > 0$, and we have the corollary. ∎

50.6e. Uniqueness of shortest spanning tree

Kotzig [1961b] characterized when there is a unique shortest spanning tree:

Theorem 50.11. *Let $G = (V, E)$ be a graph, let $l \in \mathbb{R}^E$ be a length function, and let T be a spanning tree in G. Then T is a unique shortest spanning tree if and only if $l(f) > l(e)$ for all $e \in T$ and $f \in E \setminus T$ such that $T - e + f$ is a spanning tree.*

Proof. As the proof of Theorem 50.9. ∎

This implies a sufficient condition given by Borůvka [1926a]:

Corollary 50.11a. *Let $G = (V, E)$ be a graph and let $l \in \mathbb{R}^E$ be a length function with $l(e) \neq l(f)$ if $e \neq f$. Then there is a unique shortest spanning tree.*

Proof. Directly from Theorem 50.11. ∎

Let $G = (V, E)$ be a connected graph and let $l \in \mathbb{R}^E$ be a length function, with $l(e) \neq l(f)$ if $e \neq f$. Define

(50.26) $T := \{e \in E \mid \exists \text{ cut } C \text{ such that } e \text{ is the shortest edge of } C\}.$

Then

(50.27) $E \setminus T = \{e \in E \mid \exists \text{ circuit } D \text{ such that } e \text{ is the longest edge in } D\}.$

This is easy, since if some edge e is contained in some cut C and some circuit D, then there exists an edge $f \neq e$ in $C \cap D$. If $l(f) < l(e)$, then e is not shortest in C, and if $l(f) > l(e)$, then e is not longest in D. Moreover, for any $e \in E$, if no circuit D as in (50.27) exists, then each circuit D containing e contains an edge f with $l(f) > l(e)$. Hence the set of edges f with $l(f) \geq l(e)$ contains a cut C containing e. This C is as in (50.26).

Now (Dijkstra [1960], Rosenstiehl [1967]):

(50.28) T is the unique shortest spanning tree in G.

Indeed, T is a forest, since each circuit D intersects $E \setminus T$ (namely, in the longest edge of D). Moreover, T is a connector, since each cut C intersects T (namely, in the shortest edge of C). T is the unique shortest spanning tree. This follows from Theorem 50.11, since for each $e \in T$ and each $f \notin T$, if $(T \setminus \{e\}) \cup \{f\}$ is a spanning tree, then $l(e) < l(f)$ as e is the shortest edge in the cut determined by $T - e$.

50.6f. Forest covers

Let $G = (V, E)$ be an undirected graph. A subset F of E is called a *forest cover* if F is both a forest and an edge cover. Forest covers turn out to be interesting algorithmically and polyhedrally.

As Gamble and Pulleyblank [1989] point out, White [1971] showed:

Theorem 50.12. *Given a graph $G = (V, E)$ and a weight function $w \in \mathbb{Q}^E$, a minimum-weight forest cover can be found in strongly polynomial time.*

Proof. Let E_- be the set of edges of negative weight and let V_- be the set of vertices covered by E_-. Let $V_+ := V \setminus V_-$. First find a subset F' of $E[V_+] \cup \delta(V_+)$ covering V_+, of minimum weight. This can be done in strongly polynomial time, by a variation of the strongly polynomial-time algorithm for the minimum weight edge cover problem. (In fact, it is a special case of Theorem 34.4.)

Next find a forest F'' in $E[V_-]$ of minimum weight. Again, this can be done in strongly polynomial time, by Theorem 50.6.

We can assume that any proper subset of F' does not cover V_+. It implies that F' is a forest and that for any vertex $v \in V_+$ incident with some edge e in F' with $e \in \delta(V_+)$, e is the only edge in F' incident with v.

This implies that $F' \cup F''$ is a forest. Moreover, it is an edge cover, since F' covers V_+ and F'' covers V_-, since any vertex in V_- is incident with an edge of negative weight.

So $F' \cup F''$ is a forest cover. To see that it has minimum weight, let $B \subseteq E$ be any forest cover. Let $B'' := B \cap E[V_-]$ and $B' := B \setminus B''$. Then $w(B') \geq w(F')$, since B' covers V_+. Also, $w(B'') \geq w(F'')$, since B'' is a forest. So $w(B) \geq w(F)$. ∎

Gamble and Pulleyblank [1989] showed that White's method implies a characterization of the *forest cover polytope* $P_{\text{forest cover}}(G)$ of a graph G, which is the convex hull of the incidence vectors of forest covers in G. It turns out to be equal to the intersection of the forest polytope (characterized in Corollary 50.7a) and the edge cover polytope (characterized in Corollary 27.3a):

Theorem 50.13. *For any undirected graph $G = (V, E)$:*

(50.29) $$P_{\text{forest cover}}(G) = P_{\text{forest}}(G) \cap P_{\text{edge cover}}(G).$$

Proof. The inclusion $\subseteq$ is trivial, as any forest cover is both a forest and an edge cover. Suppose that the reverse inclusion does not hold, and let x be a vertex of $P_{\text{forest}}(G) \cap P_{\text{edge cover}}(G)$ which is not in $P_{\text{forest cover}}(G)$. Let $w \in \mathbb{Q}^E$ be a weight function such that x uniquely minimizes $w^{\mathsf{T}}x$ over $P_{\text{forest}}(G) \cap P_{\text{edge cover}}(G)$. We can assume that $w(e) \neq 0$ for each edge e (as we can perturb w slightly).

Again let E_- be the set of edges of negative weight, V_- be the set of vertices covered by E_-, and $V_+ := V \setminus V_-$. Since x is in the edge cover polytope, there exists a subset F' of $E[V_+] \cup \delta(V_+)$ covering V_+ with

(50.30) $$w(F') \leq \sum_{e \in E[V_+] \cup \delta(V_+)} w(e) x_e.$$

Similarly, since x is in the forest polytope, there is a forest F'' in $E[V_-]$ with

(50.31) $$w(F'') \leq \sum_{e \in E[V_-]} w(e) x_e.$$

Now, as in the proof of Theorem 50.12, $F := F' \cup F''$ is a forest cover. Since $w(F) \leq w^{\mathsf{T}}x$, this contradicts our assumptions on x and w. ∎

White [1971] also considered the problem of finding a minimum weight forest cover of given size k. Gamble and Pulleyblank [1989] showed that the convex hull of the incidence vectors of forest covers of size k is equal to the intersection of the forest cover polytope with the hyperplane $\{x \in \mathbb{R}^E \mid x(E) = k\}$.

Cerdeira [1994] related forest covers to matroid intersection.

50.6g. Further notes

Let $G = (V, E)$ be a graph. Call a subset U of V *circuit-free* if U spans no circuit; that is, it induces a forest as subgraph of G. Ding and Zang [1999] characterized the graphs G for which the convex hull of the incidence vectors of circuit-free sets is determined by

(50.32) $$\begin{array}{ll} 0 \leq x_v \leq 1 & \text{for each vertex } v, \\ x(VC) \leq |VC| - 1 & \text{for each circuit } C. \end{array}$$

Their characterization implies that (50.32) is totally dual integral as soon as it determines an integer polytope.

Goemans [1992] studied the convex hull of the incidence vectors of (not necessarily spanning) subtrees of a graph.

Brennan [1982] reported on good experimental results with an implementation of Kruskal's method by only partially sorting the edges until the successive shortest edges to be added to the current forest can be identified.

Győri [1978] and Lovász [1977a] showed that if $G = (V, E)$ is k-connected and $v_1, \ldots, v_k$ are distinct vertices, and $n_1, \ldots, n_k$ are positive integers with $n_1 + \cdots + n_k = |V|$, then G contains a forest F such that the component containing v_i has size n_i ($i = 1, \ldots, k$). For $k = 2$, Győri's proof gives an $O(nm)$-time algorithm. A linear-time algorithm for $k = 2$ was given by Suzuki, Takahashi, and Nishizeki [1990]. More can be found in Győri [1981].

Khuller, Raghavachari, and Young [1993,1995b] considered spanning trees that belance between shortest spanning trees and shortest paths trees.

Books covering shortest spanning trees include Even [1973,1979], Christofides [1975], Lawler [1976b], Minieka [1978], Hu [1982], Papadimitriou and Steiglitz [1982], Smith [1982], Aho, Hopcroft, and Ullman [1983], Sysło, Deo, and Kowalik [1983], Tarjan [1983], Gondran and Minoux [1984], Nemhauser and Wolsey [1988], Chen [1990], Cormen, Leiserson, and Rivest [1990], Lengauer [1990]. Ahuja, Magnanti, and Orlin [1993], Cook, Cunningham, Pulleyblank, and Schrijver [1998], Jungnickel [1999], and Korte and Vygen [2000]. Pierce [1975] and Golden and Magnanti [1977] gave bibliographies on algorithms for shortest spanning tree.

50.6h. Historical notes on shortest spanning trees

We refer to Graham and Hell [1985] for an extensive historical survey of shortest tree algorithms, with several quotes (with translations) from old papers. Our notes below have profited from their investigations.

We recall some terminology for a shortest spanning tree algorithm. We call it *tree-growing* if we keep a tree on a subset of the vertices, and iteratively extend it by adding an edge joining the tree with a vertex outside of the tree. It is *forest-merging* if we keep a forest, and iteratively merge two components by joining them by an edge. It is called *parallel forest-merging* if forest-merging is performed in parallel, by connecting each component to its nearest neighbouring component (assuming all lengths are distinct).

Borůvka: parallel forest-merging

Borůvka [1926a] described the problem of finding a shortest spanning tree as follows (the paper is in Czech; we quote from its German summary; for quotes from Czech with translation, see Graham and Hell [1985]):

> In dieser Arbeit löse ich folgendes Problem:
> Es möge eine Matrix der bis auf die Bedingungen $r_{\alpha\alpha} = 0$, $r_{\alpha\beta} = r_{\beta\alpha}$ positiven und von einander verschiedenen Zahlen $r_{\alpha\beta}$ ($\alpha, \beta = 1, 2, \ldots n; n \geq 2$) gegeben sein.

> Aus dieser ist eine Gruppe von einander und von Null verschiedener Zahlen auszuwählen, so dass
> 1° in ihr zu zwei willkürlich gewählten natürlichen Zahlen p_1, p_2 ($\leq n$) eine Teilgruppe von der Gestalt
>
> $$r_{p_1c_2}, r_{c_2c_3}, r_{c_3c_4}, \ldots r_{c_{q-2}c_{q-1}}, r_{c_{q-1}p_2}$$
>
> existiere,
> 2° die Summe ihrer Glieder kleiner sei als die Summe der Glieder irgendeiner anderen, der Bedingung 1° genügenden Gruppe von einander und von Null verschiedenen Zahlen.[2]

So Borůvka stated that the spanning tree found is the unique shortest. He assumed that all edge lengths are different.

Borůvka next described parallel forest-merging, in a somewhat complicated way. (He did not have the language of graph theory at hand.) The idea is to update a number of vertex-disjoint paths $P_1, \ldots, P_k$ (initially $k = 0$). Along any P_i, the edge lengths are decreasing. Let v be the last vertex of P_k and let e be the edge of shortest length incident with v. If the other end vertex of e is not yet covered by any P_i, we extend P_k with e, and iterate. Otherwise, if not all vertices are covered yet by the P_i, we choose such a vertex v, and start a new path P_{k+1} at v. If all vertices are covered by the P_i, we shrink each of the P_i to one vertex, and iterate. At the end, the edges chosen throughout the iterations form a shortest spanning tree. It is easy to see that this in fact is 'parallel forest-merging'.

The interest of Borůvka in this problem came from a question of the Electric Power Company of Western Moravia in Brno, at the beginning of the 1920s, asking for the most economical construction of an electric power network (see Borůvka [1977]).

In a follow-up paper, Borůvka [1926b] gave a simple explanation of the method by means of an example. We refer to Nešetřil, Milková, and Nešetřilova [2001] for translations of and comments on the two papers of Borůvka.

Jarník: tree-growing

In a reaction to Borůvka's work, Jarník wrote on 12 February 1929 a letter to Borůvka in which he described a 'new solution of a minimal problem discussed by Mr Borůvka'. This 'new solution' is the tree-growing method. An extract of the letter was published as Jarník [1930]. We quote from the German summary:

> a_1 ist eine beliebige unter den Zahlen $1, 2, \ldots, n$.
> a_2 ist durch

[2] In this work, I solve the following problem:
A matrix may be given of positive distinct numbers $r_{\alpha\beta}$ ($\alpha, \beta = 1, 2 \ldots n$; $n \geq 2$), up to the conditions $r_{\alpha\alpha} = 0$, $r_{\alpha\beta} = r_{\beta\alpha}$.
From this, a group of numbers, different from each other and from zero, should be selected such that
1° for arbitrarily chosen natural numbers p_1, p_2 ($\leq n$) a subgroup of it exists of the form

$$r_{p_1c_2}, r_{c_2c_3}, r_{c_3c_4}, \ldots r_{c_{q-2}c_{q-1}}, r_{c_{q-1}p_2},$$

2° the sum of its members be smaller than the sum of the members of any other group of numbers different from each other and from zero, satisfying condition 1°.

$$r_{a_1,a_2} = \min_{\left(\substack{l=1,2,\ldots,n \\ l \neq a_1}\right)} r_{a_1,l}$$

> definiert.
> Wenn $2 \leq k < n$ und wenn $[a_1, a_2], \ldots, [a_{2k-3}, a_{2k-2}]$ bereits bestimmt sind, so wird $[a_{2k-1}, a_{2k}]$ durch
> $$r_{a_{2k-1},a_{2k}} = \min r_{i,j},$$
> definiert, wo i alle Zahlen $a_1, a_2, \ldots, a_{2k-2}$, j aber alle übrigen von den Zahlen $1, 2, \ldots, n$ durchläuft.[3]

Again, Jarník assumed that all lengths are distinct and showed that then the shortest spanning tree is unique. For a detailed discussion and translation of the article of Jarník [1930] (and of Jarník and Kössler [1934] on the Steiner tree problem), see Korte and Nešetřil [2001].

Other discoveries of parallel forest-merging

Parallel forest-merging was described also by Choquet [1938] (without proof), who gave as motivation the construction of road systems:

> Étant donné n villes du plan, il s'agit de trouver un réseau de routes permettant d'aller d'une quelconque de ces villes à une autre et tel que:
> 1° la longueur globale du réseau soit minimum;
> 2° exception faite des villes, on ne peut partir d'aucun point dans plus de deux directions, afin d'assurer la sûreté de la circulation; ceci entraîne, par exemple, que lorsque deux routes semblent se croiser en un point qui n'est pas une ville, elles passent en fait l'une au-dessus de l'autre et ne communiquent pas entre elles en ce point, qu'on appellera faux-croisement.[4]

He was one of the first concerned on the complexity of the method:

> Le réseau cherché sera tracé après $2n$ opérations élémentaires au plus, en appelant opération élémentaire la recherche du continu le plus voisin d'un continu donné.[5]

---

[3] a_1 is an arbitrary one among the numbers $1, 2, \ldots, n$.
a_2 is defined by
$$r_{a_1,a_2} = \min_{\left(\substack{l=1,2,\ldots,n \\ l \neq a_1}\right)} r_{a_1,l}.$$
If $2 \leq k < n$ and if $[a_1, a_2], \ldots, [a_{2k-3}, a_{2k-2}]$ are determined already, then $[a_{2k-1}, a_{2k}]$ is defined by
$$r_{a_{2k-1},a_{2k}} = \min r_{i,j},$$
where i runs through all numbers $a_1, a_2, \ldots, a_{2k-2}$, j however through all remaining of the numbers $1, 2, \ldots, n$.

[4] Being given n cities of the plane, the point is to find a network of routes allowing to go from an arbitrary of these cities to another and such that:
1° the global length of the network be minimum;
2° except for the cities, one cannot depart from any point in more than two directions, in order to assure the certainty of the circulation; this entails, for instance, that when two routes seem to cross each other in a point which is not a city, they pass in fact one above the other and do not communicate among them in this point, which we shall call a false crossing.

[5] The network looked for will be traced after at most $2n$ elementary operations, calling the search for the continuum closest to a given continuum an elementary operation.

Also Florek, Łukaszewicz, Perkal, Steinhaus, and Zubrzycki [1951a,1951b] described parallel forest-merging. They were motivated by clustering in anthropology, taxonomy, etc. In the latter paper, they apply the method to:

> 1° the capitals of Poland's provinces, 2° two collections of excavated skulls, 3° 42 archeological finds, 4° the liverworts of Silesian Beskid mountains with forests as their background, and to the forests of Silesian Beskid mountains with the liverworts appearing in them as their background.

Kruskal

Kruskal [1956] was motivated by Borůvka's first paper and by the application to the traveling salesman problem, described as follows (where [1] refers to Borůvka [1926a]):

> Several years ago a typewritten translation (of obscure origin) of [1] raised some interest. This paper is devoted to the following theorem: If a (finite) connected graph has a positive real number attached to each edge (the *length* of the edge), and if these lengths are all distinct, then among the spanning trees (German: Gerüst) of the graph there is only one, the sum of whose edges is a minimum; that is, the shortest spanning tree of the graph is unique. (Actually in [1] this theorem is stated and proved in terms of the "matrix of lengths" of the graph, that is, the matrix $\|a_{ij}\|$ where a_{ij} is the length of the edge connecting vertices i and j. Of course, it is assumed that $a_{ij} = a_{ji}$ and that $a_{ii} = 0$ for all i and j.) The proof in [1] is based on a not unreasonable method of constructing a spanning subtree of minimum length. It is in this construction that the interest largely lies, for it is a solution to a problem (Problem 1 below) which on the surface is closely related to one version (Problem 2 below) of the well-known traveling salesman problem.
> PROBLEM 1. Give a practical method for constructing a spanning subtree of minimum length.
> PROBLEM 2. Give a practical method for constructing an unbranched spanning subtree of minimum length.
> The construction in [1] is unnecessarily elaborate. In the present paper I give several simpler constructions which solve Problem 1, and I show how one of these constructions may be used to prove the theorem of [1]. Probably it is true that any construction which solves Problem 1 may be used to prove this theorem.

Kruskal described three algorithms: Construction A: iteratively choose the shortest edge that can be added (forest-merging); Construction B: fix a nonempty set U of vertices, and choose iteratively the shortest edge leaving some component intersecting U (a generalization of tree-growing); Construction A′: iteratively remove the longest edge that can be removed without making the graph disconnected. He proved that Construction A implies the uniqueness of shortest spanning tree if all lengths are distinct.

In his reminiscences, Kruskal [1997] wrote about Borůvka's method:

> In one way, the method of construction was very elegant. In another way, however, it was unnecessarily complicated. A goal which has always been important to me is to find simpler ways to describe complicated ideas, and that is all I tried to do here. I simplified the construction down to its essence, but it seems to me that the idea of Professor Borůvka's method is still present in my version.

Prim

Prim [1957] gave the following motivation:

> A problem of inherent interest in the planning of large-scale communication, distribution and transportation networks also arises in connection with the current rate structure for Bell System leased-line services.

He described the following algorithm: choose a component of the current forest, and connect it to the nearest component. He observed that Kruskal's constructions A and B are special cases of this.

Prim noticed that in fact only the order of the lengths determines if a spanning tree is shortest:

> The *shortest spanning subtree* of a connected labelled graph also minimizes all increasing symmetric functions, and maximizes all decreasing symmetric functions, of the edge "lengths."

Prim preferred starting at a vertex and growing a tree for computational reasons:

> This computational procedure is easily programmed for an automatic computer so as to handle quite large-scale problems. One of its advantages is its avoidance of checks for closed cycles and connectedness. Another is that it never requires access to more than two rows of distance data at a time — no matter how large the problem.

The implementation described by Prim has $O(n^2)$ running time.

Loberman and Weinberger

Loberman and Weinberger [1957] gave minimizing wire connections as motivation:

> In the construction of a digital computer in which high-frequency circuitry is used, it is desirable and often necessary when making connections between terminals to minimize the total wire length in order to reduce the capacitance and delay-line effects of long wire leads.

They described two methods: tree-growing and forest-merging. Only after they had designed their algorithms, they discovered that their algorithms were given earlier by Kruskal [1956].

> However, it is felt that the more detailed implementation and general proofs of the procedures justify this paper.

They next described how to implement Kruskal's method, in particular, how to merge forests. They also observed that the minimality of a spanning tree depends only on the order of the lengths, and not on their specific values:

> After the initial sorting into a list where the branches are of monotonically increasing length, the actual value of the length of any branch no longer appears explicitly in the subsequent manipulations. As a result, some other parameter such as the square of the length could have been used. More generally, the same minimum tree will persist for all variations in branch lengths that do not disturb the original relative order.

Dijkstra

Dijkstra [1959] gave again the tree-growing method, which he preferred (for computational reasons) above the forest-merging method of Kruskal and Loberman and Weinberger (overlooking the fact that these authors also gave the tree-growing method):

> The solution given here is to be preferred to the solution given by J.B. Kruskal [*1*] and those given by H. Loberman and A. Weinberger [*2*]. In their solutions all the — possibly $\frac{1}{2}n(n-1)$ — branches are first of all sorted according to length. Even if the length of the branches is a computable function of the node coordinates, their methods demand that data for all branches are stored simultaneously. Our method requires the simultaneous storing of the data for at most n branches, ...

Dijkstra described an $O(n^2)$ implementation.

Dijkstra [1960] gave the following alternative shortest spanning tree method: order edges arbitrarily, find the first edge that forms a circuit with previous edges; delete the longest edge from this circuit, and continue. (This method was also found by Rosenstiehl [1967].) This generalizes both forest-merging and tree-growing, by choosing the order appropriately.

Further work

Kalaba [1960] proposed the method of first choosing a spanning tree arbitrarily, and next adding, iteratively, an edge and removing the longest edge in the circuit arising.

Kotzig [1961b] gave again Kruskal's Algorithm A' (a referee pointed Kruskal's work out to Kotzig). Kotzig moreover showed that there is a unique minimum spanning tree T if and only if for each edge e not in T, e is the unique longest edge in the circuit in $T \cup \{e\}$.

As mentioned, Graham and Hell [1985] give an extensive survey on the history of the minimum spanning tree (and minimum Steiner tree) problem. See also Nešetřil [1997] for additional notes on the history of the minimum spanning tree problem.

Chapter 51

Packing and covering of trees

The basic facts on packing and covering of trees follow directly from those on matroid union. In this chapter we check what these results amount to in terms of graphs, and we give some more direct algorithms.

51.1. Unions of forests

For any graph $G = (V, E)$ and any partition $\mathcal{P}$ of V, let $\delta(\mathcal{P})$ denote the set of edges connecting distinct classes of $\mathcal{P}$. From the following consequence of the matroid union theorem we will derive other results on tree packing and covering:

Theorem 51.1. *Let $G = (V, E)$ be an undirected graph and let $k \in \mathbb{Z}_+$. Then the maximum size of the union of k forests is equal to the minimum value of*

(51.1) $$|\delta(\mathcal{P})| + k(|V| - |\mathcal{P}|)$$

taken over all partitions $\mathcal{P}$ of V into nonempty classes.

Proof. This follows directly from the matroid union theorem (Corollary 42.1a) applied to the cycle matroid M of G. Indeed, by Corollary 42.1b, the maximum size of the union of k forests is equal to the minimum value of

(51.2) $$|E \setminus F| + kr_M(F),$$

where $r_M(F)$ is the maximum size of a forest contained in F. We can assume that each component of (V, F) is an induced subgraph of G. So taking $\mathcal{P}$ equal to the set of components of (V, F), we see that $r_M(F) = |V| - |\mathcal{P}|$, and hence that the minimum of (51.2) is equal to the minimum of (51.1). ∎

51.2. Disjoint spanning trees

Theorem 51.1 has a number of consequences. First we have the following tree packing result of Tutte [1961a] and Nash-Williams [1961b]:

Corollary 51.1a (Tutte-Nash-Williams disjoint trees theorem)**.** *A graph $G = (V, E)$ contains k edge-disjoint spanning trees if and only if*

(51.3) $$|\delta(\mathcal{P})| \geq k(|\mathcal{P}| - 1)$$

for each partition $\mathcal{P}$ of V into nonempty classes.

Proof. To see necessity of (51.3), each spanning tree contains at least $|\mathcal{P}|-1$ edges in $\delta(\mathcal{P})$. To show sufficiency, it is equivalent to show that there exist $k(|V|-1)$ edges that can be covered by k forests. By Theorem 51.1, this is indeed possible, since

(51.4) $$|\delta(\mathcal{P})| + k(|V| - |\mathcal{P}|) \geq k(|\mathcal{P}| - 1) + k(|V| - |\mathcal{P}|) = k(|V| - 1)$$

for each partition $\mathcal{P}$ of V into nonempty sets. ∎

Gusfield [1983] observed that the Tutte-Nash-Williams disjoint trees theorem (Corollary 51.1a) implies that each $2k$-edge-connected undirected graph has k edge-disjoint spanning trees (since $|\delta(\mathcal{P})| \geq k|\mathcal{P}| \geq k(|\mathcal{P}|-1)$).

Similarly to the line pursued in Section 42.2, Corollary 51.1a can be formulated equivalently in polyhedral terms:

Corollary 51.1b. *The connector polytope of a graph has the integer decomposition property.*

Proof. Similar to the proof of Corollary 42.1e. ∎

For any connected graph $G = (V, E)$, define the *strength* of G by:

(51.5) $$\begin{aligned}\text{strength}(G) &:= \max\{\lambda \mid \mathbf{1} \in \lambda \cdot P_{\text{connector}}(G)\} \\ &= \max\{\sum_T \lambda_T \mid \lambda_T \geq 0, \sum_T \lambda_T \chi^T \leq \mathbf{1}\},\end{aligned}$$

where T ranges over the spanning trees of G, and where $\mathbf{1}$ denotes the all-1 vector in $\mathbb{R}^E$.

The Tutte-Nash-Williams disjoint trees theorem is equivalent to: the maximum number of disjoint spanning trees in a graph $G = (V, E)$ is equal to $\lfloor \text{strength}(G) \rfloor$. Similarly, the capacitated version of the Tutte-Nash-Williams theorem is equivalent to the integer rounding property of the system (cf. Section 42.2):

(51.6) $$\begin{aligned} x_e &\geq 0 && \text{for } e \in E, \\ x(T) &\geq 1 && \text{for each spanning tree } T. \end{aligned}$$

51.3. Covering by forests

Dual to Corollary 51.1a is the following forest covering theorem of Nash-Williams [1964], where $E[U]$ denotes the set of edges contained in U. (The theorem is also a consequence of a theorem of Horn [1955] on covering vector sets by linearly independent sets, since each graphic matroid is linear.)

Corollary 51.1c (Nash-Williams' covering forests theorem)**.** *The edge set of a graph $G = (V, E)$ can be covered by k forests if and only if*

$$(51.7) \qquad |E[U]| \leq k(|U| - 1)$$

for each nonempty subset U of V.

Proof. Since any forest has at most $|U| - 1$ edges contained in U, we have necessity of (51.7). To see sufficiency, notice that (51.7) implies

$$(51.8) \qquad |E| - |\delta(\mathcal{P})| = \sum_{U \in \mathcal{P}} |E[U]| \leq \sum_{U \in \mathcal{P}} k(|U| - 1) = k(|V| - |\mathcal{P}|)$$

for any partition $\mathcal{P}$ of V into nonempty sets. So $|\delta(\mathcal{P})| + k(|V| - |\mathcal{P}|) \geq |E|$, and hence Theorem 51.1 implies that there exist k forests covering E. ∎

(Nash-Williams [1964] derived Corollary 51.1c from Corollary 51.1a.)

Again, this corollary can be formulated in terms of the integer decomposition property:

Corollary 51.1d. *For any graph G, the forest polytope has the integer decomposition property.*

Proof. Similar to the proof of Corollary 42.1e. ∎

These results are equivalent to: the minimum number of forests needed to cover the edges of a graph $G = (V, E)$ is equal to

$$(51.9) \qquad \lceil \min\{\lambda \mid \mathbf{1} \in \lambda \cdot P_{\text{forest}}(G)\} \rceil,$$

where $\mathbf{1}$ denotes the all-one vector in $\mathbb{R}^E$. A similar relation holds for the capacitated case, which is equivalent to the integer rounding property of the system:

$$(51.10) \qquad \begin{array}{ll} x_e \geq 0 & \text{for } e \in E, \\ x(F) \leq 1 & \text{for each forest } F. \end{array}$$

The minimum number of forests needed to cover the edges of a graph G is called the *arboricity* of G.

51.4. Complexity

The complexity results on matroid union in Sections 40.3, 42.3 and 42.4 imply that these packing and covering problems for forests and trees are solvable in polynomial time:

Theorem 51.2. *For any graph $G = (V, E)$, a maximum number of edge-disjoint spanning trees and a minimum number of forests covering E can be found in polynomial time.*

Proof. See Section 42.3. ∎

Also weighted versions of it can be solved in strongly polynomial time, for instance, finding a maximum-weight union of k forests in a graph. We give in this section some direct proofs.

To study the complexity of the capacitated and fractional cases, we first observe the following auxiliary result, that is (when applied to undirected graphs) at the base of several algorithms on the forest and connector polytopes, and was observed by Rhys [1970], Picard and Ratliff [1975,1978], Picard [1976], Trubin [1978], Picard and Queyranne [1982a], Padberg and Wolsey [1983], and Cunningham [1985a]. (It also follows from the strong polynomial-time solvability of submodular function minimization, but there is an easier direct method.)

Theorem 51.3. *Given a digraph $D = (V, A)$, $x \in \mathbb{Q}_+^A$, $y \in \mathbb{Q}^V$, and disjoint subsets S and T, we can find a set U with $T \subseteq U \subseteq V \setminus S$ minimizing*

(51.11) $$x(\delta^{\mathrm{in}}(U)) + y(U)$$

in strongly polynomial time.

Proof. Extend D by two new vertices s and t, and arcs (s, v) for $v \in V$ with $y_v > 0$ and (v, t) for $v \in V$ with $y_v < 0$. This gives the digraph $D' = (V \cup \{s, t\}, A')$. Define a capacity function c on A' by:

(51.12) $$\begin{array}{ll} c(u,v) := x(u,v) & \text{for } (u,v) \in A, \\ c(s,v) := y_v & \text{if } (s,v) \in A', \\ c(v,t) := -y_v & \text{for } (v,t) \in A'. \end{array}$$

Let $\kappa := -c(\delta^{\mathrm{in}}_{A'}(t))$ (the sum of the negative y_v's). Then

(51.13) $$\begin{aligned} c(\delta^{\mathrm{in}}_{A'}(U \cup \{t\})) &= x(\delta^{\mathrm{in}}_A(U)) + \sum_{\substack{v \in U \\ y_v > 0}} y_v - \sum_{\substack{v \in V \setminus U \\ y_v > 0}} y_v \\ &= x(\delta^{\mathrm{in}}_A(U)) + \sum_{v \in U} y_v - \sum_{\substack{v \in V \\ y_v < 0}} y_v = x(\delta^{\mathrm{in}}_A(U)) + y(U) - \kappa \end{aligned}$$

for any $U \subseteq V$. Thus minimizing $x(\delta^{\mathrm{in}}_A(U)) + y(U)$ is reduced to finding a minimum-capacity $(S \cup \{s\}) - (T \cup \{t\})$ cut in D'. ∎

Testing membership and finding most violated inequalities

A first consequence of Theorem 51.3 is that we can test membership, and find a most violated inequality, for the forest polytope (Picard and Queyranne [1982b] (suggested by W.H. Cunningham) and Padberg and Wolsey [1983]).

Corollary 51.3a. *Given a graph $G = (V, E)$ and $x \in \mathbb{Q}_+^E$, we can decide if x belongs to $P_{\text{forest}}(G)$, and if not, find a most violated inequality among* (50.11)*, in strongly polynomial time.*

Proof. Define $y_v := 2 - x(\delta(v))$ for $v \in V$. Then

$$
\begin{aligned}
(51.14) \qquad 2(x(E[U]) - |U|) &= \sum_{v \in U} x(\delta(v)) - x(\delta(U)) - 2|U| \\
&= -x(\delta(U)) - y(U).
\end{aligned}
$$

So any nonempty $U \subseteq V$ minimizing $x(\delta(U))+y(U)$, maximizes $x(E[U])-|U|$. By Theorem 51.3, we can find such a U in strongly polynomial time. If $x(E[U]) \leq |U| - 1$, x belongs to $P_{\text{forest}}(G)$, and otherwise U gives a most violated inequality. ∎

A similar result holds for the up hull of the connector polytope, which we show with a method of Jünger and Pulleyblank [1995]:

Corollary 51.3b. *Given a graph $G = (V, E)$ and $x \in \mathbb{Q}_+^E$, we can find a partition $\mathcal{P}$ of V into nonempty sets minimizing*

$$(51.15) \qquad x(\delta(\mathcal{P})) - |\mathcal{P}|$$

in strongly polynomial time.

Proof. We first construct a vector $y \in \mathbb{Q}^V$, by updating a vector y. Throughout, y satisfies

$$(51.16) \qquad y(U) \leq x(\delta(U)) - 2 \text{ for each nonempty } U \subseteq V.$$

Start with $y_v := -2$ for all $v \in V$. Successively, for each $v \in V$, reset y_v to $y_v + \alpha$, where α is the minimum value of

$$(51.17) \qquad x(\delta(U)) - 2 - y(U)$$

taken over all $U \subseteq V$ containing v. Such a U can be found in strongly polynomial time by Theorem 51.3.

We end up with a y satisfying (51.16). Moreover, each $v \in V$ is contained in some set U with $y(U) = x(\delta(U)) - 2$.

Let $\mathcal{P}$ be the inclusionwise maximal sets U satisfying $y(U) = x(\delta(U)) - 2$. Then $\mathcal{P}$ is a partition of V, since if $T, U \in \mathcal{P}$ and $T \cap U \neq \emptyset$, then (by the submodularity of $x(\delta(Y))$) $y(T \cup U) = x(\delta(T \cup U)) - 2$, and hence $T = U = T \cup U$.

This $\mathcal{P}$ is as required, since for each partition $\mathcal{Q}$ of V into nonempty sets we have

$$(51.18) \qquad 2x(\delta(\mathcal{Q})) - 2|\mathcal{Q}| = \sum_{U \in \mathcal{Q}} (x(\delta(U)) - 2) \geq \sum_{U \in \mathcal{Q}} y(U) = y(V),$$

with equality if $\mathcal{Q} = \mathcal{P}$. ∎

(This method is analogous to calculating the Dilworth truncation as discussed in Theorem 48.4.)

Corollary 51.3b implies for finding the most violated inequality:

Corollary 51.3c. *Given a graph $G = (V, E)$ and $x \in \mathbb{Q}_+^E$, we can decide if x belongs to $P^{\uparrow}_{\text{connector}}(G)$, and if not, find a most violated inequality among* (50.17)(ii)*, in strongly polynomial time.*

Proof. By Corollary 51.3b, we can find a partition $\mathcal{P}$ of V into nonempty sets, minimizing $x(\delta(\mathcal{P})) - |\mathcal{P}|$. If this value is at least -1, then x belongs to the up hull of the connector polytope, while otherwise $\mathcal{P}$ gives a most violated inequality among (50.17)(ii). ∎

Barahona [1992] showed that membership in the connector polytope can be tested by solving $O(n)$ maximum flow computations (improving Cunningham [1985c]).

Fractional decomposition into trees

By definition, any vector in $P_{\text{forest}}(G)$ or $P_{\text{connector}}(G)$ can be decomposed as a convex combination of incidence vectors of forests or of connectors. These decompositions can be found in strongly polynomial time, a result due to Cunningham [1984] and Padberg and Wolsey [1984] (for the forest polytope).

In order to decompose a vector in the forest polytope as a convex combination of forests, by the following theorem it suffices to have a method to decompose a vector in the spanning tree polytope as a convex combination of spanning trees:

Theorem 51.4. *Given a connected graph $G = (V, E)$ and $x \in P_{\text{forest}}(G)$, we can find a $z \in P_{\text{spanning tree}}(G)$ with $x \leq z$ in strongly polynomial time.*

Proof. We reset x successively for each edge $e = uv$ of G as follows. Reset x_e to $x_e + \alpha$, where α is the largest value such that x remains to belong to $P_{\text{forest}}(G)$. That is, α equals the minimum value of

$$(51.19) \qquad |U| - 1 - x(E[U]) = |U| - 1 - \tfrac{1}{2}\sum_{v \in U} x(\delta(v)) + \tfrac{1}{2}x(\delta(U)),$$

taken over subsets U of V with $u, v \in U$. Such a U can be found in strongly polynomial time by Theorem 51.3.

As $P_{\text{forest}}(G) = P^{\downarrow}_{\text{spanning tree}}(G) \cap \mathbb{R}_+^E$, the final x is a z as required. ∎

Hence, to decompose a vector in the forest polytope, we can do with decomposing vectors in the spanning tree polytope:

Theorem 51.5. *Given a graph $G = (V, E)$ and $y \in P_{\text{spanning tree}}(G)$, we can find spanning trees $T_1, \ldots, T_k$ and $\lambda_1, \ldots, \lambda_k \geq 0$ satisfying*

$$(51.20) \qquad y = \lambda_1 \chi^{T_1} + \cdots + \lambda_k \chi^{T_k}$$

and $\lambda_1 + \cdots + \lambda_k = 1$, in strongly polynomial time.

Proof. Iteratively resetting y, we keep an integer weight function w such that y maximizes $w^{\mathsf{T}} y$ over the spanning tree polytope. Initially, $w := \mathbf{0}$. We describe the iteration.

Let T be a spanning tree in G with $T \subseteq \text{supp}(y)$, maximizing $w(T)$. Let $a := y - \chi^T$. If $a = \mathbf{0}$ we stop; then $y = \chi^T$. If $a \neq \mathbf{0}$, let λ be the largest rational such that

$$(51.21) \qquad \chi^T + \lambda \cdot a$$

belongs to $P^{\uparrow}_{\text{spanning tree}}(G)$.

We describe an inner iteration to find λ. We iteratively consider vectors y along the halfline $L := \{\chi^T + \lambda \cdot a \mid \lambda \geq 0\}$. Note that the function $w^{\mathsf{T}} x$ is constant on L. First we let λ be the largest rational such that $\chi^T + \lambda \cdot a$ is nonnegative, and set $z := \chi^T + \lambda \cdot a$.

We iteratively reset z. We check if z belongs to the spanning tree polytope, and if not, we find a constraint among (50.12) most violated by z. That is, we find a nonempty subset U of V minimizing $|U| - 1 - z(E[U])$. Let z' be the vector on L attaining $x(E[U]) \leq |U| - 1$ with equality.

Consider any inequality $x(E[U']) \leq |U'| - 1$ violated by z'. Then

$$(51.22) \qquad |U'| - 1 - |T \cap E[U']| < |U| - 1 - |T \cap E[U]|.$$

This can be seen by considering the function $d(x) := (|U| - 1 - x(E[U])) - (|U'| - 1 - x(E[U']))$. We have $d(z) \leq 0$ and $d(z') > 0$, and hence, as d is linear, $d(\chi^T) > 0$; that is, we have (51.22). So resetting $z := z'$, there are at most $|V|$ inner iterations.

Let y' be the final z found. Since $\lambda \geq 1$ (as $y \in P_{\text{spanning tree}}(G)$) and $y = \lambda^{-1} \cdot y' + (1 - \lambda^{-1}) \cdot \chi^T$, any convex decomposition of y' into incidence vectors of spanning trees, yields such a decomposition of y. We show that this recursion terminates.

If we apply no iteration, then $\text{supp}(y') \subset \text{supp}(y)$. So replacing y, w by y', w gives a reduction.

If we do at least one iteration, we find a U such that y' satisfies $y'(E[U]) = |U| - 1$ while $|T \cap E[U]| < |U| - 1$. In this case we replace y, w by $y', w' := 2w + \chi^{E[U]}$.

Then y' maximizes $w'^{\mathsf{T}} x$ over the spanning tree polytope. Indeed, for any x in the spanning tree polytope, we have

$$(51.23) \qquad \begin{aligned} w'^{\mathsf{T}} x &= 2w^{\mathsf{T}} x + x(E[U]) \leq 2w^{\mathsf{T}} y + |U| - 1 = 2w^{\mathsf{T}} y' + y'(E[U]) \\ &= w'^{\mathsf{T}} y'. \end{aligned}$$

Moreover, each tree T' maximizing $w'(T')$ also maximizes $w(T')$ (by the greedy method: for any ordering of V for which w' is nondecreasing, also w is nondecreasing). However, T does not maximize $w'(T)$, since $w'(T) = 2w(T) + |T \cap E[U]| < 2w(T) + |U| - 1 = 2w^{\mathsf{T}}y + |U| - 1 = w'^{\mathsf{T}}y'$. So the dimension of the face of vectors x maximizing $w'^{\mathsf{T}}x$ is less than the dimension of the face of vectors x maximizing $w^{\mathsf{T}}x$.

So the number of iterations is at most $|E|$. This shows that the method is strongly polynomial-time. ∎

Now we can derive from the previous two theorems, an algorithmic result for fractional forest decomposition:

Corollary 51.5a. *Given a graph $G = (V, E)$ and $y \in P_{\text{forest}}(G)$, we can find forests $F_1, \ldots, F_k$ and $\lambda_1, \ldots, \lambda_k \geq 0$ satisfying*

(51.24) $$y = \lambda_1 \chi^{F_1} + \cdots + \lambda_k \chi^{F_k}$$

and $\lambda_1 + \cdots + \lambda_k = 1$, in strongly polynomial time.

Proof. We can assume that G is connected, as we can consider each component of G separately. By Theorem 51.4, we can find a $z \in P_{\text{spanning tree}}(G)$ with $y \leq z$ in strongly polynomial time. By Theorem 51.5, we can decompose z as a convex combination of incidence vectors of spanning trees in strongly polynomial time. By restricting the spanning trees to subforests if necessary, we obtain a convex decomposition of y into incidence vectors of forests. ∎

We can proceed similarly for decomposing a vector in the connector polytope. To this end, we show the analogue for connectors of Theorem 51.4:

Theorem 51.6. *Given a graph $G = (V, E)$ and $x \in P^{\uparrow}_{\text{connector}}(G)$, we can find a $z \in P_{\text{spanning tree}}(G)$ with $x \geq z$, in strongly polynomial time.*

Proof. The method described in the proof of Corollary 51.3b gives a vector $y \in \mathbb{Q}^V$ satisfying

(51.25) $$y(U) \leq x(\delta(U)) - 2 \text{ for each nonempty } U \subseteq V,$$

and a partition $\mathcal{P}$ of V into nonempty sets with $y(U) = x(\delta(U)) - 2$ for each $U \in \mathcal{P}$. Hence

(51.26) $$y(V) = \sum_{U \in \mathcal{P}} (x(\delta(U)) - 2) = 2x(\delta(\mathcal{P})) - 2|\mathcal{P}| \geq -2.$$

By decreasing components of y appropriately, we can achieve that $y(V) = -2$, while maintaining (51.25).

We are going to modify y and x, maintaining (51.25) and $y(V) = -2$. For each $u, v \in V$ with $e = uv \in E$, we do the following. Let α be the minimum value of $x(\delta(U)) - 2 - y(U)$ taken over subsets U of V with $u \in U$, $v \notin U$. So $\alpha \geq 0$. Let $\beta := \min\{x_e, \frac{1}{2}\alpha\}$ and reset

(51.27) $\qquad x_e := x_e - \beta,\ y_u := y_u + \beta,\ y_v := y_v - \beta.$

Then (51.25) is maintained, and the collection $\mathcal{C}$ of subsets U having equality in (51.25) is not reduced. Moreover, in the new situation, $x_e = 0$ or there is a $U \in \mathcal{C}$ with $u \in U$ and $v \notin U$. Also, the new x belongs to $P^{\uparrow}_{\text{connector}}(G)$, as for any partition $\mathcal{Q}$ of V into nonempty sets we have

(51.28) $$\sum_{U \in \mathcal{Q}} x(\delta(U)) \geq y(V) + 2|\mathcal{Q}| = 2|\mathcal{Q}| - 2.$$

Doing this for each edge e (in both directions), we end up with x, y satisfying (51.25) such that

(51.29) for all adjacent u, v, if $x_{uv} > 0$, then there is a $U \in \mathcal{C}$ with $u \in U$ and $v \notin U$.

This implies that

(51.30) $$y_u = x(\delta(u)) - 2$$

for each $u \in V$. Indeed, $\mathcal{C}$ is closed under unions and intersections of intersecting sets. Let U be the smallest set in $\mathcal{C}$ containing u. (This exists, since $V \in \mathcal{C}$.) To show (51.30), we must show $U = \{u\}$. Suppose therefore that $U \neq \{u\}$. By (51.29), there is no edge e connecting u and $U \setminus \{u\}$ with $x_e > 0$. Hence

(51.31) $$\begin{aligned} y(U) &= y_u + y(U \setminus \{u\}) \leq x(\delta(u)) - 2 + x(\delta(U \setminus \{u\})) - 2 \\ &= x(\delta(U)) - 4 < x(\delta(U)) - 2, \end{aligned}$$

contradicting the fact that $U \in \mathcal{C}$. This proves (51.30).

Hence

(51.32) $$2x(E) = \sum_{u \in V} x(\delta(u)) = y(V) + 2|V| = 2(|V| - 1),$$

and so $x(E) = |V| - 1$. This implies that x belongs to the spanning tree polytope. ∎

This implies for fractional connector decomposition:

Corollary 51.6a. *Given a graph $G = (V, E)$ and $x \in P_{\text{connector}}(G)$, we can find connectors $C_1, \ldots, C_k$ and $\lambda_1, \ldots, \lambda_k \geq 0$ satisfying*

(51.33) $$x = \lambda_1 \chi^{C_1} + \cdots + \lambda_k \chi^{C_k}$$

and $\lambda_1 + \cdots + \lambda_k = 1$, in strongly polynomial time.

Proof. By Theorem 51.6, we can find a $z \in P_{\text{spanning tree}}(G)$ with $x \geq z$ in strongly polynomial time. By Theorem 51.5, we can decompose z as a convex combination of incidence vectors of spanning trees in strongly polynomial time. This gives a decomposition as required. ∎

Fractionally packing and covering trees and forests

We now consider the problem of finding a maximum fractional packing of spanning trees subject to a given capacity function, and its dual, finding a minimum fractional covering by forests of a given demand function.

Since we have proved above that convex decompositions can be found in strongly polynomial time, we only need to give a method to find the optimum *values* of the fractional packing and covering.

The method is a variant of a 'fractional programming method' initiated by Isbell and Marlow [1956], and developed by Dinkelbach [1967], Schaible [1976], Picard and Queyranne [1982a], Padberg and Wolsey [1984], and Cunningham [1985c].

It implies the following result of Picard and Queyranne [1982a] and Padberg and Wolsey [1984]:

Theorem 51.7. *Given a graph $G = (V, E)$ and $y \in \mathbb{Q}_+^E$, we can find the minimum λ such that $y \in \lambda \cdot P_{\text{forest}}(G)$, in strongly polynomial time.*

Proof. We can assume that y does not belong to the forest polytope. (Otherwise multiply y by a sufficiently large scalar.) Let L be the line through $\mathbf{0}$ and y. We iteratively reset y as follows. Find a nonempty subset U of V minimizing $|U| - 1 - y(E[U])$. Let y' be the vector on L with $|U| - 1 - y'(E[U]) = 0$.

Now if y' violates $x(E[U']) \leq |U'| - 1$ for some U', then $|U'| < |U|$, since the function $d(x) := (|U| - 1 - x(E[U])) - (|U'| - 1 - x(E[U']))$ is nonpositive at y and positive at y', implying that it is positive at $\mathbf{0}$ (as d is linear in x).

We reset $y := y'$ and iterate, until y belongs to $P_{\text{forest}}(G)$. So after at most $|V|$ iterations the process terminates, with a y on the boundary of $P_{\text{forest}}(G)$. Comparing the final y with the original y gives the required λ. ∎

Hence we have for fractional forest covering:

Corollary 51.7a. *Given a graph $G = (V, E)$ and $y \in \mathbb{Q}_+^E$, we can find forests $F_1, \ldots, F_k$ and rationals $\lambda_1, \ldots, \lambda_k \geq 0$ such that*

$$y = \lambda_1 \chi^{F_1} + \cdots + \lambda_k \chi^{F_k} \tag{51.34}$$

with $\lambda_1 + \ldots + \lambda_k$ minimal, in strongly polynomial time.

Proof. By Theorem 51.7, we can find the minimum value of λ such that y belongs to $\lambda \cdot P_{\text{forest}}(G)$. If $\lambda = 0$, then $y = \mathbf{0}$, and (51.34) is trivial. If $\lambda > 0$, then by Corollary 51.5a we can decompose $\lambda^{-1} \cdot y$ as a convex combination of incidence vectors of forests. This gives the required decomposition of y. ∎

Similar results holds for fractional tree packing (Cunningham [1984, 1985c]). First one has:

Theorem 51.8. *Given a connected graph $G = (V, E)$ and $y \in \mathbb{Q}_+^E$, we can find the maximum λ such that $y \in \lambda \cdot P_{\text{connector}}(G)$, in strongly polynomial time.*

Proof. If $\text{supp}(y)$ is not a connector, then $\lambda = 0$. So we may assume that $\text{supp}(y)$ is a connector. We can also assume that $y \notin P_{\text{connector}}(G)$. Let L be the line through $\mathbf{0}$ and y. We iteratively reset y as follows. Find a partition $\mathcal{P}$ of V into nonempty sets minimizing $y(\delta(\mathcal{P})) - (|\mathcal{P}| - 1)$ (by Corollary 51.3b). Let y' be the vector on L with $y'(\delta(\mathcal{P})) = |\mathcal{P}| - 1$.

Now if y' violates $x(\delta(\mathcal{P}')) \geq |\mathcal{P}'| - 1$ for some partition $\mathcal{P}'$ of V into nonempty sets, then $|\mathcal{P}'| < |\mathcal{P}|$, since the function $d(x) := (x(\delta(\mathcal{P})) - |\mathcal{P}| + 1) - (x(\delta(\mathcal{P}')) - |\mathcal{P}'| + 1)$ is nonpositive at y and positive at y', implying that it is negative at $\mathbf{0}$ (as d is linear in x).

We reset $y := y'$ and iterate, until y belongs to $P_{\text{connector}}(G)$. So after at most $|V|$ iterations the process terminates, in which case we have a y on the boundary of $P_{\text{connector}}(G)$. Comparing the final y with the original y gives the required λ. ∎

This implies for fractional tree packing:

Corollary 51.8a. *Given a connected graph $G = (V, E)$ and $x \in \mathbb{Q}_+^E$, we can find spanning trees $T_1, \ldots, T_k$ and rationals $\lambda_1, \ldots, \lambda_k \geq 0$ such that*

(51.35) $$x \geq \lambda_1 \chi^{T_1} + \cdots + \lambda_k \chi^{T_k}$$

with $\lambda_1 + \ldots + \lambda_k$ maximal, in strongly polynomial time.

Proof. By Theorem 51.8, we can find the maximum value of λ such that x belongs to $\lambda \cdot P_{\text{connector}}(G)$. If $\lambda = 0$, we take $k = 0$. If $\lambda > 0$, by Corollary 51.6a we can decompose $\lambda^{-1} \cdot x$ as a convex combination of incidence vectors of connectors. This gives the required decomposition of x. ∎

Integer packing and covering of trees

It is not difficult to derive integer versions of the above algorithms, but they are not strongly polynomial-time, as we round numbers in it. In fact, an integer packing or covering cannot be found in strongly polynomial time, as it would imply a strongly polynomial-time algorithm for testing if an integer k is even (which algorithm does not exist[6]): k is even if and only if K_3 has $\frac{3}{2}k$ spanning trees containing each edge at most k times.

[6] For any strongly polynomial-time algorithm with one integer k as input, there is a number L and a rational function $q : \mathbb{Z} \to \mathbb{Q}$ such that if $k > L$, then the output equals $q(k)$. (This can be proved by induction on the number of steps of the algorithm.) However, there do not exist a rational function q and a number L such that for $k > L$, $q(k) = 0$ if k is even, and $q(k) = 1$ if k is odd.

Weakly polynomial-time algorithms follow directly from the fractional case with the help of the theorems of Nash-Williams and Tutte on disjoint trees and covering forests.

Theorem 51.9. *Given a graph $G = (V, E)$ and $y \in \mathbb{Z}_+^E$, we can find forests $F_1, \ldots, F_t$ and integers $\lambda_1, \ldots, \lambda_t \geq 0$ such that*

(51.36) $$y = \lambda_1 \chi^{F_1} + \cdots + \lambda_t \chi^{F_t}$$

with $\lambda_1 + \ldots + \lambda_t$ minimal, in polynomial time.

Proof. First find $F_1, \ldots, F_k$ and $\lambda_1, \ldots, \lambda_k$ as in Corollary 51.7a. We can assume that $k \leq |E|$ (by Carathéodory's theorem). Let

(51.37) $$y' := \sum_{i=1}^{k} (\lambda_i - \lfloor \lambda_i \rfloor) \chi^{F_i} = y - \sum_{i=1}^{k} \lfloor \lambda_i \rfloor \chi^{F_i}.$$

So y' is integer.

Replace each edge e by y'_e parallel edges, making G'. By Theorem 51.2, we can find a minimum number of forests partitioning the edges of G', in polynomial time (as $y'_e \leq |E|$ for each $e \in E$). This gives forests $F_{k+1}, \ldots, F_t$ in G.

Setting $\lambda_i := 1$ for $i = k + 1, \ldots, t$, we show that this gives a solution of our problem. Trivially, (51.36) is satisfied (with λ_i replaced by $\lfloor \lambda_i \rfloor$). By Nash-Williams' covering forests theorem (Theorem 51.1c), using (51.37),

(51.38) $$t - k \leq \left\lceil \sum_{i=1}^{k} (\lambda_i - \lfloor \lambda_i \rfloor) \right\rceil.$$

Therefore,

(51.39) $$\sum_{i=1}^{t} \lfloor \lambda_i \rfloor = (t - k) + \sum_{i=1}^{k} \lfloor \lambda_i \rfloor \leq \left\lceil \sum_{i=1}^{k} \lambda_i \right\rceil,$$

proving that the decomposition is optimum. ∎

One similarly shows for tree packing:

Theorem 51.10. *Given a connected graph $G = (V, E)$ and $y \in \mathbb{Z}_+^E$, we can find spanning trees $T_1, \ldots, T_t$ and integers $\lambda_1, \ldots, \lambda_t \geq 0$ such that*

(51.40) $$y \geq \lambda_1 \chi^{T_1} + \cdots + \lambda_t \chi^{T_t}$$

with $\lambda_1 + \ldots + \lambda_t$ maximal, in polynomial time.

Proof. First find $T_1, \ldots, T_k$ and $\lambda_1, \ldots, \lambda_k$ as in Corollary 51.8a. We can assume that $k \leq |E|$ (by Carathéodory's theorem). Let

(51.41) $$y' := \left\lceil \sum_{i=1}^{k} (\lambda_i - \lfloor \lambda_i \rfloor) \chi^{T_i} \right\rceil.$$

Replace each edge e by y'_e parallel edges, making G'. By Theorem 51.2, we can find a maximum number of edge-disjoint spanning trees in G', in polynomial time (as $y'_e \leq |E|$ for each $e \in E$). This gives spanning trees $T_{k+1}, \ldots, T_t$ in G.

Setting $\lambda_i := 1$ for $i = k+1, \ldots, t$, we show that this gives a solution of our problem. Trivially, (51.40) is satisfied (with λ_i replaced by $\lfloor \lambda_i \rfloor$). By the Tutte-Nash-Williams disjoint trees theorem using (51.41),

$$(51.42) \qquad t - k \geq \lfloor \sum_{i=1}^{k} (\lambda_i - \lfloor \lambda_i \rfloor) \rfloor.$$

Therefore,

$$(51.43) \qquad \sum_{i=1}^{t} \lfloor \lambda_i \rfloor = (t-k) + \sum_{i=1}^{k} \lfloor \lambda_i \rfloor \geq \lfloor \sum_{i=1}^{k} \lambda_i \rfloor,$$

proving that the decomposition is optimum. ∎

51.5. Further results and notes

51.5a. Complexity survey for tree packing and covering

Complexity survey for finding a maximum number of (or k) disjoint spanning trees ($*$ indicates an asymptotically best bound in the table):

*	$O(kn^2\log k + m\log m)$	Gabow and Westermann [1988,1992]
*	$O(\frac{m^2}{k}\log k + m\log m)$	Gabow and Westermann [1988,1992]

Roskind and Tarjan [1985] (cf. Clausen and Hansen [1980]) gave an $O(k^2n^2 + m\log m)$-time algorithm for finding a maximum-weight union of k disjoint spanning trees, in a simple graph.

As for **the capacitated case**, the methods given in Section 51.4 indicate that packing and covering problems on forests and trees can be solved by a series of minimum-capacity cut problem (as they reduce to Theorem 51.3). A parametric minimum cut method designed by Gallo, Grigoriadis, and Tarjan [1989] allows to combine several consecutive minimum cut computations, improving the efficiency of the corresponding tree packing and covering problem, as was done by Gusfield [1991].

The published algorithms for integer packing and coverings of trees all are based on rounding the fractional version, not increasing the complexity of the problem, except that rounding is included as an operation. This blocks these algorithms from being strongly polynomial-time: as we saw in Section 51.4, it can be proved that there exists no strongly polynomial-time algorithm for finding an optimum integer packing of spanning trees under a given capacity (similarly, for integer covering by forests).

The following table gives a complexity survey for finding a maximum fractional packing of spanning trees subject to a given integer capacity function c, or a minimum fractional covering by forests subject to a given demand function c. Here it seems that the optimum value can be found faster than an explicit fractional packing or covering. The problems of finding an optimum fractional packing of trees is close to that of finding an optimum fractional covering of forests (or trees), so we present their complexity in one survey.

For any graph $G = (V, E)$ and $c : E \to \mathbb{R}_+$, the *strength* is the maximum value of λ such that c belongs to $\lambda \cdot P_{\text{connector}}(G)$. It is equal to the maximum size of a fractional packing of spanning trees subject to c. The *fractional arboricity* is the minimum value of λ such that c belongs to $\lambda \cdot P_{\text{forest}}(G)$. This is equal to the minimum size of a fractional c-covering by forest.

	$O(nm^8)$	Cunningham [1984]: finding an optimum fractional packing of trees
	$O(nm \cdot \text{MF}(n, n^2))$	Cunningham [1985c]: computing strength
	$O(n^4 m^2 \log^2 C)$	Gabow [1991a] (announced): computing strength
*	$O(n^3 m)$	Gusfield [1991]: computing strength
	$O(nm^2 \log(n^2/m))$	Gusfield [1991]: computing strength
	$O(n^3 \cdot \text{MF}(n, m))$	Trubin [1991]: finding an optimum fractional packing of trees
	$O(n^2 \cdot \text{MF}(n, n^2))$	Barahona [1992]: computing strength
	$O(n^2 \cdot \text{MF}(n, n^2))$	Barahona [1995]: finding optimum fractional packing of trees
*	$O(n \cdot \text{MF}(n, m))$	Cheng and Cunningham [1994]: computing strength
*	$O(n \cdot \text{MF}(n, m))$	Gabow [1995b,1998]: computing strength and fractional arboricity
*	$O(n^3 m \log(n^2/m))$	Gabow and Manu [1995,1998]: finding an optimum fractional packing of trees and an optimum fractional covering by forests
*	$O(n^2 m \log C \log(n^2/m))$	Gabow and Manu [1995,1998]: finding an optimum fractional packing of trees and an optimum fractional covering by forests

Here $\text{MF}(n, m)$ is the complexity of finding a maximum-value $s - t$ flow subject to c in a digraph with n vertices and m arcs, and $C := \|c\|_{\max}$ (assuming c integer).

51.5b. Further notes

A special case of a question asked by A. Frank (cf. Schrijver [1979b], Frank [1995]) amounts to the following:

(51.44) (?) Let $G = (V, E)$ be an undirected graph and let $s \in V$. Suppose that for each vertex $t \neq s$, there exist k internally vertex-disjoint $s-t$ paths. Then G has k spanning trees such that for each vertex $t \neq s$, the $s-t$ paths in these trees are internally vertex-disjoint. (?)

(The spanning trees need not be edge-disjoint — otherwise $G = K_3$ would form a counterexample.) For $k = 2$, (51.44) was proved by Itai and Rodeh [1984,1988], and for $k = 3$ by Cheriyan and Maheshwari [1988] and Zehavi and Itai [1989].

Peng, Chen, and Koh [1991] showed that for any undirected graph $G = (V, E)$ and any $p, k \in \mathbb{Z}_+$, there exist k disjoint forests each with p components if and only if

(51.45) $$|\delta(\mathcal{P})| \geq k(|\mathcal{P}| - p)$$

for each partition $\mathcal{P}$ of V into nonempty sets. This in fact is the matroid base packing theorem (Corollary 42.1d) applied to the $(|V| - p)$-truncation of the cycle matroid of G.

Theorem 42.10 of Seymour [1998] implies that if the edges of a graph $G = (V, E)$ can be partitioned into k forests and if for each $e \in E$ a subset L_e of $\{1, 2, \ldots\}$ with $|L_e| = k$ is given, then we can partition E into forests $F_1, F_2, \ldots$ such that $j \in L_e$ for each $j \geq 1$ and each $e \in F_j$.

Henneberg [1911] and Laman [1970] characterized those graphs which have, after adding any edge, two edge-disjoint spanning trees. This was extended to k edge-disjoint spanning trees by Frank and Szegő [2001].

Farber, Richter, and Shank [1985] showed the following. Let $G = (V, E)$ be an undirected graph. Let $\mathcal{V}$ be the collection of pairs (T_1, T_2) of edge-disjoint spanning trees T_1 and T_2 in G. Call two pairs (T_1, T_2) and (S_1, S_2) in $\mathcal{V}$ *adjacent* if $|(T_1 \cup T_2) - (S_1 \cup S_2)| = 2$. Then this determines a connected graph on $\mathcal{V}$.

Cunningham [1985c] gave a strongly polynomial-time algorithm ($O(nm \min\{n^2, m \log n\})$) to find a minimum-cost set of capacities to be added to a capacitated graph so as to create the existence of k edge-disjoint spanning trees; that is, given $G = (V, E)$ and $c, k \in \mathbb{Z}_+^E$, solving

(51.46) $$\sum_{e \in E} k(e) x_e$$

where $x \in \mathbb{Z}_+^E$ satisfies

(51.47) $$(c + x)(\delta(\mathcal{P})) \geq k(|\mathcal{P}| - 1)$$

for each partition $\mathcal{P}$ of V into nonempty sets. (It amounts to finding a minimum-cost integer vector in a contrapolymatroid.) Related work can be found in Baïou, Barahona, and Mahjoub [2000].

Chapter 52

Longest branchings and shortest arborescences

We next consider trees in directed graphs. We recall some terminology and facts. Let $D = (V, A)$ be a digraph. A *branching* is a subset B of A such that B contains no undirected circuit and such that for each vertex v there is at most one arc in B entering v. A *root* of B is a vertex not entered by any arc in B. For any branching B, each weak component of (V, B) contains a unique root.
A branching B is called an *arborescence* if the digraph (V, B) is weakly connected; equivalently, if (V, B) is a rooted tree. So each arborescence B has a unique root r. We say that B is *rooted at* r, and we call B an *r-arborescence*. An r-arborescence can be characterized as a directed spanning tree B such that each vertex is reachable in B from r. A digraph $D = (V, A)$ contains an r-arborescence if and only if each vertex of D is reachable from r.

52.1. Finding a shortest r-arborescence

Let be given a digraph $D = (V, A)$, a vertex r, and a length function $l : A \to \mathbb{Q}_+$. We consider the problem of finding a shortest (= minimum-length) r-arborescence.

We cannot apply here the greedy method of starting at the root r and iteratively extending an r-arborescence on a subset U of V, by the shortest arc leaving U. This is shown by the example of Figure 52.1.

The following algorithm was given by Chu and Liu [1965], Edmonds [1967a], and Bock [1971]:

Algorithm to find a shortest r-arborescence. Let $A_0 := \{a \in A \mid l(a) = 0\}$. If A_0 contains an r-arborescence B, then B is a shortest r-arborescence. If A_0 contains no r-arborescence, there is a strong component K of (V, A_0) with $r \notin K$ and with $l(a) > 0$ for each $a \in \delta^{\text{in}}(K)$. Let $\alpha := \min\{l(a) \mid a \in \delta^{\text{in}}(K)\}$. Set $l'(a) := l(a) - \alpha$ if $a \in \delta^{\text{in}}(K)$ and $l'(a) := l(a)$ otherwise.

Find (recursively) a shortest r-arborescence B with respect to l'. As K is a strong component of (V, A_0), we can choose B such that $|B \cap \delta^{\text{in}}(K)| = 1$

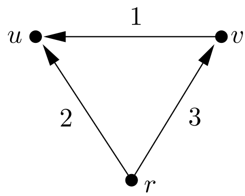

Figure 52.1
In a greedy method one would first choose the shortest arc leaving r, which is (r,u). This arc however is not contained in the shortest r-arborescence.

(since if $|B \cap \delta^{\text{in}}(K)| \geq 2$, then there exists an $a \in B \cap \delta^{\text{in}}(K)$ such that the set $(B \setminus \{a\}) \cup A_0$ contains an r-arborescence, say B', with $l'(B') \leq l'(B) - l'(a) \leq l'(B)$).

Then B is also a shortest r-arborescence with respect to l, since for any r-arborescence B':

$$(52.1) \qquad l(B') = l'(B') + \alpha|B' \cap \delta^{\text{in}}(K)| \geq l'(B') + \alpha \geq l'(B) + \alpha = l(B).$$

Since the number of iterations is at most m (as in each step A_0 increases), we have:

Theorem 52.1. *A shortest r-arborescence can be found in strongly polynomial time.*

Proof. See above. ∎

In fact, direct analysis gives the following result of Chu and Liu [1965], Edmonds [1967a], and Bock [1971]:

Theorem 52.2. *A shortest r-arborescence can be found in time $O(nm)$.*

Proof. First note that there are at most $2n$ iterations. This can be seen as follows. Let k be the number of strong components of (V, A_0), and let k_0 be the number of strong components K of (V, A_0) with $d^{\text{in}}_{A_0}(K) = 0$. Then at any iteration, the number $k + k_0$ decreases. Indeed, if the strong component K selected remains a strong component, then $d^{\text{in}}_{A_0}(K) \neq 0$ in the next iteration; so k_0 decreases. Otherwise, k decreases. Hence there are at most $2n$ iterations.

Next, each iteration can be performed in time $O(m)$. Indeed, in time $O(m)$ we can identify the set U of vertices not reachable in (V, A_0) from r. Next, by Theorem 6.6 one can identify the strong components of the subgraph of (V, A_0) induced by U, in time $O(m)$. Moreover, by Theorem 6.5 we can order the vertices in U pre-topologically. Then the first vertex in this order belongs to a strong component K such that each arc a entering K has $l(a) > 0$. ∎

Tarjan [1977] showed that this algorithm has an $O(\min\{n^2, m \log n\})$-time implementation.

52.1a. *r*-arborescences as common bases of two matroids

Let $D = (V, A)$ be a digraph and let $r \in V$. The r-arborescences can be considered as the common bases in two matroids on A: M_1 is the cycle matroid of the underlying undirected graph, and M_2 is the partition matroid on A induced by the sets $\delta^{\text{in}}(v)$ for $v \in V \setminus \{r\}$. We assume without loss of generality that no arc of D enters r.

Then the r-arborescences are exactly the common bases of M_1 and M_2. This gives us a reduction of polyhedral and algorithmic results to matroid intersection. In particular, Theorem 52.1 follows from the strong polynomial-time solvability of weighted matroid intersection.

52.2. Related problems

The complexity results of Section 52.1 immediately imply similar results for finding optimum branchings and arborescences without specifying a root. First we note:

Corollary 52.2a. *Given a digraph $D = (V, A)$, $r \in V$, and a length function $l : A \to \mathbb{Q}$, a longest r-arborescence can be found in $O(nm)$ time.*

Proof. Define $L := \max\{l(a) \mid a \in A\}$ and $l'(a) := L - l(a)$ for each $a \in A$. Then an r-arborescence B minimizing $l'(B)$ is an r-arborescence maximizing $l(B)$. ∎

Then we have for longest branching:

Corollary 52.2b. *Given a digraph $D = (V, A)$ and a length function $l \in \mathbb{Q}^A$, a longest branching can be found in time $O(nm)$.*

Proof. We can assume that l is nonnegative, by deleting all arcs of negative length. Extend D by a new vertex r and new arcs (r, v) for all $v \in V$, each of length 0. Let B be a longest r-arborescence in D' (this can be found in $O(nm)$-time by Corollary 52.2a). Then trivially $B \cap A$ is a longest branching in D. ∎

Similarly, for finding a shortest arborescence, without prescribing a root:

Corollary 52.2c. *Given a digraph $D = (V, A)$ and a length function $l \in \mathbb{Q}_+^A$, a shortest arborescence can be found in time $O(nm)$.*

Proof. Extend D by a new vertex r and arcs (r, v) for each $v \in V$, giving digraph D'. Let $l(r, v) := Ln$, where $L := \max\{l(a) \mid a \in A\}$. If D has an arborescence, then a shortest r-arborescence in D' has only one arc leaving r, and deleting this arc gives a shortest arborescence in D. ∎

52.3. A min-max relation for shortest r-arborescences

We now characterize the minimum length of an r-arborescence. Let $D = (V, A)$ be a digraph and let $r \in V$. Call a set C of arcs an *r-cut* if there exists a nonempty subset U of $V \setminus \{r\}$ with

(52.2) $\quad C = \delta^{\text{in}}(U).$

It is not difficult to show that

(52.3) the collection of inclusionwise minimal arc sets intersecting each r-arborescence is equal to the collection of inclusionwise minimal r-cuts,

and

(52.4) the collection of inclusionwise minimal arc sets intersecting each r-cut is equal to the collection of r-arborescences.

The following theorem follows directly from the method of Edmonds [1967a], and was stated explicitly by Bock [1971] (and also by Fulkerson [1974]):

Theorem 52.3 (optimum arborescence theorem). *Let $D = (V, A)$ be a digraph, let $r \in V$, and let $l : A \to \mathbb{Z}_+$. Then the minimum length of an r-arborescence is equal to the maximum size of a family of r-cuts such that each arc a is in at most $l(a)$ of them.*

Proof. Clearly, the maximum is not more than the minimum, as each r-cut intersects each r-arborescence.

We prove the reverse inequality by induction on $\sum_{a \in A} l(a)$. Let $A_0 := \{a \in A \mid l(a) = 0\}$. If A_0 contains an r-arborescence, the minimum is 0, while the maximum is at least 0.

If A_0 contains no r-arborescence, there exists a strong component K of the digraph (V, A_0) with $r \notin K$ and with $l(a) > 0$ for each $a \in \delta^{\text{in}}(K)$. Define $l' := l - \chi^{\delta^{\text{in}}(K)}$. By induction there exist an r-arborescence B and r-cuts $C_1, \ldots, C_t$ such that each arc a is in at most $l'(a)$ of the C_i and such that $l'(B) = t$. We may assume that $|B \cap \delta^{\text{in}}(K)| = 1$, since if $|B \cap \delta^{\text{in}}(K)| \geq 2$, then for each $a \in B \cap \delta^{\text{in}}(K)$, $(B \setminus \{a\}) \cup A_0$ contains an r-arborescence, say B', with $l'(B') \leq l'(B) - l'(a) \leq l'(B)$.

It follows that $l(B) = t + 1$. Moreover, taking $C_{t+1} := \delta^{\text{in}}(K)$, each arc a is in at most $l(a)$ of the $C_1, \ldots, C_{t+1}$. ∎

Note that if B is a shortest r-arborescence, then $|B \cap C| = 1$ for any r-cut C in the maximum-size family. Moreover, for any $a \in B$, $l(a)$ is equal to the number of r-cuts C chosen with $a \in C$.

52.4. The r-arborescence polytope

Given a digraph $D = (V, A)$ and a vertex $r \in V$, the *r-arborescence polytope* is defined as the convex hull of the incidence vectors (in $\mathbb{R}^A$) of the r-arborescences; that is,

(52.5) $$P_{r\text{-arborescence}}(D) := \text{conv.hull}\{\chi^B \mid B \ r\text{-arborescence}\}.$$

Theorem 52.3 implies that the r-arborescence polytope of D is determined by:

(52.6)
$$\begin{array}{rll} \text{(i)} & x_a \geq 0 & \text{for } a \in A, \\ \text{(ii)} & x(C) \geq 1 & \text{for each } r\text{-cut } C, \\ \text{(iii)} & x(\delta^{\text{in}}(v)) = 1 & \text{for } v \in V \setminus \{r\}. \end{array}$$

To prove this, we first characterize the up hull of the r-arborescence polytope, where as usual the up hull of the r-arborescence polytope is defined as

(52.7) $$P^{\uparrow}_{r\text{-arborescence}}(D) := P_{r\text{-arborescence}}(D) + \mathbb{R}^A_+.$$

Corollary 52.3a. $P^{\uparrow}_{r\text{-arborescence}}(D)$ *is determined by*

(52.8)
$$\begin{array}{rll} \text{(i)} & x_a \geq 0 & \text{for } a \in A, \\ \text{(ii)} & x(C) \geq 1 & \text{for each } r\text{-cut } C. \end{array}$$

Proof. The incidence vector of any r-arborescence trivially satisfies (52.8); hence $P^{\uparrow}_{r\text{-arborescence}}(D)$ is contained in the polyhedron Q determined by (52.8).

Suppose that the reverse inclusion does not hold. Then there exists a rational length function $l \in \mathbb{Q}^A_+$ such that the minimum value of $l^{\mathsf{T}}x$ over Q is less than the minimum length of an r-arborescence. We can assume that l is integer. However, the minimum value of $l^{\mathsf{T}}x$ over Q cannot be less than the maximum described in Theorem 52.3. So we have a contradiction. ∎

Since the r-arborescence polytope is a face of its up hull, this implies:

Corollary 52.3b. *The r-arborescence polytope is determined by* (52.6).

Proof. Directly from Corollary 52.3a. ∎

Corollary 52.3a also implies for the restriction to the unit cube:

Corollary 52.3c. *The convex hull of incidence vectors of arc sets containing an r-arborescence is determined by*

(52.9) (i) $0 \leq x_a \leq 1$ for $a \in A$,
(ii) $x(C) \geq 1$ for each r-cut C.

Proof. Directly from Corollary 52.3a with Theorem 5.19. ∎

Theorem 52.3 can be reformulated in TDI terms as:

Corollary 52.3d. *System* (52.8) *is TDI.*

Proof. Choose a length function $l \in \mathbb{Z}_+^A$, and consider the dual problem of minimizing $l^\mathsf{T} x$ over (52.8). For each r-cut C, let y_C be the number of times C is chosen in the maximum family in Theorem 52.3. Moreover, let B be a shortest r-arborescence. Then by Theorem 52.3, $x := \chi^B$ and the y_C form a dual pair of optimum solutions. As the y_C are integer, it follows that (52.8) is TDI. ∎

This in turn implies for the r-arborescence polytope:

Corollary 52.3e. *System* (52.6) *is TDI.*

Proof. Directly from Corollary 52.3d, with Theorem 5.25, since (52.6) arises from (52.8) by setting some of the inequalities to equality. ∎

For the intersection with the unit cube it gives:

Corollary 52.3f. *System* (52.9) *is TDI.*

Proof. Directly from Corollary 52.3d, with Theorem 5.23. ∎

In fact, (poly)matroid intersection theory gives the box-total dual integrality of (52.8):

Theorem 52.4. *System* (52.8) *is box-TDI.*

Proof. Let M_1 be the cycle matroid of the undirected graph underlying $D = (V, A)$, and let M_2 be the partition matroid induced by the sets $\delta^{\text{in}}(v)$ for $v \in V \setminus \{r\}$. By Corollary 46.1d, the system

(52.10) $x(B) \geq |V| - 1 - r_{M_i}(A \setminus B)$ for $i = 1, 2$ and $B \subseteq A$,

is box-TDI. Now any inequality in (52.10) is a nonnegative integer combination of inequalities (52.8).

Indeed, if $i = 1$, then $r_{M_1}(A \setminus B)$ is equal to $|V|$ minus the number of weak components of the digraph $(V, A \setminus B)$. So the inequality in (52.10) states that $x(B)$ is at least the number of weak components of $(V, A \setminus B)$ not containing r.

Hence it is a sum of the inequalities $x(\delta^{\text{in}}(K)) \geq 1$ for each weak component K of $(V, A \setminus B)$ not containing r, and of $x_a \geq 0$ for all $a \in B$ not entering any of these components.

If $i = 2$, then $r_{M_2}(A \setminus B)$ is equal to the number of $v \neq r$ entered by at least one arc in $A \setminus B$. So the inequality in (52.10) states that $x(B)$ is at least the number of $v \neq r$ with $\delta^{\text{in}}(v) \subseteq B$. It therefore is a sum of the inequalities $x(\delta^{\text{in}}(v)) \geq 1$ for these v, and $x_a \geq 0$ for all $a \in B$ not entering any of these vertices.

So Corollary 46.1d implies that (52.8) is box-TDI. ∎

52.4a. Uncrossing cuts

Edmonds and Giles [1977] and Frank [1979b] gave the following procedure of proving that system (52.8) is box-TDI (cf. Corollary 52.3b). The proof is longer than that given above, but it is a special case of a far more general approach (to be discussed in Chapter 60), and is therefore worth noting at this point.

System (52.8) is equivalent to:

$$\text{(52.11)} \qquad \begin{array}{lll} \text{(i)} & x_a \geq 0 & \text{for } a \in A, \\ \text{(ii)} & x(\delta^{\text{in}}(U)) \geq 1 & \text{for } \emptyset \neq U \subseteq V \setminus \{r\} \end{array}$$

Consider any length function $l \in \mathbb{R}^A_+$. Let y_U form an optimum solution to the problem dual to minimizing $l^{\mathsf{T}}x$ over (52.11):

$$\text{(52.12)} \qquad \begin{array}{ll} \text{maximize} & \sum_U y_U \\ \text{subject to} & y_U \geq 0 \text{ for all } U, \\ & \sum_U y_U \chi^{\delta^{\text{in}}(U)} \leq l, \end{array}$$

where U ranges over the nonempty subsets of $V \setminus \{r\}$.

Choose the y_U in such a way that

$$\text{(52.13)} \qquad \sum_U y_U |U||V \setminus U|$$

is as small as possible. Then the collection

$$\text{(52.14)} \qquad \mathcal{F} := \{U \mid y_U > 0\}$$

is laminar; that is,

$$\text{(52.15)} \qquad U \cap W = \emptyset \text{ or } U \subseteq W \text{ or } W \subseteq U \text{ for all } U, W \in \mathcal{F}.$$

For suppose not. Let $\alpha := \min\{y_U, y_W\}$. Decrease y_U and y_W by α, and increase $y_{U\cap W}$ and $y_{U\cup W}$ by α. Then y remains a feasible dual solution, since

$$\text{(52.16)} \qquad \chi^{\delta^{\text{in}}(U\cap W)} + \chi^{\delta^{\text{in}}(U\cup W)} \leq \chi^{\delta^{\text{in}}(U)} + \chi^{\delta^{\text{in}}(W)}.$$

Moreover, y remains trivially optimum. However, sum (52.13) decreases (by Theorem 2.1), contradicting our assumption. So $\mathcal{F}$ is laminar.

Now the $\mathcal{F} \times A$ matrix M with

$$\text{(52.17)} \qquad M_{U,a} := \begin{cases} 1 & \text{if } a \in \delta^{\text{in}}(U), \\ 0 & \text{otherwise,} \end{cases}$$

is totally unimodular. In fact, it is a network matrix. For make a directed tree T as follows. The vertex set of T is the set $\mathcal{F}' := \mathcal{F} \cup \{V\}$, while for each $U \in \mathcal{F}$ there is an arc a_U from W to U where W is the smallest set in $\mathcal{F}'$ with $W \supset U$. This is in fact an arborescence with root V.

We also define a digraph $\widetilde{D} = (\mathcal{F}', \widetilde{A})$. For each arc $a = (u, v)$ of D, let $\tilde{a}$ be an arc from the smallest set in $\mathcal{F}'$ containing both u and v, to the smallest set in $\mathcal{F}'$ containing v. Let $\widetilde{A} := \{\tilde{a} \mid a \in A\}$.

Identifying any set U in $\mathcal{F}$ with the arc a_U of T, the network matrix generated by directed tree T and digraph $\widetilde{D}$ is an $\mathcal{F} \times \widetilde{A}$ matrix which is the same as M. So M is totally unimodular. Therefore, by Theorem 5.35, (52.11) is box-TDI.

52.5. A min-max relation for longest branchings

We now consider longest branchings. Characterizing the maximum size of a branching is easy:

Theorem 52.5. *Let $D = (V, A)$ be a digraph. Then the maximum size of a branching is equal to $|V|$ minus the number of strong components K of D with $d_A^{\text{in}}(K) = 0$.*

Proof. The theorem follows directly from: (i) each branching has at least one root in any strong component K of D with $d_A^{\text{in}}(K) = 0$, and (ii) if a set R intersects each such K, then there is a branching with root set R (since each vertex of D is reachable from R). ∎

From Theorem 52.3 one can derive a min-max relation for the maximum length of a branching in a digraph. The reduction is similar to the reduction of the algorithmic problem of finding a longest branching to that of finding a shortest r-arborescence.

However, a direct proof can be derived from matroid intersection. Consider the system:

$$\text{(52.18)} \quad \begin{array}{rll} \text{(i)} & x_a \geq 0 & \text{for } a \in A, \\ \text{(ii)} & x(\delta^{\text{in}}(v)) \leq 1 & \text{for } v \in V, \\ \text{(iii)} & x(A[U]) \leq |U| - 1 & \text{for } U \subseteq V,\ U \neq \emptyset. \end{array}$$

Theorem 52.6. *System* (52.18) *is TDI.*

Proof. Directly from Theorem 41.12, applied to the cycle matroid M_1 of the undirected graph underlying $D = (V, A)$, and the partition matroid M_2 induced by the sets $\delta^{\text{in}}(v)$ for $v \in V$. Then each inequality $x(B) \leq r_{M_1}(B)$ is the sum of the inequalities $x(A[U]) \leq |U| - 1$ for the weak components U of (V, B), and $-x_a \leq 0$ for those arcs $a \in A \setminus B$ contained in any weak component of (V, B). Each inequality $x(B) \leq r_{M_2}(B)$ is the sum of the inequalities $x(\delta^{\text{in}}(v)) \leq 1$ for those v entered by at least one arc in B, and

$-x_a \leq 0$ for those arcs $a \in A \setminus B$ that enter a vertex v entered by at least one arc in B. ∎

52.6. The branching polytope

The previous corollary immediately implies a description of the *branching polytope* $P_{\text{branching}}(D)$ of D, which is the convex hull of the incidence vectors of branchings in D (stated by Edmonds [1967a]):

Corollary 52.6a. *The branching polytope of $D = (V, A)$ is determined by (52.18).*

Proof. Directly from Theorem 52.6, since the integer solutions of (52.18) are the incidence vectors of the branchings. ∎

Also the following theorem of Edmonds [1967a] follows from matroid intersection theory:

Corollary 52.6b. *Let $D = (V, A)$ be a digraph and let $k \in \mathbb{Z}_+$. Then the convex hull of the incidence vectors of branchings of size k is equal to the intersection of the branching polytope of D with the hyperplane $\{x \mid x(A) = k\}$.*

Proof. This is the common base polytope of the k-truncations of the matroids M_1 and M_2 defined in the proof of Theorem 52.6. ∎

In Corollary 53.3a we shall see that the convex hull of the incidence vectors of branchings of size k has the integer decomposition property (McDiarmid [1983]).

Giles and Hausmann [1979] characterized which pairs of branchings give adjacent vertices of the branching polytope, and Giles [1975,1978b] and Grötschel [1977a] characterized the facets of the branching polytope.

52.7. The arborescence polytope

The results on branchings in the previous section can be specialized to arborescences (without prescribed root). Given a digraph $D = (V, A)$, the *arborescence polytope* of D, denoted by $P_{\text{arborescence}}(D)$, is the convex hull of the incidence vectors of arborescences.

Corollary 52.6c. *The arborescence polytope is determined by*

$$
(52.19) \qquad \begin{array}{rll}
\text{(i)} & x_a \geq 0 & \text{for } a \in A, \\
\text{(ii)} & x(\delta^{\text{in}}(v)) \leq 1 & \text{for } v \in V, \\
\text{(iii)} & x(A[U]) \leq |U| - 1 & \text{for } U \subseteq V,\ U \neq \emptyset, \\
\text{(iv)} & x(A) = |V| - 1. &
\end{array}
$$

Proof. Directly from Corollary 52.6a, since $P_{\text{arborescence}}(D)$ is the face of $P_{\text{branching}}(D)$ determined by the hyperplane $x(A) = |V| - 1$. ∎

One similarly obtains from Theorem 52.6 the following, which yields a min-max relation for the minimum length of an arborescence:

Corollary 52.6d. *System* (52.19) *is TDI.*

Proof. From Theorem 52.6, with Theorem 5.25. ∎

52.8. Further results and notes

52.8a. Complexity survey for shortest r-arborescence

	$O(nm)$	Chu and Liu [1965], Edmonds [1967a], Bock [1971]
	$O(n^2)$	Tarjan [1977] (cf. Camerini, Fratta, and Maffioli [1979])
	$O(m \log n)$	Tarjan [1977] (cf. Camerini, Fratta, and Maffioli [1979])
	$O(n \log n + m \log\log\log_{m/n} n)$	Gabow, Galil, and Spencer [1984]
*	$O(m + n \log n)$	Gabow, Galil, Spencer, and Tarjan [1986]

As before, $*$ indicates an asymptotically best bound in the table.

X. Guozhi (see Guan [1979]), Gabow and Tarjan [1979,1984], and Gabow, Galil, Spencer, and Tarjan [1986] studied the problem of finding a shortest r-arborescence with exactly k arcs leaving r, yielding an $O(m+n \log n)$-time algorithm. Hou [1996] gave an $O(k^3 m^3)$-time algorithm to find the k shortest r-arborescences in a digraph.

Gabow and Tarjan [1988a] gave $O(m+n \log n)$- and $O(m \log^* n)$-time algorithms for the *bottleneck* r-arborescence problem (that is, minimizing the maximum arc cost), improving the $O(m \log n)$-time algorithm of Camerini [1978]. (Here $\log^* n$ is the minimum i with $\log_2^{(i)} n \leq 1$.)

52.8b. Concise LP-formulation for shortest r-arborescence

Wong [1984] and Maculan [1986] observed that the problem of finding a shortest r-arborescence can be formulated as a concise linear programming problem. In fact, the dominant $P^{\uparrow}_{r\text{-arborescence}}(D)$ of the r-arborescence polytope is the projection of a polyhedron in nm dimensions determined by at most $n(2m+n)$ constraints.

Theorem 52.7. *Let $D = (V, A)$ be a digraph and let $r \in V$. Then $P^{\uparrow}_{r\text{-arborescence}}(D)$ is equal to the set Q of all vectors $x \in \mathbb{R}^A_+$ such that for each $u \in V \setminus \{r\}$ there exists an $r-u$ flow f_u of value 1 satisfying $f_u \leq x$.*

Proof. Since the incidence vector $x = \chi^B$ of any r-arborescence satisfies the constraints, we know that $P^{\uparrow}_{r\text{-arborescence}}(D)$ is contained in Q.

To see the reverse inclusion, let $x \in Q$. Then for each nonempty subset U of $V \setminus \{r\}$ one has

(52.20) $$x(\delta^{\text{in}}(U)) \geq f_u(\delta^{\text{in}}(U)) \geq 1,$$

where u is any vertex in U and where f_u is an $r-u$ flow of value 1 with $f_u \leq x$. So by Corollary 52.3a, x belongs to $P^{\uparrow}_{r\text{-arborescence}}(D)$. ∎

This implies that a shortest r-arborescence can be found by solving a linear programming problem of polynomial size:

Corollary 52.7a. *Let $D = (V, A)$ be a digraph and let $r \in V$ and $l \in \mathbb{R}^A_+$. Then the length of a shortest r-arborescence is equal to the minimum value of*

(52.21) $$\sum_{a \in A} l(a) x_a,$$

where $x \in \mathbb{R}^A$ is such that for each $u \in V \setminus \{r\}$ there exists an $r-u$ flow f_u of value 1 with $f_u \leq x$.

Proof. Directly from Theorem 52.7. ∎

52.8c. Further notes

Frank [1979b] showed the following. Let $D = (V, A)$ be a digraph and let $r \in V$. Then a subset A' of A is contained in an r-arborescence if and only if $|\mathcal{U}| \leq |V| - 1 - |A'|$ for each laminar collection $\mathcal{U}$ of nonempty subsets of $V \setminus \{r\}$ such that each arc of D enters at most one set in $\mathcal{U}$ and no arc in A' enters any set in $\mathcal{U}$.

Goemans [1992,1994] studied the convex hull of (not necessarily spanning) partial r-arborescences.

Karp [1972a] gave a shortening of the proof of Edmonds [1967a] of the correctness of the shortest r-arborescence algorithm.

Books covering shortest arborescences include Minieka [1978], Papadimitriou and Steiglitz [1982], and Gondran and Minoux [1984].

Chapter 53

Packing and covering of branchings and arborescences

Packing arborescences is a special case of packing common bases in two matroids. However, no general matroid theorem is known that covers this case. In Section 42.6c the maximum number of common bases in two strongly base orderable matroids was characterized, but this does not apply to packing arborescences, as graphic matroids are generally not strongly base orderable. Yet, min-max relations and polyhedral characterizations can be proved for packing arborescences, and similarly for covering by branchings.

53.1. Disjoint branchings

Edmonds [1973] gave the following characterization of the existence of disjoint branchings in a given directed graph $D = (V, A)$. We give the proof of Lovász [1976c]. The *root set* of a branching B is the set of roots of B, that is, the set of sources of the digraph (V, B).

Theorem 53.1 (Edmonds' disjoint branchings theorem)**.** *Let $D = (V, A)$ be a digraph and let $R_1, \ldots, R_k$ be subsets of V. Then there exist disjoint branchings $B_1, \ldots, B_k$ such that B_i has root set R_i (for $i = 1, \ldots, k$) if and only if*

(53.1) $\qquad d^{\text{in}}(U) \geq |\{i \mid R_i \cap U = \emptyset\}|,$

for each nonempty subset U of V.

Proof. Necessity being trivial, we show sufficiency, by induction on $|V \setminus R_1| + \cdots + |V \setminus R_k|$. If $R_1 = \cdots = R_k = V$, the theorem is trivial, so we can assume that $R_1 \neq V$. For each $U \subseteq V$, define

(53.2) $\qquad g(U) := |\{i \mid R_i \cap U = \emptyset\}|.$

Let W be an inclusionwise minimal set with the properties that $W \cap R_1 \neq \emptyset$, $W \setminus R_1 \neq \emptyset$, and $d^{\text{in}}(W) = g(W)$. Such a set exists, since $W = V$ would qualify.

Then

(53.3) $$d^{\text{in}}(W \setminus R_1) \geq g(W \setminus R_1) > g(W) = d^{\text{in}}(W),$$

and hence there exists an arc $a = (u, v)$ in A with $u \in W \cap R_1$ and $v \in W \setminus R_1$. It suffices to show that (53.1) is maintained after resetting $A := A \setminus \{a\}$ and $R_1 := R_1 \cup \{v\}$, since after resetting we can apply induction, and assign a to B_1.

To see that (53.1) is maintained, suppose that to the contrary there is a $U \subseteq V$ violating the condition after resetting. Then in resetting, $d^{\text{in}}(U)$ decreases by 1 while $g(U)$ is unchanged. So a enters U, and, before resetting we had $d^{\text{in}}(U) = g(U)$ and $U \cap R_1 \neq \emptyset$. This implies (before resetting):

(53.4) $$\begin{aligned} d^{\text{in}}(U \cap W) &\leq d^{\text{in}}(U) + d^{\text{in}}(W) - d^{\text{in}}(U \cup W) \\ &\leq g(U) + g(W) - g(U \cup W) \leq g(U \cap W). \end{aligned}$$

So we have equality throughout. Hence $d^{\text{in}}(U \cap W) = g(U \cap W)$ and $R_1 \cap (U \cap W) \neq \emptyset$ (as $R_1 \cap W \neq \emptyset$ and $R_1 \cap U \neq \emptyset$, and $g(U \cap W) = g(U) + g(W) - g(U \cup W)$). Also $(U \cap W) \setminus R_1 \neq \emptyset$ (since $v \in U \cap W$) and $U \cap W \subset W$ (as $u \notin U \cap W$). This contradicts the minimality of W. ∎

(Also the method of Tarjan [1974a] is based on the existence of an arc a as in this proof. Fulkerson and Harding [1976] gave another proof of the existence of such ar arc (more complicated than that of Lovász given above).)

53.2. Disjoint r-arborescences

The previous theorem implies a characterization of the existence of disjoint arborescences with prescribed roots:

Corollary 53.1a. *Let $D = (V, A)$ be a digraph and let $r_1, \ldots, r_k \in V$. Then there exist k disjoint arborescences $B_1, \ldots, B_k$, where B_i has root r_i (for $i = 1, \ldots, k$) if and only if each nonempty subset U of V is entered by at least as many arcs as there exist i with $r_i \notin U$.*

Proof. Directly from Edmonds' disjoint branchings theorem (Theorem 53.1) by taking $R_i := \{r_i\}$ for all i. ∎

If all roots are equal, we obtain the following min-max relation, announced by Edmonds [1970b]. Recall that an *r-cut* is a cut $\delta^{\text{in}}(U)$ where U is a nonempty subset of $V \setminus \{r\}$.

Corollary 53.1b (Edmonds' disjoint arborescences theorem). *Let $D = (V, A)$ be a digraph and let $r \in V$. Then the maximum number of disjoint r-arborescences is equal to the minimum size of an r-cut.*

Proof. Directly from Corollary 53.1a by taking k equal to the minimum size of an r-cut and $r_i := r$ for $i = 1, \ldots, k$. ∎

Note that Edmonds' disjoint arborescences theorem implies Menger's theorem: for any digraph $D = (V, A)$ and $r, s \in V$, if k is the minimum size of an $r - s$ cut, we can extend D by k parallel arcs from s to v, for each vertex $v \neq s$; in the extended graph, the minimum size of an r-cut is k, and hence it contains k arc-disjoint r-arborescences. This gives k arc-disjoint $r - s$ paths in the original graph D.

One can reformulate Edmonds' disjoint arborescences theorem in a number of ways (Edmonds [1975]):

Corollary 53.1c. *Let $D = (V, A)$ be a digraph and let $r \in V$. Then for each $k \in \mathbb{Z}_+$ the following are equivalent:*

(53.5)
(i) *there exist k disjoint r-arborescences;*
(ii) *for each nonempty $U \subseteq V \setminus \{r\}$, $d^{\text{in}}(U) \geq k$;*
(iii) *for each $s \neq r$ there exist k arc-disjoint $r - s$ paths in D;*
(iv) *there exist k edge-disjoint spanning trees in the underlying undirected graph such that for each $s \neq r$ there are exactly k arcs entering s covered by these trees.*

Proof. The equivalence of (i) and (ii) follows from Edmonds' disjoint arborescences theorem (Theorem 53.1b), and the equivalence of (ii) and (iii) is a direct consequence of Menger's theorem.

The implication (i) $\Rightarrow$ (iv) is trivial. To prove (iv) $\Rightarrow$ (ii), suppose that (iv) holds, and let U be a nonempty subset of $V \setminus \{r\}$. Each spanning tree has at most $|U| - 1$ arcs contained in U. So the spanning trees of (iv) together have at most $k(|U| - 1)$ arcs contained in U. Moreover, they have exactly $k|U|$ arcs with head in U. Hence, at least k arcs enter U. ∎

An interesting consequence of Edmonds' disjoint arborescences theorem was observed by Shiloach [1979a] and concerns the arc-connectivity of a directed graph:

Corollary 53.1d. *A digraph $D = (V, A)$ is k-arc-connected if and only if for all $s_1, t_1, \ldots, s_k, t_k \in V$ there exist arc-disjoint paths $P_1, \ldots, P_k$, where P_i runs from s_i to t_i $(i = 1, \ldots, k)$.*

Proof. Sufficiency follows by taking $s_1 = \cdots = s_k$ and $t_1 = \cdots = t_k$. To see necessity, extend D by a vertex r and arcs (r, s_i) for $i = 1, \ldots, k$. By Edmonds' disjoint arborescences theorem (Corollary 53.1b), the extended digraph has k disjoint r-arborescences, since each nonempty subset U of V is entered by at least k arcs of D'. Choosing the $s_i - t_i$ path in the r-arborescence containing (r, s_i), for $i = 1, \ldots, k$, we obtain paths as required. ∎

53.3. The capacitated case

The capacitated version of the min-max relation for disjoint r-arborescences reads:

Corollary 53.1e. *Let $D = (V, A)$ be a digraph, let $r \in V$, and let $c \in \mathbb{Z}_+^A$ be a capacity function. Then the minimum capacity of an r-cut is equal to the maximum value of $\sum_B \lambda_B$, where λ_B is a nonnegative integer for each r-arborescence B such that*

(53.6) $$\sum_B \lambda_B \chi^B \leq c.$$

Proof. Directly from Corollary 53.1b by replacing each arc a by $c(a)$ parallel arcs. ∎

One can equivalently formulate this in term of total dual integrality. To see this, consider the *r-cut polytope* $P_{r\text{-cut}}(D)$ of D, defined as the convex hull of the incidence vectors of the r-cuts in D. In particular, consider the up hull

(53.7) $$P^{\uparrow}_{r\text{-cut}}(D) := P_{r\text{-cut}}(D) + \mathbb{R}_+^A$$

of the r-cut polytope.

In Corollary 52.3a we saw that the up hull $P^{\uparrow}_{r\text{-arborescence}}(D)$ of the r-arborescence polytope of D is determined by:

(53.8)
(i) $x_a \geq 0$ for each arc a,
(ii) $x(C) \geq 1$ for each r-cut C.

By the theory of blocking polyhedra, this implies that $P^{\uparrow}_{r\text{-cut}}(D)$ is determined by:

(53.9)
(i) $x_a \geq 0$ for each arc a,
(ii) $x(B) \geq 1$ for each r-arborescence B.

In fact:

Corollary 53.1f. *System* (53.9) *determines $P^{\uparrow}_{r\text{-cut}}(D)$ and is TDI.*

Proof. The first part follows from the theory of blocking polyhedra applied to Corollary 52.3a, and the second part is equivalent to Corollary 53.1e. ∎

Another equivalent form is:

(53.10) For any digraph $D = (V, A)$ and $r \in V$, the r-arborescence polytope has the integer decomposition property.

By Theorem 5.30, the number of r-arborescences B with $\lambda_B \geq 1$ in Corollary 53.1e can be taken to be at most $2|A| - 1$. (This improves a result of Pevzner [1979a] giving an $O(nm)$ upper bound.) Gabow and Manu [1995, 1998] showed an upper bound of $|V| + |A| - 2$.

53.4. Disjoint arborescences

Frank [1979a,1981c] derived from Corollary 53.1a the following min-max relation for disjoint arborescences without a prescribed root. (A *subpartition* of V is a partition of a subset of V.)

Corollary 53.1g. *Let $D = (V, A)$ be a digraph and let $k \in \mathbb{Z}_+$. Then A contains k disjoint arborescences if and only if*

$$(53.11) \qquad \sum_{U \in \mathcal{P}} d^{\text{in}}(U) \geq k(|\mathcal{P}| - 1)$$

for each subpartition $\mathcal{P}$ of V with nonempty classes.

Proof. Necessity being easy, we show sufficiency. Choose $x \in \mathbb{Z}_+^V$ such that

$$(53.12) \qquad x(U) \geq k - d^{\text{in}}(U)$$

for each nonempty subset U of V, with $x(V)$ as small as possible. We show that $x(V) = k$. Since $x(V) \geq k$ by (53.12), it suffices to show $x(V) \leq k$.

Let $\mathcal{P}$ be the collection of inclusionwise maximal nonempty sets having equality in (53.12). Then $\mathcal{P}$ is a subpartition, for suppose that $U, W \in \mathcal{P}$ with $U \cap W \neq \emptyset$. Then

$$(53.13) \qquad \begin{aligned} x(U \cup W) &= x(U) + x(W) - x(U \cap W) \\ &\leq (k - d^{\text{in}}(U)) + (k - d^{\text{in}}(W)) - (k - d^{\text{in}}(U \cap W)) \\ &\leq (k - d^{\text{in}}(U \cup W)), \end{aligned}$$

and hence $U \cup W \in \mathcal{P}$. So $U = W$.

Now for each $v \in V$ with $x_v > 0$ there exists a set U in $\mathcal{P}$ containing v, since otherwise we could decrease x_v. Hence

$$(53.14) \qquad x(V) = \sum_{U \in \mathcal{P}} x(U) = \sum_{U \in \mathcal{P}} (k - d^{\text{in}}(U)) \leq k,$$

by (53.11).

So $x(V) = k$. Now let $r_1, \ldots, r_k$ be vertices such that any vertex v occurs x_v times among the r_i. Then by Corollary 53.1a there exist disjoint arborescences $B_1, \ldots, B_k$, where B_i has root r_i. This shows the corollary. ∎

53.5. Covering by branchings

Let $A[U]$ denote the set of arcs in A with both ends in U. Frank [1979a] observed that the following min-max relation for covering by branchings can be derived from Edmonds' disjoint arborescences theorem:

Corollary 53.1h. *Let $D = (V, A)$ be a digraph and let $k \in \mathbb{Z}_+$. Then A can be covered by k branchings if and only if*

(53.15) (i) $\deg^{\text{in}}(v) \leq k$ *for each* $v \in V$,
(ii) $|A[U]| \leq k(|U| - 1)$ *for each nonempty subset* U *of* V.

Proof. Necessity being trivial, we show sufficiency. Extend D by a new vertex r, and for each $v \in V$, $k - \deg^{\text{in}}(v)$ parallel arcs from r to v. Let D' be the digraph thus arising. So each vertex in V is entered by exactly k arcs of D', and D' has $k|V|$ arcs.

Now each nonempty subset U of V is entered by at least k arcs of D', since exactly $k|U|$ arcs have their head in U and at most $k(|U|-1)$ arcs have both ends in U. So by Edmonds' disjoint arborescences theorem (Theorem 53.1b), D' has k disjoint r-arborescences. Since D' has exactly $k|V|$ arcs, these arborescences partition the arc set of D'. Hence restricting them to the arcs of the original graph D, we obtain k branchings partitioning A. ∎

(This was also shown by Markosyan and Gasparyan [1986].)

Corollary 53.1h is equivalent to:

Corollary 53.1i. *Let $D = (V, A)$ be a digraph and let $k \in \mathbb{Z}_+$. Then A can be covered by k branchings if and only if* $\deg^{\text{in}}(v) \leq k$ *for each $v \in V$ and A can be covered by k forests of the underlying undirected graph.*

Proof. Directly from Corollary 53.1h with Corollary 51.1c. ∎

Corollary 53.1h implies a polyhedral result of Baum and Trotter [1981] (attributing the proof to R. Giles):

Corollary 53.1j. *The branching polytope of a digraph $D = (V, A)$ has the integer decomposition property.*

Proof. Let $k \in \mathbb{Z}_+$ and let x be an integer vector in $k \cdot P_{\text{branching}}(D)$. Let $D' = (V, A')$ be the digraph obtained from D by replacing any arc $a = (u, v)$ by x_a parallel arcs from u to v. Then by Corollary 53.1h, A' can be partitioned into k branchings. This gives a decomposition of x as a sum of the incidence vectors of k branchings in D. ∎

53.6. An exchange property of branchings

We derive an exchange property of branchings from Edmonds' disjoint branchings theorem (Theorem 53.1). It implies that the branchings in an optimum covering can be taken of almost equal size. It will also be used in Section 59.5 on the total dual integrality of the matching forest constraints.

We first show a lemma. For any branching B, let $R(B)$ denote the set of roots of B.

Lemma 53.2α. *Let B_1 and B_2 be branchings partitioning the arc set A of a digraph $D = (V, A)$. Let R_1 and R_2 be sets with $R_1 \cup R_2 = R(B_1) \cup R(B_2)$ and $R_1 \cap R_2 = R(B_1) \cap R(B_2)$. Then A can be split into branchings B'_1 and B'_2 with $R(B'_i) = R_i$ for $i = 1, 2$ if and only if each strong component K of D with $d^{\text{in}}(K) = 0$ intersects both R_1 and R_2.*

Proof. Necessity is easy, since the root set of any branching intersects any strong component K with $d^{\text{in}}(K) = 0$.

To see sufficiency, by Edmonds' disjoint branchings theorem (Theorem 53.1), branchings B'_1 and B'_2 as required exist if and only if

(53.16) $\qquad d^{\text{in}}(U) \geq |\{i \in \{1, 2\} \mid U \cap R_i = \emptyset\}|$

for each nonempty $U \subseteq V$. (Actually, Edmonds' theorem gives the existence of disjoint branchings B'_1 and B'_2 satisfying $R(B'_i) = R_i$ for $i = 1, 2$. That $B'_1 \cup B'_2 = A$ follows from the fact that $|B'_1| + |B'_2| = |B_1| + |B_2|$, as $|R(B'_1)| + |R(B'_2)| = |R(B_1)| + |R(B_2)|$.)

Suppose that inequality (53.16) does not hold. Then the right-hand side is positive. If it is 2, then U is disjoint from both R_1 and R_2, and hence from both $R(B_1)$ and $R(B_2)$ (since $R_1 \cup R_2 = R(B_1) \cup R(B_2)$), implying that both B_1 and B_2 enter U, and so $d^{\text{in}}(U) \geq 2$.

So the right-hand side is 1, and hence the left-hand side is 0. We can assume that U is an inclusionwise minimal set with this property. It implies that U is a strong component of D. Then by the condition, U intersects both R_1 and R_2, contradicting the fact that the right-hand side in (53.16) is 1. ∎

First, this implies the following exchange property of branchings:

Theorem 53.2. *Let B_1 and B_2 be branchings in a digraph $D = (V, A)$. Let s be a root of B_2 and let r be the root of the arborescence in B_1 containing s. Then D contains branchings B'_1 and B'_2 satisfying*

(53.17) $\qquad B'_1 \cup B'_2 = B_1 \cup B_1,\ B'_1 \cap B'_2 = B_1 \cap B_2,$
$\qquad\qquad$ *and* $R(B'_1) = R(B_1) \cup \{s\}$ *or* $R(B'_1) = (R(B_1) \setminus \{r\}) \cup \{s\}$.

Proof. We may assume that B_1, B_2 partition A, since we can delete all arcs not occurring in $B_1 \cup B_2$, and add parallel arcs for those in $B_1 \cap B_2$. We may also assume that $s \neq r$ (since the theorem is trivial if $s = r$).

Let K be the strong component of D containing s. If no arc of D enters K, then $r \in K$ (as B_1 contains a directed path from r to s), and hence r is not a root of B_2 (as otherwise no arc enters r while K is strongly connected); define $R_1 := (R(B_1) \setminus \{r\}) \cup \{s\}$ and $R_2 := (R(B_2) \setminus \{s\}) \cup \{r\}$.

Alternatively, if some arc of D enters K, define $R_1 := R(B_1) \cup \{s\}$ and $R_2 := R(B_2) \setminus \{s\}$. Then Lemma 53.2$\alpha$ implies that A can be split into branchings B'_1 and B'_2 with $R(B'_i) = R_i$ for $i = 1, 2$. ∎

The lemma also implies that a packing of branchings can be balanced in the following sense:

Theorem 53.3. *Let $D = (V, A)$ be a digraph. If A can be covered by k branchings, then A can be covered by k branchings each of size $\lfloor |A|/k \rfloor$ or $\lceil |A|/k \rceil$.*

Proof. Consider any two branchings B_1, B_2 in the covering which differ in size by at least 2. Consider the digraph $D' = (V, B_1 \cup B_2)$. We can find subsets R_1 and R_2 of V with $R_1 \cup R_2 = R(B_1) \cup R(B_2)$ and $R_1 \cap R_2 = R(B_1) \cap R(B_2)$, such that each strong component K of D' with $d^{\text{in}}_{D'}(K) = 0$ intersects both R_1 and R_2, and such that R_1 and R_2 differ by at most 1 in size. (We can first include, for any such component K, one element in $K \cap R(B_1)$ in R_1, and one element in $K \cap R(B_2)$ in R_2; next we distribute the remaining elements in $R(B_1)$ and $R(B_2)$ almost equally over R_1 and R_2).

Then, by Lemma 53.2α, $B_1 \cup B_2$ can be partitioned into branchings B'_1 and B'_2 with $R(B'_i) = R_i$ for $i = 1, 2$. Then B'_1 and B'_2 differ by at most 1 in size. Replacing B_1 and B_2 in the covering by B'_1 and B'_2, and iterating this, we end up with a covering by k branchings, any two of which differ in size by at most 1. This is a covering as required. ∎

This theorem implies the integer decomposition property of the convex hull of branchings of size k (McDiarmid [1983]):

Corollary 53.3a. *Let $D = (V, A)$ be a digraph and let $k \in \mathbb{Z}_+$. Then the convex hull of the incidence vectors of the branchings of size k has the integer decomposition property.*

Proof. Choose $p \in \mathbb{Z}_+$, and let x be an integer vector in $p \cdot \text{conv.hull}\{\chi^B \mid B$ branching, $|B| = k\}$. By Corollary 53.1j, x is a sum of the incidence vectors of p branchings. Let $D' = (V, A')$ be the digraph arising from D by replacing any arc a by x_a parallel arcs. Then A' can be partitioned into p branchings. Now $|A'|/p = x(A)/p = k$. So, by Theorem 53.3, we can take these branchings all of size k. Hence x is the sum of the incidence vectors of p branchings each of size k. ∎

53.7. Covering by r-arborescences

Vidyasankar [1978a] proved the following covering analogue of Edmonds' disjoint branchings theorem. (A weaker version was shown by Frank [1979a] (cf. Frank [1979b]).) For any digraph $D = (V, A)$ and $U \subseteq V$, let $H(U)$ denote the set of outneighbours of $V \setminus U$; that is, the set of the heads of the arcs entering U. So $H(U) \subseteq U$.

Theorem 53.4. *Let $D = (V, A)$ be a digraph, let $r \in V$, and let $k \in \mathbb{Z}_+$. Then A can be covered by k r-arborescences if and only if*

(53.18) $\quad \deg^{\text{in}}(v) \leq k$ *for each* $v \in V$, *and* $\deg^{\text{in}}(r) = 0$,

and

(53.19)
$$\sum_{v \in H(U)} (k - \deg^{\text{in}}(v)) \geq k - d^{\text{in}}(U)$$

for each nonempty subset U of $V \setminus \{r\}$.

Proof. Necessity of (53.18) is trivial. To see necessity of (53.19), let U be a nonempty subset of $V \setminus \{r\}$. Then each r-arborescence B intersects the set

(53.20)
$$\bigcup_{v \in H(U)} \delta^{\text{in}}(v) \setminus \delta^{\text{in}}(U)$$

in at most $|H(U)| - 1$ arcs, since at least one arc of B should enter U. Hence if A can be covered by k r-arborescences, the size of set (53.20) is at most $k(|H(U)| - 1)$, implying (53.19).

To see sufficiency, we can assume that for any arc a of D, if we would add a parallel arc to a, then (53.18) or (53.19) is violated (since deleting parallel arcs does not increase the minimum number of r-arborescences needed to cover the arcs).

If $\deg^{\text{in}}(v) = k$ for each vertex $v \neq r$, then A can be decomposed into k r-arborescences by Edmonds' disjoint arborescences theorem (Corollary 53.1b), since then (53.19) implies that $d^{\text{in}}(U) \geq k$ for each nonempty subset U of $V \setminus \{r\}$.

So we can assume that there exists a vertex $u \neq r$ with $\deg^{\text{in}}(u) < k$. Consider the collection $\mathcal{C}$ of nonempty subsets U of $V \setminus \{r\}$ having equality in (53.19) and with $u \in H(U)$. Then $\mathcal{C}$ is closed under taking union and intersection. Indeed, let U and W be in $\mathcal{C}$. Then

(53.21)
$$\begin{aligned}
&\sum_{v \in H(U \cap W)} (k - \deg^{\text{in}}(v)) + \sum_{v \in H(U \cup W)} (k - \deg^{\text{in}}(v)) \\
&\leq \sum_{v \in H(U)} (k - \deg^{\text{in}}(v)) + \sum_{v \in H(W)} (k - \deg^{\text{in}}(v)) \\
&= (k - d^{\text{in}}(U)) + (k - d^{\text{in}}(W)) \\
&\leq (k - d^{\text{in}}(U \cap W)) + (k - d^{\text{in}}(U \cup W)).
\end{aligned}$$

The first inequality follows from

(53.22)
$$\begin{aligned}
&H(U \cap W) \cap H(U \cup W) \subseteq H(U) \cap H(W) \text{ and} \\
&H(U \cap W) \cup H(U \cup W) \subseteq H(U) \cup H(W),
\end{aligned}$$

as one easily checks.

By (53.19), (53.21) implies that we have equality throughout, As we have equality in the first inequality in (53.21), and as $k - \deg^{\text{in}}(u) > 0$, we know that $u \in H(U \cap W) \cap H(U \cup W)$. So $U \cap W$ and $U \cup W$ belong to $\mathcal{C}$.

Now for each arc a entering u, if we would add an arc parallel to a, (53.19) is violated for some U. This implies that for each arc a entering u there exists a $U \in \mathcal{C}$ such that the tail of a is in U. We can take for U the largest set in $\mathcal{C}$. Hence for each arc a entering u, the tail of a is in U. This contradicts the fact that $u \in H(U)$. ∎

Frank [1979b] showed the following consequence of this result:

Corollary 53.4a. *Let $D = (V, A)$ be a digraph, let $r \in V$, and let $k \in \mathbb{Z}_+$. Then A can be covered by k r-arborescences if and only if*

(53.23) $\quad k \cdot s(A') \geq |A'|$

for each $A' \subseteq A$. Here $s(A')$ denotes the maximum of $|B \cap A'|$ over r-arborescences B.

Proof. As necessity is trivial, we show sufficiency, by showing that (53.23) implies (53.18) and (53.19). To see (53.18), apply (53.23) to $A' := \delta^{\text{in}}(v)$. To see (53.19), apply (53.23) to A' equal to the set (53.20). ∎

Note that for *acyclic* digraphs, the minimum number of r-arborescences needed to cover all arcs is easily characterized (Vidyasankar [1978a]):

Theorem 53.5. *Let $D = (V, A)$ be an acyclic digraph and let $r \in V$. Then A can be covered by k r-arborescences if and only if r is the only source of D and each indegree is at most k.*

Proof. Necessity being easy, we show sufficiency. Trivially, we can cover A by sets $B_1, \ldots, B_k$ such that each B_i enters each $v \neq r$ precisely once. As D is acyclic, each B_i is an r-arborescence. ∎

53.8. Minimum-length unions of k r-arborescences

Let $D = (V, A)$ be a digraph, let $r \in V$, and let $k \in \mathbb{Z}_+$. Consider the following system in the variable $x \in \mathbb{R}^A$:

(53.24) $\quad$ (i) $x_a \geq 0$ for each $a \in A$,
(ii) $x(\delta^{\text{in}}(U)) \geq k$ for each nonempty $U \subseteq V \setminus \{r\}$.

The following basic result of Frank [1979b] follows from Theorem 52.4.

Theorem 53.6. *System* (53.24) *is box-TDI.*

Proof. Directly from Theorem 52.4, since if a system $Ax \leq b$ is box-TDI, then for any $k \geq 0$, the system $Ax \leq k \cdot b$ is box-TDI. ∎

This theorem has several consequences. First consider the system

(53.25) (i) $0 \leq x_a \leq 1$ for each $a \in A$,
(ii) $x(\delta^{\text{in}}(U)) \geq k$ for each nonempty $U \subseteq V \setminus \{r\}$.

The following (cf. Frank [1979b]) implies a min-max relation for the minimum length of the union of k disjoint r-arborescences in D:

Corollary 53.6a. *System* (53.25) *is TDI, and determines the convex hull of subsets of A containing k disjoint r-arborescences.*

Proof. Directly from Theorem 53.6 and Edmonds' disjoint arborescences theorem (Corollary 53.1b). ∎

Another consequence of Theorem 53.6 is as follows. Let $D = (V, A)$ and $D' = (V, A')$ be digraphs, let $r \in V$, and let $k \in \mathbb{Z}_+$. Consider the system in the variable $x \in \mathbb{R}^A$:

(53.26) (i) $x_a \geq 0$ for each $a \in A$,
(ii) $x(\delta^{\text{in}}_A(U)) \geq k - d^{\text{in}}_{A'}(U)$ for each nonempty $U \subseteq V \setminus \{r\}$.

Then:

Corollary 53.6b. *System* (53.26) *is box-TDI.*

Proof. Choose $d, c \in \mathbb{Z}^A_+$. We must show that the system

(53.27) (i) $d(a) \leq x_a \leq c(a)$ for each $a \in A$,
(ii) $x(\delta^{\text{in}}_A(U)) \geq k - d^{\text{in}}_{A'}(U)$ for each nonempty $U \subseteq V \setminus \{r\}$

is TDI. Let $D'' = (V, A'')$ be the digraph with $A'' := A \cup A'$ (taking arcs multiple if they occur both in A and A'). By Theorem 53.6, the following system in the variable $x \in \mathbb{R}^{A''}$ is TDI:

(53.28) (i) $d(a) \leq x_a \leq c(a)$ for each $a \in A$,
(ii) $1 \leq x_a \leq 1$ for each $a \in A'$,
(iii) $x(\delta^{\text{in}}_{A''}(U)) \geq k$ for each nonempty $U \subseteq V \setminus \{r\}$.

This implies the total dual integrality of (53.27) by Corollary 5.27a. ∎

Frank [1979a] derived the following 'rank' formula for coverings by k r-arborescences:

Corollary 53.6c. *Let $D = (V, A)$ be a digraph, let $r \in V$, and let $A' \subseteq A$. Then the maximum number of arcs in A' that can be covered by k r-arborescences is equal to the minimum value of*

(53.29) $$k(|V| - 1) + \sum_{i=1}^{t} (d^{\text{in}}_{A'}(V_i) - k),$$

where $V_1, \ldots, V_t$ is a laminar collection of nonempty subsets of $V \setminus \{r\}$ such that each arc in A enters at most one of these sets.

Proof. Let μ be the maximum number of arcs in A' that can be covered by k r-arborescences. Consider the system (in $x \in \mathbb{R}^A$)

(53.30) (i) $x_a \geq 0$ for $a \in A$,
(ii) $x(\delta^{\text{in}}_A(U)) \geq k - d^{\text{in}}_{A'}(U)$ for each nonempty $U \subseteq V \setminus \{r\}$.

By Corollary 53.6b, this system is TDI. Let x be an integer vector attaining the minimum of $x(A)$ over (53.30). Then

(53.31) $\mu = k(|V| - 1) - x(A).$

Indeed, by (53.30) and by Edmonds' disjoint arborescences theorem, there exist k r-arborescences $B_1, \ldots, B_k$ with

(53.32) $x + \chi^{A'} \geq \chi^{B_1} + \cdots + \chi^{B_k}.$

Let A'' be the set of arcs in A' covered by no B_i. By the minimality of $x(A)$, we have that $x(A) + |A'| = k(|V| - 1) + |A''|$. As $\mu \geq |A'| - |A''|$ we have $\geq$ in (53.31). Since we can reverse this construction (starting from a set of k r-arborescences covering μ arcs in A', and making x), we have the equality in (53.31).

By the total dual integrality of (53.30), $x(A)$ is equal to the maximum value of

(53.33) $$\sum_{i=1}^{t}(k - d^{\text{in}}_{A'}(V_i)),$$

taken over nonempty subsets $V_1, \ldots, V_t$ of $V \setminus \{r\}$ such that each arc in A enters at most one of these sets. If, say, $V_1 \cap V_2 \neq \emptyset$ and $V_1 \not\subseteq V_2 \not\subseteq V_1$, we can replace V_1 and V_2 by $V_1 \cap V_2$ and $V_1 \cup V_2$ without violating these conditions. Such replacements terminate by Theorem 2.1. We end up with $V_1, \ldots, V_t$ laminar as required. Therefore, with (53.31) we have the corollary. ∎

Taking $A' = A$, we get (Frank [1979b]):

Corollary 53.6d. *Let $D = (V, A)$ be a digraph and let $r \in V$. Then the maximum number of arcs that can be covered by k r-arborescences is equal to the minimum value of*

(53.34) $$k(|V| - 1) + \sum_{i=1}^{t}(d^{\text{in}}(V_i) - k),$$

where $V_1, \ldots, V_t$ form a laminar collection of nonempty subsets of $V \setminus \{r\}$ such that each arc enters at most one of these sets.

Proof. This is the case $A' = A$ in Corollary 53.6c. ∎

This directly implies a min-max characterization for the minimum number of r-arborescences needed to cover all arcs. However, Theorem 53.4 gives a stronger relation.

As for unions of k branchings, Frank [1979a] derived from Corollary 53.6c:

Corollary 53.6e. *Let $D = (V, A)$ be a digraph and let $k \in \mathbb{Z}_+$. The maximum number of arcs of D that can be covered by k branchings is equal to the minimum value of*

$$(53.35) \qquad k(|V| - |\mathcal{P}|) + \sum_{U \in \mathcal{P}} d^{\text{in}}(U)$$

taken over all subpartitions $\mathcal{P}$ of V with nonempty classes.

Proof. Let D' be the digraph obtained from D by adding a new vertex r and arcs (r, v) for each $v \in V$. Then the maximum number of arcs of D that can be covered by k branchings in D is equal to the maximum number of arcs in A that can be covered by k r-arborescences in D'. So Corollary 53.6c gives a min-max relation for this.

The subsets V_i form a subpartition of V since if V_i and V_j would intersect in a vertex v say, then the arc (r, v) of D' enters two sets among the V_i, contradicting the condition. ∎

As for unions of k arborescences without prescribed root, Frank [1979a] derived:

Corollary 53.6f. *Let $D = (V, A)$ be a digraph and let $k \in \mathbb{Z}_+$. Then A can be covered by k arborescences if and only if*

$$(53.36) \qquad k(|V| - 1 + \lambda) \geq |A| + \sum_{i=1}^{t} (k - d^{\text{in}}(V_i))$$

for each laminar family $(V_1, \ldots, V_t)$ of nonempty sets such that no arc enters more than one of the V_i. Here λ denotes the maximum number of V_i's having nonempty intersection.

Proof. Necessity can be seen as follows. Let A be covered by arborescences $B_1, \ldots, B_k$. For each $v \in V$, let $r(v)$ be the number of B_i having v as root. So $r(V) = k$. For each $a \in A$, let $s(a)$ be the number of B_i containing a. So $s(a) \geq 1$ for each $a \in A$. Moreover, $s(\delta^{\text{in}}(V_i)) + r(V_i) \geq k$ for each i. Hence

$$\begin{aligned}(53.37) \qquad |A| + \sum_{i=1}^{t} (k - d^{\text{in}}(V_i)) &\leq |A| + \sum_{i=1}^{t} \big(r(V_i) + s(\delta^{\text{in}}(V_i)) - d^{\text{in}}(V_i)\big) \\ &\leq |A| + \sum_{a \in A} (s(a) - 1) + \sum_{i=1}^{t} r(V_i) = \sum_{a \in A} s(a) + \sum_{i=1}^{t} r(V_i) \\ &= k(|V| - 1) + \sum_{i=1}^{t} r(V_i) \leq k(|V| - 1) + k\lambda.\end{aligned}$$

The second inequality holds as each arc enters at most one of the V_i. For the last inequality, we use that $r(V) = k$ and that $V_1, \ldots, V_t$ can be partitioned into λ collections, each consisting of disjoint sets. (53.37) shows necessity.

To see sufficiency, extend D by a vertex r and by the arc set $A' := \{(r, v) \mid v \in V\}$, yielding the digraph $D' = (V \cup \{r\}, A \cup A')$. Consider the following constraints for $x \in \mathbb{R}^{A \cup A'}$:

$$\text{(53.38)} \qquad \begin{array}{rll} \text{(i)} & x_a \geq 0 & \text{for each } a \in A \cup A', \\ \text{(ii)} & x(\delta^{\text{in}}_{D'}(U)) \geq k - d^{\text{in}}_D(U) & \text{for each nonempty } U \subseteq V, \\ \text{(iii)} & x(\delta^{\text{in}}_{D'}(V)) = k. & \end{array}$$

Let x attain the minimum of $x(A)$ over (53.38). Since system (53.38) is TDI by Corollary 53.6b (with Theorem 5.25), we can assume that x is integer. We show

$$\text{(53.39)} \qquad x(A) = k(|V| - 1) - |A|.$$

First, $x(A) \geq k(|V| - 1) - |A|$, since

$$\text{(53.40)} \qquad \begin{aligned} & x(A) + |A| + k = x(A) + |A| + x(\delta^{\text{in}}_{A'}(V)) \\ & = \sum_{v \in V} \left(x(\delta^{\text{in}}_{A'}(v)) + x(\delta^{\text{in}}_{A}(v)) + d^{\text{in}}_A(v) \right) \geq k|V|. \end{aligned}$$

To see the reverse inequality, $x(A)$ is equal to the optimum value μ of the problem dual to the above minimization problem: maximize

$$\text{(53.41)} \qquad \sum_{U \in \mathcal{P}(V) \setminus \{\emptyset\}} z_U (k - d^{\text{in}}_A(U))$$

where $z \in \mathbb{R}^{\mathcal{P}(V) \setminus \{\emptyset\}}_+$ such that

$$\text{(53.42)} \qquad \sum_U z_U \chi^{\delta^{\text{in}}_{D'}(U)} \leq \chi^A.$$

So we should prove that $\mu \leq k(|V| - 1) - |A|$.

Now let $\mathcal{U}$ be the collection of nonempty proper subsets U of V with $z_U = 1$. We may assume that $\mathcal{U}$ is laminar. Let λ be the maximum number of $U \in \mathcal{U}$ containing any vertex. Then (53.42) implies that $\lambda \leq -z_V$ (since $\chi^A(a) = 0$ for each $a = (r, v)$). Hence

$$\text{(53.43)} \qquad \begin{aligned} & \mu = k \cdot z_V + \sum_{U \in \mathcal{U}} (k - d^{\text{in}}_A(U)) \leq -k\lambda + \sum_{U \in \mathcal{U}} (k - d^{\text{in}}_A(U)) \\ & \leq k(|V| - 1) - |A| \end{aligned}$$

by (53.36), and we have the required inequality. This proves (53.39).

Then the vector $y := x + \chi^A$ satisfies:

$$\text{(53.44)} \qquad \begin{aligned} & y(\delta^{\text{in}}_{D'}(U)) \geq k \text{ for each nonempty } U \subseteq V, \\ & y(\delta^{\text{in}}_{D'}(V)) = k, \\ & y(A \cup A') = x(A) + x(A') + |A| = k(|V| - 1) - |A| + k + |A| = k|V|. \end{aligned}$$

So by Edmonds' disjoint arborescences theorem (Corollary 53.1b), y is the sum of the incidence vectors of k r-arborescences, each with exactly one arc leaving r. Hence (by the definition of y) A can be covered by k arborescences. ∎

53.9. The complexity of finding disjoint arborescences

By Edmonds' disjoint arborescences theorem, the maximum number of disjoint r-arborescences can be calculated in polynomial time, just by determining the minimum size of an r-cut. This can be done by determining, for each $v \in V \setminus \{r\}$, the minimum size of an $r - v$ cut, and taking the minimum of these values.

Lovász [1976c] and Tarjan [1974a] showed that actually also a maximum collection of disjoint r-arborescences can be found in polynomial time.

The proof (due to Lovász [1976c]) of Theorem 53.1 described above gives such a polynomial-time algorithm. In fact, Lovász observed that it implies the following result (obtained also by Tarjan [1974a]). Call a subset B of the arc set A of a digraph $D = (V, A)$ a *partial r-arborescence* if B is an r-arborescence for the subgraph of D induced by the set $V(B)$ of vertices covered by B. We take $V(B) := \{r\}$ if B is empty.

Theorem 53.7. *Given a digraph $D = (V, A)$ and a vertex $r \in V$, a maximum number k of disjoint r-arborescences can be found in time $O(k^2m^2)$.*

Proof. First, the number k can be determined in time $O(knm)$. Since k is equal to the minimum size of a cut $d^{\text{in}}(U)$ over nonempty subsets U of $V \setminus \{r\}$, we can determine for each $v \in V \setminus \{r\}$ a maximum set of arc-disjoint $r - v$ paths, by the augmenting path method described in Section 9.2. Actually, for $i = 1, \ldots, k$, we determine the ith augmenting paths for all $v \in V \setminus \{r\}$, before searching for the $(i + 1)$th augmenting paths. In this way we can stop if for some $v \in V \setminus \{r\}$ no augmenting path exists. So in total we do at most $(n - 1)(k + 1)$ augmenting path searches. Thus it takes $O(knm)$ time to determine k.

Next, we can find an r-arborescence B such that

(53.45) $\quad d^{\text{in}}_{A \setminus B}(U) \geq k - 1$ for each nonempty $U \subseteq V \setminus \{r\}$,

in time $O(km^2)$. This recursively implies the theorem.

To find B, as in the proof of Theorem 53.1, we can grow a partial r-arborescence B satisfying (53.45), starting with $B = \emptyset$. By the proof of Theorem 53.1, if $V(B) \neq V$, there exists an arc a leaving $V(B)$ such that resetting $B := B \cup \{a\}$ maintains (53.45). For any given arc a leaving $V(B)$ it amounts to testing if there exists a set $U \subseteq V \setminus \{r\}$ such that $a \in \delta^{\text{in}}(U)$ and $d^{\text{in}}_{A \setminus B}(U) = k - 1$. This can be done in $O(km)$ time with a minimum cut algorithm.

Now it is important to observe that for each arc a we need to do this test at most once: if the test result is negative, then in growing B we never have to consider arc a anymore; if the result is positive, a is added to B, and again we will not consider a again.

So to obtain an r-arborescence, we determine at most m minimum cuts, and so finding the r-arborescence B takes $O(km^2)$ time. ∎

Tong and Lawler [1983] observed that the following quite easily follows from Edmonds' disjoint arborescences theorem:

Theorem 53.8. *Given a digraph $D = (V, A)$ and a vertex $r \in V$, we can find in time $O(knm)$ a set of arcs that is the union of a maximum number k of disjoint r-arborescences.*

Proof. As in the proof of Theorem 53.7 we can determine the number k in time $O(knm)$. Now consider any vertex $v \in V$. Find k arc-disjoint $r-v$ paths in D, and delete from D each arc entering v that is on none of these paths. After that we still have $d^{\text{in}}(U) \geq k$ for any nonempty $U \subseteq V \setminus \{r\}$, since if $v \notin U$, then no arc entering U has been deleted, and if $v \in U$, then k arcs entering U are maintained, as after deletion there are still k arc-disjoint $r-v$ paths in D.

Doing this successively for all vertices $v \in V$, we are left with a digraph D with $\deg^{\text{in}}(v) = k$ if $v \neq r$ and $\deg^{\text{in}}(r) = 0$, and with $d^{\text{in}}(U) \geq k$ for each nonempty $U \subseteq V \setminus \{r\}$. So the remaining arc set is the union of k disjoint r-arborescences. As k arc-disjoint $r-v$-paths can be found in time $O(km)$, we have the required result. ∎

This implies with Theorem 53.7 a sharpening of Theorem 53.7:

Corollary 53.8a. *Given a digraph $D = (V, A)$ and a vertex $r \in V$, a maximum number k of disjoint r-arborescences can be found in time $O(knm + k^4n^2)$.*

Proof. By Theorem 53.8, we can find in time $O(knm)$ a set A' that is the union of k disjoint r-arborescences. So $m' := |A'| = k(n-1)$. Then by Theorem 53.7 we can find k disjoint r-arborescences in A', in time $O(k^2{m'}^2)$. Since $O(k^2{m'}^2) = O(k^4n^2)$, the corollary follows. ∎

Tong and Lawler [1983] in fact showed that the method of Lovász [1976c] has an $O(k^2nm)$-time implementation, yielding with Theorem 53.8 an $O(knm + k^3n^2)$-time algorithm for finding k disjoint r-arborescences.

Also the capacitated case can be solved in strongly polynomial time (Gabow [1991a,1995a]), as can be shown with the help of Edmonds' disjoint branchings theorem. (Pevzner [1979a] proved that it can be solved in *semi-strongly polynomial time*, that is, by taking rounding as one arithmetic step.)

Theorem 53.9. *Given a digraph $D = (V, A)$, $r \in V$, and a capacity function $c : A \to \mathbb{Z}_+$, we can find r-arborescences $B_1, \ldots, B_k$ and integers $\lambda_1, \cdots, \lambda_k \geq 0$ with $\sum_{i=1}^{k} \lambda_i \chi^{B_i} \leq c$ and with $\sum_{i=1}^{k} \lambda_i$ maximized, in strongly polynomial time.*

Proof. We can find the maximum value in strongly polynomial time, as it is equal to the minimum capacity of an r-cut. To find the λ_i explicitly, we show more generally that the following problem is solvable in strongly polynomial time (where $R(B)$ denotes the set of roots of B):

(53.46) given: a digraph $D = (V, A)$, a capacity function $c : A \to \mathbb{Z}_+$, a collection $\mathcal{R}$ of nonempty subsets of V, and a demand function $d : \mathcal{R} \to \mathbb{Z}_+$,
find: a collection $\mathcal{B}$ of branchings and a function $\lambda : \mathcal{B} \to \mathbb{Z}_+$, with $\sum_{B \in \mathcal{B}} \lambda_B \chi^B \leq c$ and $\sum(\lambda_B \mid B \in \mathcal{B}, R(B) = R) = d(R)$ for each $R \in \mathcal{R}$.

For any $U \subseteq V$, define

(53.47) $$g(U) := \sum(d(R) \mid R \in \mathcal{R}, R \cap U = \emptyset).$$

By replacing each arc a by $c(a)$ parallel arcs, it follows from Edmonds' disjoint branchings theorem (Theorem 53.1) that a necessary and sufficient condition for the existence of a solution of (53.46) is that

(53.48) $$c(\delta^{\text{in}}(U)) \geq g(U)$$

for each nonempty $U \subseteq V$.

We can assume that $c(a) > 0$ for each $a \in A$ and $d(R) > 0$ for each $R \in \mathcal{R}$, and that we have an $R_1 \in \mathcal{R}$ with $R_1 \neq V$.

We may also assume that (53.46) has a solution. This implies that there exists an arc $a = (u, v) \in A$ leaving R_1 and a $\mu \geq 1$ such that resetting $d(R_1) := d(R_1) - \mu$, $d(R_1 \cup \{v\}) := d(R_1 \cup \{v\}) + \mu$, $c(a) := c(a) - \mu$, maintains feasibility of (53.46). (If $R_1 \cup \{v\}$ did not belong to $\mathcal{R}$, we add it to $\mathcal{R}$.) We apply this for the maximum possible μ. This value of μ can be calculated in strongly polynomial time, as it satisfies

(53.49) $$\mu = \min\{c(a), \min\{c(\delta^{\text{in}}(W)) - g(W) \mid a \in \delta^{\text{in}}(W), W \cap R_1 \neq \emptyset\}\}$$

(for the original c and g).

To minimize $c(\delta^{\text{in}}(W)) - g(W)$ over W with $a \in \delta^{\text{in}}(W)$ and $W \cap R_1 \neq \emptyset$, add, for each $R \in \mathcal{R}$, a new vertex v_R and, for each $v \in R$, a new arc (v_R, v) of capacity $d(R)$. Moreover, add a new vertex r, and for each $R \in \mathcal{R}$, a new arc (r, v_R) of capacity $d(R)$. Let $D' = (V', A')$ be the extended digraph. With a minimum cut algorithm we can find a subset W' of $V' \setminus \{r\}$ with $a \in \delta^{\text{in}}(W)$

and $W \cap R_1 \neq \emptyset$, minimizing the capacity of $\delta^{\mathrm{in}}_{A'}(W)$. Then $W := W' \cap V$ is a set as required.

We next apply the algorithm recursively. This describes the algorithm.

Running time. In each iteration, the number of arcs a with $c(a) > 0$ decreases or the collection $\mathcal{C} := \{U \subseteq V \mid U \neq \emptyset, c(\delta^{\mathrm{in}}(U)) = g(U)\}$ increases. As $\mathcal{C}$ is an intersecting family, the number of times $\mathcal{C}$ increases is at most $|V|^3$ (since for each $v \in V$, the collection $\mathcal{C}_v := \{U \in \mathcal{C} \mid v \in U\}$ is a lattice family, and since each lattice family $\mathcal{L}$ is determined by the preorder $\preceq$ given by: $s \preceq t \iff$ each set in $\mathcal{L}$ containing t contains s; if $\mathcal{L}$ increases, then $\preceq$ decreases, which can happen at most $|V|^2$ times.)

So the number of iterations is at most $|A| + |V|^3$. ∎

With the reductions given earlier, this implies that the capacitated versions of packing arborescences and covering by branchings also can be solved in strongly polynomial time.

Edmonds [1975] observed that matroid intersection and union theory implies:

Theorem 53.10. *Given a digraph $D = (V, A)$, $r \in V$, $k \in \mathbb{Z}_+$, and a length function $l \in \mathbb{Q}^A$, we can find k disjoint r-arborescences $B_1, \ldots, B_k$ minimizing $l(B_1) + \cdots + l(B_k)$ in strongly polynomial time.*

Proof. This follows, with Corollary 53.1c and Theorem 53.7, from Theorem 41.8 applied to the intersection of two matroids: one being the union of k times the cycle matroid of the undirected graph underlying D; the other being the matroid in which a subset B of A is independent if and only if any $v \in V \setminus \{r\}$ is entered by at most k arcs in B. ∎

This implies:

Corollary 53.10a. *Given a digraph $D = (V, A)$, $r \in V$, $k \in \mathbb{Z}_+$, and a length function $l \in \mathbb{Q}^A$, we can find a minimum-length subset B of A with $\delta^{\mathrm{in}}_B(U) \geq k$ for each nonempty $U \subseteq V \setminus \{r\}$ in strongly polynomial time.*

Proof. Directly from Theorem 53.10, with Edmonds' disjoint arborescences theorem (Corollary 53.1b). ∎

53.10. Further results and notes

53.10a. Complexity survey for disjoint arborescences

Finding k disjoint r-arborescences in an uncapacitated digraph ($*$ indicates an asymptotically best bound in the table):

	$O(k^2m^2)$	Lovász [1976c], Tarjan [1974a]
	$O(knm + k^3n^2)$	Tong and Lawler [1983]
*	$O(k^2n^2 + m)$	Gabow [1991a,1995a]

(As noticed by Tong and Lawler [1983], the paper of Shiloach [1979a] claiming an $O(k^2nm)$ bound, contains an essential error (the set A constructed on page 25 of Shiloach [1979a] need not have the desired properties: it is maximal under the condition that $y \notin A$, while it should be maximal under the condition that $A \cup V(T) \neq V$).)

The $O(k^2m^2)$ bound for finding k pairwise disjoint r-arborescences implies the $O(n^2\Delta^4 \log \Delta)$ bound of Markosyan and Gasparyan [1986] for finding a minimum number of branchings covering all arcs (where Δ is the maximum indegree of the vertices), by the construction given in the proof of Corollary 53.1h (as we can take $m \leq n\Delta$ and $k \leq 2\Delta$).

Tarjan [1974c] gave an $O(m + n \log n)$-time algorithm to find two disjoint r-arborescences (actually, to find two r-arborescences with smallest intersection). This was improved to $O(m\alpha(m,n))$ by Tarjan [1976] (where $\alpha(m,n)$ is the inverse Ackermann function), and to $O(m)$ by Gabow and Tarjan [1985].

Clearly, each of the bounds in the table above implies a complexity bound for the capacitated case, by replacing arcs by multiple arcs. However, this can increase the number m of arcs dramatically, and does not lead to a polynomial-time algorithm. Better bounds are given in the following table:

	$O(n^3 \cdot \mathrm{MF}(n,m))$	Pevzner [1979a] *taking rounding as one arithmetic step*
*	$O(k^2n^2 + m)$	Gabow [1991a,1995a]
*	$O(n^3m \log \frac{n^2}{m})$	Gabow and Manu [1995,1998]
*	$O(n^2m \log C \log \frac{n^2}{m})$	Gabow and Manu [1995,1998]

In these bounds, m is the number of arcs in the original graph, $\mathrm{MF}(n,m)$ denotes the time needed to solve a maximum flow problem in a digraph with n vertices and m arcs, and C is the maximum capacity (for integer capacity function).

The bounds of Gabow [1991a,1995a] and Gabow and Manu [1995,1998] in these tables also apply to the problem considered in Edmonds' disjoint branching theorem (Theorem 53.1): finding k disjoint branchings $B_1, \ldots, B_k$ where B_i has a given root set R_i ($i = 1, \ldots, k$), finding minimum coverings by branchings, and related problems. Gabow and Manu [1995,1998] also gave an $O(n^3m \log \frac{n^2}{m})$ fractional packing algorithm of r-arborescences.

Gabow [1991a,1995a] announced $O(kn(m+n\log n)\log n)$- and $O(k\sqrt{n \log n}(m+kn\log n)\log(nK))$-time algorithms to find a minimum-cost union of k disjoint r-arborescences (where K is the maximum cost, with integer cost function).

53.10b. Arborescences with roots in given subsets

Let $D = (V, A)$ be a digraph. Call a vector $x \in \mathbb{Z}_+^V$ a *root vector* if there exist disjoint arborescences such that for each $v \in V$, exactly x_v of these arborescences have root v. By Corollary 53.1a, root vectors are the integer solutions of the following system:

$$\text{(53.50)} \qquad \begin{array}{lll} \text{(i)} & x_v \geq 0 & \text{for } v \in V, \\ \text{(ii)} & x(U) \leq d^{\text{out}}(U) & \text{for each } U \subset V. \end{array}$$

This system generally does not define an integer polytope P, as is shown by the digraph with vertices u, v, w and arcs (u, v), (v, w), and (w, u), where $\frac{1}{2} \cdot \mathbf{1}$ is in P, but each integer vector x in P satisfies $\mathbf{1}^{\mathsf{T}} x \leq 1$.

Moreover, sets R of vertices for which there exist $|R|$ disjoint arborescences, rooted at distinct vertices in R, do not form the independent sets of a matroid, as is shown by the graph of Figure 53.1.

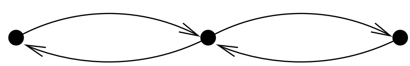

Figure 53.1

However, for any $k \in \mathbb{Z}_+$, the system

$$\text{(53.51)} \qquad x(U) \geq k - d^{\text{in}}(U) \text{ for each nonempty } U \subseteq V,$$

is box-TDI, since the right-hand side in (ii) is intersecting supermodular (cf. Sections 44.5 and 48.1).

Cai [1983] proved the following result, with a method (described below) of Frank [1981c] for proving a special case (Corollary 53.11a):

Theorem 53.11. *Let $D = (V, A)$ be a digraph such that D has k arc-disjoint arborescences. Let $l, u \in \mathbb{Z}_+^V$ with $l \leq u$. Then D has k arc-disjoint arborescences such that, for each $v \in V$, at least $l(v)$ and most $u(v)$ of these arborescences are rooted at v if and only if*

$$\text{(53.52)} \qquad u(U) + d^{\text{in}}(U) \geq k \text{ and } l(U) + \sum_{W \in \mathcal{P}} (k - d^{\text{in}}(W)) \leq k$$

for each nonempty subset U of V and each partition $\mathcal{P}$ of $V \setminus U$ into nonempty sets.

Proof. Necessity being easy, we show sufficiency. Choose $x \in \mathbb{Z}_+^V$ such that $l \leq x \leq u$ and such that (53.51) holds, with $x(V)$ as small as possible. (Such an x exists since $u(U) \geq k - d^{\text{in}}(U)$ for each nonempty subset U of V.)

We show that $x(V) = k$. Since $x(V) \geq k$ by (53.51), it suffices to show $x(V) \leq k$. Let $\mathcal{P}$ be the collection of inclusionwise maximal sets having equality in (53.51). Then $\mathcal{P}$ is a subpartition, for suppose that $U, W \in \mathcal{P}$ with $U \cap W \neq \emptyset$. Then

$$\text{(53.53)} \qquad \begin{aligned} x(U \cup W) &= x(U) + x(W) - x(U \cap W) \\ &\leq (k - d^{\text{in}}(U)) + (k - d^{\text{in}}(W)) - (k - d^{\text{in}}(U \cap W)) \\ &\leq (k - d^{\text{in}}(U \cup W)), \end{aligned}$$

and hence $U \cup W \in \mathcal{P}$. So $U = W$.

Now for each $v \in V$ with $x_v > l(v)$ there exists a set W in $\mathcal{P}$ containing v, since otherwise we could decrease x_v. Hence

$$(53.54) \qquad x(V) - l(V) = \sum_{W \in \mathcal{P}} (x(W) - l(W)) = \sum_{W \in \mathcal{P}} (k - d^{\text{in}}(W) - l(W)) \\ \leq k - l(V),$$

by (53.52).

So $x(V) = k$. Now let $r_1, \ldots, r_k$ be vertices such that each vertex v occurs x_v times among the r_i. Then by Corollary 53.1a there exist disjoint arborescences $B_1, \ldots, B_k$, where B_i has root r_i. This shows the theorem. ∎

(In this proof we did not use the box-total dual integrality of (53.51), but we applied a similar argument.)

This has as special case the following result of Frank [1981c]:

Corollary 53.11a. *Let $D = (V, A)$ be a digraph such that D has k arc-disjoint arborescences. Let $u \in \mathbb{Z}_+^V$. Then D has k arc-disjoint arborescences such that, for each $v \in V$, at most $u(v)$ of these arborescences have their root in v if and only if*

$$(53.55) \qquad u(U) + d^{\text{in}}(U) \geq k$$

for each nonempty subset U of V.

Proof. Directly from Theorem 53.11. ∎

A related theorem is:

Theorem 53.12. *Let $D = (V, A)$ be a digraph and let $R_1, \ldots, R_k$ be subsets of V. Then there exist disjoint arborescences $B_1, \ldots, B_k$, where B_i has its root in R_i (for $i = 1, \ldots, k$) if and only if*

$$(53.56) \qquad \sum_{U \in \mathcal{P}} (k - d^{\text{in}}(U)) \leq |\{i \mid R_i \cap \bigcup \mathcal{P} \neq \emptyset\}|$$

for each subpartition $\mathcal{P}$ of V with nonempty classes.

Proof. Necessity is easy, since if the B_i exist, with roots $r_i \in R_i$, then for each $U \in \mathcal{P}$ one has that $r_i \in U$ or B_i contains at least one arc entering U. That is,

$$(53.57) \qquad |\{r_i\} \cap U| + d^{\text{in}}_{B_i}(U) \geq 1.$$

Summing this inequality over $U \in \mathcal{P}$ and over $i = 1, \ldots, k$ we obtain (53.56), with R_i replaced by $\{r_i\}$. This implies (53.56) for the original R_i.

To see sufficiency, first observe that the condition implies that the R_i are nonempty (by taking $\mathcal{P} := \{V\}$). If the R_i are singletons, the theorem is equivalent to Corollary 53.1a. So we can assume that $|R_1| \geq 2$. Choose distinct vertices $u, w \in R_1$.

If the condition is maintained after replacing R_1 by $R_1 \setminus \{u\}$, the theorem follows by induction. So we can assume that this violates the condition. That is, there exists a subpartition $\mathcal{P}$ of V into nonempty classes such that (setting $X := \bigcup \mathcal{P}$):

(53.58) $$\sum_{U \in \mathcal{P}} (k - d^{\text{in}}(U)) = |\{i \mid R_i \cap X \neq \emptyset\}|$$

and such that $X \cap R_1 = \{u\}$ (for the original R_1). Similarly we can assume that there exists a subpartition $\mathcal{Q}$ of V into nonempty classes such that (setting $Y := \bigcup \mathcal{Q}$):

(53.59) $$\sum_{U \in \mathcal{Q}} (k - d^{\text{in}}(U)) = |\{i \mid R_i \cap Y \neq \emptyset\}|$$

and such that $Y \cap R_1 = \{w\}$.

Let $\mathcal{F}$ be the union of $\mathcal{P}$ and $\mathcal{Q}$ (any set occurring both in $\mathcal{P}$ and in $\mathcal{Q}$ occurs twice in $\mathcal{F}$). Now iteratively replace any $T, U \in \mathcal{F}$ with $T \cap U \neq \emptyset$ and $T \not\subseteq U \not\subseteq T$ by $T \cap U$ and $T \cup U$. Then the final family $\mathcal{F}$ is laminar. Let $\mathcal{R}$ be the collection of inclusionwise minimal sets in $\mathcal{F}$ and let $\mathcal{S}$ be the collection of inclusionwise maximal sets in $\mathcal{F}$. Then $\mathcal{R}$ and $\mathcal{S}$ are subpartitions of V into nonempty classes, and $\bigcup \mathcal{R} = X \cap Y$ and $\bigcup \mathcal{S} = X \cup Y$. Moreover

(53.60) $$\begin{aligned} &\sum_{U \in \mathcal{R}} (k - d^{\text{in}}(U)) + \sum_{U \in \mathcal{S}} (k - d^{\text{in}}(U)) = \sum_{U \in \mathcal{F}} (k - d^{\text{in}}(U)) \\ &\geq \sum_{U \in \mathcal{P}} (k - d^{\text{in}}(U)) + \sum_{U \in \mathcal{Q}} (k - d^{\text{in}}(U)) \\ &= |\{i \mid R_i \cap X \neq \emptyset\}| + |\{i \mid R_i \cap Y \neq \emptyset\}| \\ &> |\{i \mid R_i \cap (X \cap Y) \neq \emptyset\}| + |\{i \mid R_i \cap (X \cup Y) \neq \emptyset\}|. \end{aligned}$$

The first inequality follows from the submodularity of $d^{\text{in}}(U)$. The last inequality holds as (i) if R_i intersects $X \cup Y$, then it intersects X or Y, (ii) if R_i intersects $X \cap Y$, then it intersects X and Y, and (iii) R_1 intersects X and Y but not $X \cap Y$, since $R_1 \cap X = \{u\}$ and $R_1 \cap Y = \{w\}$.

However, (53.60) contradicts (53.56). ∎

53.10c. Disclaimers

The equivalence of (i) and (iii) in Corollary 53.1c suggests the following question, raised by A. Frank (cf. Schrijver [1979b], Frank [1995]; it generalizes a similar question for the undirected case, described in Section 51.5b):

(53.61) (?) Let $D = (V, A)$ be a k-arc-connected digraph and let $r \in V$. Suppose that for each $s \in V$ there exist k internally vertex-disjoint $r - s$ paths in D. Then there exist k r-arborescences such that, for any vertex s, the k $r - s$ paths determined by the respective r-arborescences are internally vertex-disjoint. (?)

For $k = 2$ this was proved by Whitty [1987]. However, for $k = 3$, a counterexample was found by Huck [1995].

Two potential generalizations of Edmonds' disjoint arborescences theorem have been raised, neither of which holds however. For vertices s, t, let $\lambda(s, t)$ denote the maximum number of arc-disjoint $s - t$ paths. It is not true that for any digraph $D = (V, A)$, $r \in V$, and $T \subseteq V \setminus \{r\}$, there exist k disjoint subsets $A_1, \ldots, A_k$ of A such that each A_i contains an $r - t$ path for each $t \in T$ if and only if $\lambda(r, t) \geq k$ for each $t \in T$ (see Figure 53.2, for $k = 2$).

N. Robertson raised the question if it is true that in any digraph $D = (V, A)$ and any $r \in V$, there exist partial r-arborescences $B_1, B_2, \ldots$ such that each vertex $v \in V \setminus \{r\}$ is in exactly $\lambda(r, v)$ of them. Lovász [1973b] showed that Figure 53.3 is a counterexample. (Related work is reported by Bang-Jensen, Frank, and Jackson [1995] and Gabow [1996].)

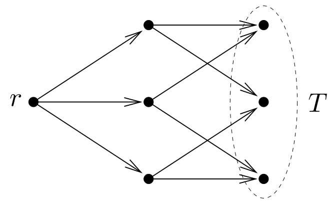

Figure 53.2

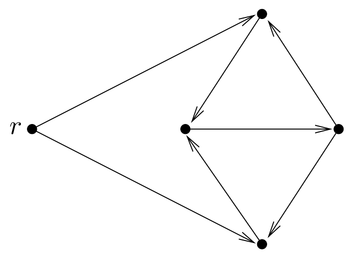

Figure 53.3

53.10d. Further notes

Frank [1981c] gave the following results for mixed graphs. Let $G = (V, E, A)$ be a mixed graph (that is, (V, E) is an undirected graph and (V, A) is a directed graph). A *mixed branching* is a subset B of $E \cup A$ such that the undirected edges in B can be oriented such that B becomes a branching. Then E can be covered by k mixed branchings if and only if

(53.62) (i) $d_A^{\text{in}}(U) + |E[U]| \leq k|U|$ for each $U \subseteq V$,
(ii) $|A[U]| + |E[U]| \leq k(|U| - 1)$ for each $\emptyset \neq U \subseteq V$.

Similarly, a *mixed r-arborescence* is a subset B of $E \cup A$ such that the undirected edges in B can be oriented such that B becomes an r-arborescence. Then for any $r \in V$, G has k disjoint mixed r-arborescences if and only if for each subpartition $\mathcal{P}$ of $V \setminus \{r\}$ with nonempty classes, the number of edges (directed or not) entering any class of $\mathcal{P}$, is at least $k|\mathcal{P}|$.

Cai [1989] characterized when, for given digraphs $D_1 = (V, A_1)$ and $D_2 = (V, A_2)$, $a, b \in \mathbb{Z}_+^V$, and $k \in \mathbb{Z}_+$, there exists an $r \in \mathbb{Z}_+^V$ with $a \leq r \leq b$ and there exist, for $i = 1, 2$, k disjoint arborescences in D_i such that for each $v \in V$, $r(v)$ of these arborescences have root v. This can be proved using polymatroid intersection theory, in particular the box-total dual integrality of

(53.63) $x(U) \geq k - d_{A_i}^{\text{in}}(U)$ for $i = 1, 2$ and nonempty $U \subseteq V$

(Theorem 48.5). (For a generalization, see Cai [1990a,1993].)

Cai [1990b] showed, for given digraph $D = (V, A)$, $r \in V$, $d, c \in \mathbb{Z}_+^A$, and $k \in \mathbb{Z}_+$: there exist k r-arborescences such that each arc is covered at least $d(a)$ times and at most $c(a)$ times, if and only if $d(\delta^{\text{in}}(v)) \leq k$, for each $v \in V \setminus \{r\}$, and

$$\sum_{v \in U} \min\{k - d(\delta^{\text{in}}(v) \setminus \delta^{\text{in}}(U)), c(\delta^{\text{in}}(v) \cap \delta^{\text{in}}(U))\} \geq k \tag{53.64}$$

for each nonempty subset U of $V \setminus \{r\}$.

Chapter 54

Biconnectors and bibranchings

The concept of biconnector is a generalization of that of a connector. Let $G = (V, E)$ be an undirected graph and let V be partitioned into classes R and S. An $R - S$ *biconnector* is a subset F of E such that each component of (V, F) intersects both R and S. So contracting R or S gives a connector. If R is a singleton, $R - S$ biconnectors are precisely the connectors.

For biconnectors, min-max relations, polyhedral characterizations, and complexity results similar to those for connectors hold.

In this chapter we also consider the forest analogue of biconnector, the biforest. An $R - S$ *biforest* is a forest F such that each component of (V, F) has at most one edge in the cut $\delta(R)$. So contracting R or S gives a forest. Also biforests show good polyhedral and algorithmical behaviour.

Similar results hold for the directed analogues of biconnectors and biforests, the bibranchings and the bifurcations. An $R - S$ *bibranching* is a set B of arcs such that for each $s \in S$, B contains an $R - s$ path and for each $r \in R$, B contains an $r - S$ path. Bibranchings form a generalization of arborescences, and give rise to similar min-max relations and polyhedral characterizations. An $R - S$ *bifurcation* is a set B of arcs containing no undirected circuit, such that each vertex in R is left by at most one arc in B, each vertex in S is entered by at most one arc in B, and B contains no arcs from S to R.

Theorem 54.11 on disjoint bibranchings will be the only result of this chapter that will be used later in this book, namely in Chapter 56 to obtain a dual form of the Lucchesi-Younger theorem, on packing directed cut covers in a source-sink connected digraph. The proof of Theorem 54.11 uses no other results from this chapter.

54.1. Shortest $R - S$ biconnectors

Let $G = (V, E)$ be a graph and let V be partitioned into two sets R and S. A subset F of E is called an $R - S$ *biconnector* if each component of the graph (V, F) intersects both R and S. So F is an $R - S$ biconnector if and only if each component of (V, F) has at least one edge in $\delta(R)$.

A min-max relation for the minimum size of an $R - S$ biconnector can be derived easily from the Kőnig-Rado edge cover theorem:

Theorem 54.1. *Let $G=(V,E)$ be a graph and let V be partitioned into sets R and S such that each component of G intersects both R and S. Then the minimum size of an $R-S$ biconnector is equal to the maximum size of a subset of V spanning no edge connecting R and S.*

Proof. To see that the minimum is not less than the maximum, let F be a minimum $R-S$ biconnector and let U attain the maximum. Then F is a forest. For each $r \in U \cap R$, let $\phi(r)$ be the first edge in any $r-S$ path in F; and for each $s \in U \cap S$ let $\phi(s)$ be the first edge in any $s-R$ path in F. Then ϕ is injective from U to F (as U spans no edge in $\delta(R)$). Hence $|U| \leq |F|$.

To see equality, let $H := (N(R) \cup N(S), \delta(R))$, where $N(R)$ and $N(S)$ are the sets of neighbours of R and of S respectively. (So $N(R) \subseteq S$ and $N(S) \subseteq R$, and H is bipartite.) Let U' be a maximum-size stable set in H. Let F' be a minimum-size edge cover in H. By the Kőnig-Rado edge cover theorem (Theorem 19.4) we know $|F'| = |U'|$. Let $U := U' \cup (V \setminus (N(R) \cup N(S)))$. Then U spans no edge connecting R and S. By adding $|V \setminus (N(R) \cup N(S))|$ edges to F' we obtain an $R-S$ biconnector F with

(54.1) $$|F| = |U'| + |V \setminus (N(R) \cup N(S))| = |U|.$$

This shows the required equality. ∎

To obtain a min-max relation for the minimum length of an $R-S$ biconnector (given a length function on the edges), consider the system

(54.2)
(i)	$0 \leq x_e \leq 1$	for each $e \in E$,
(ii)	$x(\delta(\mathcal{P})) \geq \lvert\mathcal{P}\rvert$	for each subpartition $\mathcal{P}$ of R or S with nonempty classes.

Here a *subpartition* of a set X is a partition of a subset of X (that is, a collection of disjoint subsets of X). $\delta(\mathcal{P})$ denotes the set of edges incident with but not spanned by any set in $\mathcal{P}$. Then system (54.2) determines the *$R-S$ biconnector polytope* — the convex hull of the incidence vectors of $R-S$ biconnectors:

Theorem 54.2. *System* (54.2) *is box-totally dual integral and determines the $R-S$ biconnector polytope.*

Proof. This follows from matroid intersection theory, applied to the matroids M_1 and M_2 on E, where M_1 is obtained from the cycle matroid $M(G)$ of G by contracting R to one vertex, making all edges spanned by R to a loop, and where M_2 is obtained similarly from $M(G)$ by contracting S to one vertex, making all edges spanned by S to a loop.

So the spanning sets of M_1 are the subsets F of E such that each component of (V,F) intersects R. Similarly, the spanning sets of M_2 are the subsets F of E such that each component of (V,F) intersects S. Hence the common spanning sets are precisely the $R-S$ biconnectors. Therefore, by Corollaries

41.12f and 50.8a, system (54.2) determines the convex hull of the incidence vectors of $R - S$ biconnectors. To see that the system is box-TDI, we use Corollary 41.12g and the fact that for each $F \subseteq E$, the inequality

(54.3) $$x(F) \geq r_{M_i}(E) - r_{M_i}(E \setminus F)$$

is a nonnegative integer combination of the inequalities (54.2). Indeed (for $i = 1$), if $\mathcal{P}$ denotes the collection of the components of $(V, E \setminus F)$ contained in S, then

(54.4) $$x(F) \geq x(\delta(\mathcal{P})) \geq |\mathcal{P}| \geq r_{M_1}(E) - r_{M_1}(E \setminus F),$$

as $r_{M_1}(E) \leq |S|$ and $r_{M_1}(E \setminus F) = |S| - |\mathcal{P}|$. ∎

This implies a min-max relation for the minimum length of an $R - S$ biconnector. The reduction to matroid intersection also immediately implies that one can find a shortest $R - S$ biconnector in strongly polynomial time.

54.2. Longest $R - S$ biforests

Again, let $G = (V, E)$ be a graph and let V be partitioned into two sets R and S. Call a subset F of E an $R - S$ *biforest* if F is a forest and each component of F contains at most one edge in $\delta(R)$.

A min-max relation for the maximum size of an $R - S$ biforest can be derived easily from Kőnig's matching theorem:

Theorem 54.3. *Let $G = (V, E)$ be a graph and let V be partitioned into sets R and S. Then the maximum size of an $R - S$ biforest is equal to the minimum value of $|V| - |\mathcal{U}|$, where $\mathcal{U}$ is a collection of components of $G - R$ and $G - S$ such that no edge connects any two sets in $\mathcal{U}$.*

Proof. We may assume that G has no loops. To see that the maximum is not more than the minimum, consider any $R - S$ biforest F and any collection $\mathcal{U}$ as in the theorem. Then F contains no path connecting two distinct sets in $\mathcal{U}$. Hence $|F| \leq |V| - |\mathcal{U}|$.

The reverse inequality is proved by induction on the number of edges not in $\delta(R)$.

If $E = \delta(R)$, then G is bipartite, and $R - S$ biforests coincide with matchings. Then the theorem is equivalent to Kőnig's matching theorem (Theorem 16.2).

If $E \neq \delta(R)$, choose an edge $e = uv$ in $E \setminus \delta(R)$. If we contract e, the minimum value in the theorem reduces by precisely 1. Moreover, the maximum reduces by at least 1, since any $R - S$ forest in the contracted graph gives with e an $R - S$ forest in the original graph. So we are done by induction. ∎

To obtain a min-max relation for the maximum length of an $R - S$ biforest (given a length function on the edges), consider the following system:

(54.5) (i) $0 \leq x_e \leq 1$ for each $e \in E$,
(ii) $x(E[U]) \leq |U| - 1$ for each nonempty subset U of R or S,
(iii) $x(E[U] \cup (\delta(U) \cap \delta(R))) \leq |U|$
for each subset U of R or S.

This determines the $R-S$ *biforest polytope* — the convex hull of the incidence vectors of $R-S$ biforests:

Theorem 54.4. *System* (54.5) *is box-totally dual integral and determines the* $R-S$ *biforest polytope.*

Proof. This can be reduced to matroid intersection theory, similar to the proof of Theorem 54.3. ∎

Again, this theorem implies a min-max relation for the maximum length of an $R-S$ biforest, and the reduction to matroid intersection also implies that a longest $R-S$ biforest can be found in strongly polynomial time.

54.3. Disjoint $R-S$ biconnectors

We give a min-max relation for the maximum number of disjoint $R-S$ biconnectors (Keijsper and Schrijver [1998]). It generalizes the Tutte-Nash-Williams disjoint trees theorem (Corollary 51.1a) — which theorem however is used in the proof — and the disjoint edge covers theorem for bipartite graphs (Theorem 20.5).

We follow the (algorithmic) proof method of Keijsper [1998a], based on the following lemma:

Lemma 54.5α. *Let $T_1 = (V, E_1)$ and $T_2 = (V, E_2)$ be edge-disjoint spanning trees and let $r \in V$. For each $e = rv \in \delta_{T_1}(r)$, let $\phi(e)$ be the first edge of the $v-r$ path in T_2 that leaves the component of $T_1 - e$ containing v. Let $B \subseteq \delta_{T_1}(r)$ be such that $\phi(B)$ contains at most one edge not in $\delta_{T_2}(r)$. Then $(E_1 \setminus B) \cup \phi(B)$ and $(E_2 \setminus \phi(B)) \cup B$ are spanning trees again.*

Proof. By induction on $|B|$, the case $|B| \leq 1$ being easy. Let $|B| \geq 2$. Then there exists an edge $f = rw \in B$ with $\phi(f) \in \delta_{T_2}(r)$ (by the condition given in the theorem). Define

(54.6) $T_1' := (T_1 \setminus \{f\}) \cup \{\phi(f)\}$ and $T_2' := (T_2 \setminus \{\phi(f)\}) \cup \{f\}$.

Let $B' := B \setminus \{f\}$. Then for each $e = rv \in B'$,

(54.7) $\phi(e)$ is equal to the first edge of the $v-r$ path in T_2' that leaves the component K of $T_1' - e$ containing v.

To see this, let L be the component of $T_1 - f$ containing w. Since $\phi(f)$ connects L and r, K is equal to the component of $T_1 - e$ containing v. Moreover, the

$v - r$ path P in T'_2 does not differ from the $v - r$ path in T_2 before entering L, and hence the first edge of P leaving K equals $\phi(e)$. This shows (54.7).

Now $(T_1 \setminus B) \cup \phi(B) = (T'_1 \setminus B') \cup \phi(B')$ and $(T_2 \setminus \phi(B)) \cup B = (T'_2 \setminus \phi(B')) \cup B'$, and by induction, they are spanning trees. ∎

Notice that the function $\phi : E_1 \cap \delta(r) \to E_2$ defined in the lemma is injective.

In the following lemma, we consider forests as edge sets. We recall that G/R denotes the graph obtained from G by contracting all vertices in R to one new vertex, denoted by R. The edges in the contracted graph are named after the edges in the original graph.

Lemma 54.5β. *Let $G = (V, E)$ be a graph and let V be partitioned into sets R and S. Let X_1 and X_2 be disjoint forests in G/R and let Y_1 and Y_2 be disjoint forests in G/S. Then there exist disjoint forests X'_1 and X'_2 in G/R and disjoint forests Y'_1 and Y'_2 in G/S with $X'_1 \cup X'_2 = X_1 \cup X_2$, $Y'_1 \cup Y'_2 = Y_1 \cup Y_2$, $X'_1 \cap Y'_2 = \emptyset$, and $X'_2 \cap Y'_1 = \emptyset$.*

Proof. By adding new edges spanned by S, we can assume that the X_i are spanning trees in G/R. Similarly, we can assume that the Y_i are spanning trees in G/S. (At the conclusion, we delete the new edges from the X'_i and Y'_i.)

If $X_1 \cap Y_2 = \emptyset$ and $X_2 \cap Y_1 = \emptyset$, we are done. So, by symmetry, we can assume that $X_1 \cap Y_2 \neq \emptyset$.

For each $e = rs \in X_1 \cap \delta(R)$, with $r \in R, s \in S$, let $\phi(e)$ be the first edge on the $s - R$ path in X_2 that leaves the component of $X_1 - e$ containing s. For each $e = rs \in Y_2 \cap \delta(R)$, with $r \in R, s \in S$, let $\psi(e)$ be the first edge on the $r - S$ path in Y_1 that leaves the component of $Y_2 - e$ containing r.

This gives injective functions

(54.8) $$\phi : X_1 \cap \delta(R) \to X_2 \text{ and } \psi : Y_2 \cap \delta(R) \to Y_1.$$

Observe that $X_1 \cap (Y_1 \cup Y_2) \subseteq \delta(R)$ and $Y_2 \cap (X_1 \cup X_2) \subseteq \delta(R)$. Consider the directed graph with vertex set E and arc set

(54.9) $$A := \{(e, \phi(e)) \mid e \in X_1 \cap \delta(R)\} \cup \{(e, \psi(e)) \mid e \in Y_2 \cap \delta(R)\}.$$

Choose $e_0 \in X_1 \cap Y_2$ and set $e_1 := \phi(e_0)$. Then D contains a unique directed path $e_0, e_1, \ldots, e_h$ such that $e_0, \ldots, e_{h-1} \in X_1 \cup Y_2$ and $e_h \notin X_1 \cup Y_2$. (This because each vertex in $X_1 \cap Y_2$ has outdegree 2 and indegree 0 in D, and each vertex in $(X_1 \cup Y_2) \setminus (X_1 \cap Y_2)$ has outdegree 1 and indegree at most 1.)

It follows that for each $j < h$ one has $e_{j+1} = \phi(e_j)$ if j is even and $e_{j+1} = \psi(e_j)$ if j is odd. Define

(54.10) $$B := \{e_j \mid 0 \leq j < h, j \text{ even}\} \text{ and } C := \{e_j \mid 1 \leq j < h, j \text{ odd}\}.$$

Then by Lemma 54.5α,

(54.11) $X_1' := (X_1 \setminus B) \cup \phi(B)$, $X_2' := (X_2 \setminus \phi(B)) \cup B$,
$Y_1' := (Y_1 \setminus \psi(C)) \cup C$, $Y_2' := (Y_2 \setminus C) \cup \psi(C)$,

are again spanning tree of G/R and G/S respectively. Note that $X_1' \cap X_2' = \emptyset$, $Y_1' \cap Y_2' = \emptyset$, $X_1' \cup X_2' = X_1 \cup X_2$ and $Y_1' \cup Y_2' = Y_1 \cup Y_2$.

Now $\phi(B) \cap \psi(C) = \emptyset$, $\phi(B) \cap (Y_2 \setminus C) = \emptyset$ (since $\phi(B) \cap Y_2 \subseteq C$, as $e_h \notin Y_2$), and $\psi(C) \cap (X_1 \setminus B) = \emptyset$ (since $\psi(C) \cap X_1 \subseteq B$, as $e_h \notin X_1$). So $X_1' \cap Y_2' \subseteq (X_1 \cap Y_2) \setminus \{e_0\}$ (since $e_0 \notin X_1'$).

Moreover, $B \cap C = \emptyset$, $B \cap (Y_1 \setminus \psi(C)) = \emptyset$ (since $B \cap Y_1 \subseteq \psi(C)$, as $e_0 \notin Y_1$), and $C \cap (X_2 \setminus \phi(B)) = \emptyset$ (since $C \cap X_2 \subseteq \phi(B)$, as $e_0 \notin X_2$). So $X_2' \cap Y_1' \subseteq X_2 \cap Y_1$.

Concluding, $|X_1' \cap Y_2'| + |X_2' \cap Y_1'| < |X_1 \cap Y_2| + |X_2 \cap Y_1|$. Therefore, iterating this, we obtain trees as required. ∎

Now a min-max relation for disjoint $R - S$ biconnectors can be deduced:

Theorem 54.5. *Let $G = (V, E)$ be a graph, let V be partitioned into sets R and S, and let $k \in \mathbb{Z}_+$. Then there exist k disjoint $R - S$ biconnectors if and only if $|\delta(\mathcal{P})| \geq k|\mathcal{P}|$ for each subpartition $\mathcal{P}$ of R or S with nonempty classes.*

Proof. Necessity being easy, we show sufficiency. By Corollary 51.1a, the graph G/R (obtained from G by contracting R) has k disjoint spanning trees $X_1, \ldots, X_k$. Similarly, the graph G/S has k disjoint spanning trees $Y_1, \ldots, Y_k$. Then $X_i \cap Y_j$ is a subset of $\delta(R)$, for all i, j. Choose the X_i and Y_i in such a way that

$$(54.12) \qquad \sum_{i=1}^{k} |X_i \cap Y_i|$$

is as large as possible.

Then $X_i \cap Y_j = \emptyset$ for all distinct i, j, for if, say, $X_1 \cap Y_2 \neq \emptyset$, we can replace X_1, X_2, Y_1, Y_2 by X_1', X_2', Y_1', Y_2' as in Lemma 54.5β. Then we have

$$(54.13) \qquad \begin{aligned} &|X_1' \cap Y_1'| + |X_2' \cap Y_2'| = |(X_1' \cup X_2') \cap (Y_1' \cup Y_2')| \\ &= |(X_1 \cup X_2) \cap (Y_1 \cup Y_2)| > |X_1 \cap Y_1| + |X_2 \cap Y_2|. \end{aligned}$$

This contradicts the maximality of sum (54.12).

Hence $X_1 \cup Y_1, \ldots, X_k \cup Y_k$ form k disjoint $R - S$ biconnectors as required. ∎

This proof gives a polynomial-time algorithm to find a maximum number of disjoint $R - S$ biconnectors. Keijsper [1998a] gave an $O(\mathrm{DT}(n, m) + nm)$-time algorithm for this problem, where $\mathrm{DT}(n, m)$ denotes the time needed to find a maximum number of disjoint spanning trees in an undirected graph with n vertices and m edges.

By replacing edges by parallel edges, one obtains a capacitated version of Theorem 54.5. The corresponding optimization problem can be solved in polynomial time, by a straightforward adaptation of the methods described in the proofs of Theorems 51.8 and 51.10 and Corollary 51.8a. However, the capacitated problem cannot be solved in strongly polynomial time if we do not allow rounding (cf. the argument given in Section 51.4).

A generalization of Theorem 54.5 is given by Keijsper [1998a].

54.4. Covering by $R-S$ biforests

With the foregoing two lemmas, one can also derive a min-max relation for the minimum number of $R-S$ biforests that cover all edges (Keijsper [1998b]). It generalizes the Nash-Williams' covering forests theorem (Corollary 51.1c) — which theorem however is used in the proof — and Kőnig's edge-colouring theorem for bipartite graphs (Theorem 20.1).

Theorem 54.6. *Let $G=(V,E)$ be a graph, let V be partitioned into sets R and S, and let $k \in \mathbb{Z}_+$. Then E can be covered by k $R-S$ biforests if and only if*

(54.14) $\quad |E[U]| \leq k(|U|-1)$ *and* $|E[U]| + |\delta(U) \cap \delta(R)| \leq k|U|$

for each nonempty subset U of R or S.

Proof. Necessity being easy, we show sufficiency. We can assume that G is connected, as otherwise we can consider any component of G separately.

By Corollary 51.1c, the edges of the graph G/R can be partitioned into k forests $X_1, \ldots, X_k$. Similarly, the edges of the graph G/S can be partitioned into k forests $Y_1, \ldots, Y_k$. So $X_i \cap Y_j \subseteq \delta(R)$, for all i, j. Choose the X_i and Y_i in such a way that sum (54.12) is as large as possible. Then, as in the proof of Theorem 54.5, $X_i \cap Y_j = \emptyset$ for distinct i, j. Hence each $e \in \delta(R)$ belongs to $X_i \cap Y_i$ for some $i = 1, \ldots, k$. Concluding, $X_1 \cup Y_1, \ldots, X_k \cup Y_k$ form $R-S$ biforests as required. ∎

This proof gives a polynomial-time algorithm for finding a minimum covering by $R-S$ biforests. The methods of Section 51.4 can be extended to imply the polynomial-time solvability of the corresponding capacitated version, while strong polynomial-time solvability is again impossible.

54.5. Minimum-size bibranchings

We now turn to the directed analogues of biconnectors and biforests. Let $D=(V,A)$ be a digraph and let V be partitioned into two sets R and S. Call a subset B of A an $R-S$ *bibranching* if in the graph (V,B), each vertex in S is reachable from R, and each vertex in R reaches S.

Similarly to minimum $R - S$ biconnectors, a min-max relation for the minimum size of an $R - S$ bibranching follows easily from the Kőnig-Rado edge cover theorem.

Theorem 54.7. *Let $D = (V, A)$ be a graph and let V be partitioned into sets R and S such that each vertex in R can reach S and such that each vertex in S is reachable from R. Then the minimum size of an $R - S$ bibranching is equal to the maximum size of a subset of V spanning no arc in $\delta^{\text{out}}(R)$.*

Proof. To see that the minimum is not less than the maximum, let B be a minimum-size $R - S$ bibranching and let U attain the maximum. For each $r \in U \cap R$, let $\phi(r)$ be any arc in B leaving r, and for each $s \in U \cap S$ let $\phi(s)$ be any arc in B entering s. Then ϕ is injective from U to B, and hence $|U| \leq |B|$.

To see equality, let U' be a maximum stable set in the bipartite graph H with colour classes $N^{\text{in}}(S) \subseteq R$ and $N^{\text{out}}(R) \subseteq S$, with $r \in N^{\text{in}}(S)$ and $s \in N^{\text{out}}(R)$ adjacent if and only if D has an arc from r to s. (Here $N^{\text{out}}(X)$ and $N^{\text{in}}(X)$ are the sets of outneighbours and of inneighbours of X, respectively.)

Let B' be a minimum-size edge cover in H. By the Kőnig-Rado edge cover theorem (Theorem 19.4) we know $|B'| = |U'|$. Now by adding $|V \setminus (N^{\text{out}}(R) \cup N^{\text{in}}(S))|$ arcs to B' we obtain an $R - S$ bibranching B with

(54.15) $$|B| = |U'| + |V \setminus (N^{\text{out}}(R) \cup N^{\text{in}}(S))| = |U|,$$

where $U := U' \cup (V \setminus (N^{\text{out}}(R) \cup N^{\text{in}}(S)))$. This shows the required equality. ∎

If each arc of D belongs to $\delta^{\text{out}}(R)$, then Theorem 54.7 reduces to the Kőnig-Rado edge cover theorem (Theorem 19.4).

The proof gives a polynomial-time algorithm to find a minimum-size $R-S$ bibranching (as we can find a minimum-size edge cover in a bipartite graph in polynomial time (Corollary 19.3a)).

54.6. Shortest bibranchings

To obtain a min-max relation for the minimum length of an $R-S$ bibranching (given a length function on the arcs), define a set of arcs C to be an $R - S$ *bicut* if $C = \delta^{\text{in}}(U)$ for some nonempty proper subset U of V satisfying $U \subseteq S$ or $S \subseteq U$.

Consider the system:

(54.16)
(i) $x_a \geq 0$ for each $a \in A$,
(ii) $x(C) \geq 1$ for each $R - S$ bicut C.

Then the following implies a min-max relation for the minimum length of an $R-S$ bibranching.

Theorem 54.8. *System* (54.16) *is box-TDI.*

Proof. Let $w : A \to \mathbb{R}_+$. Let $\mathcal{U}$ be the collection of nonempty proper subsets U of V satisfying $U \subseteq S$ or $S \subseteq U$. Consider the maximum value of

(54.17) $$\sum_{U \in \mathcal{U}} y_U$$

where $y : \mathcal{U} \to \mathbb{R}_+$ satisfies

(54.18) $$\sum_{U \in \mathcal{U}} y_U \chi^{\delta^{\text{in}}(U)} \leq w.$$

Choose $y : \mathcal{U} \to \mathbb{R}_+$ attaining the maximum, such that

(54.19) $$\sum_{U \in \mathcal{U}} y_U |U||V \setminus U|$$

is minimized. We show that the collection $\mathcal{F} := \{U \in \mathcal{U} \mid y_U > 0\}$ is cross-free; that is, for all $T, U \in \mathcal{F}$ one has

(54.20) $$T \subseteq U \text{ or } U \subseteq T \text{ or } T \cap U = \emptyset \text{ or } T \cup U = V.$$

Suppose that this is not true. Let $\alpha := \min\{y_T, y_U\}$. Decrease y_T and y_U by α, and increase $y_{T\cap U}$ and $y_{T\cup U}$ by α. Now (54.18) is maintained, and (54.17) did not change. However, (54.19) decreases (by Theorem 2.1), contradicting our minimality assumption.

So $\mathcal{F}$ is cross-free. Now the $\mathcal{F} \times A$ matrix M with

(54.21) $$M_{U,a} := \begin{cases} 1 & \text{if } a \in \delta^{\text{in}}(U), \\ 0 & \text{otherwise,} \end{cases}$$

is totally unimodular. To see this, let $T = (W, B)$ and $\pi : V \to W$ form a tree-representation of $\mathcal{F}$ (see Section 13.4). That is, T is a directed tree and $\mathcal{F} = \{V_b \mid b \in B\}$, where

(54.22) $V_b := \{v \in V \mid \pi(v)$ belongs to the same component of $T - b$ as the head of $b\}$.

Then for any arc $a = (u, v)$ of D, the set of forward arcs in the undirected $\pi(u) - \pi(v)$ path in T is contiguous, that is, forms a directed path, say from u' to v'. This follows from the fact that there exist no arcs b, c, d in this order on the path with b and d forward and c backward.

Define $a' := (u', v')$, and let $D' = (W, A')$ be the digraph with $A' := \{a' \mid a \in A\}$. Then M is equal to the network matrix generated by T and D' (identifying $b \in B$ with the set V_b in $\mathcal{F}$ determined by b). Hence by Theorem 13.20, M is totally unimodular.

This implies with Theorem 5.35 that (54.16) is box-TDI. ∎

This implies that the $R-S$ *bibranching polytope* — the convex hull of the incidence vectors of $R-S$ bibranchings — can be described as follows:

Corollary 54.8a. *The $R-S$ bibranching polytope is determined by*

$$\text{(54.23)} \qquad \begin{array}{lll} \text{(i)} & 0 \leq x_a \leq 1 & \text{for each } a \in A, \\ \text{(ii)} & x(C) \geq 1 & \text{for each } R-S \text{ bicut } C. \end{array}$$

Proof. By Theorem 54.8, (54.23) determines an integer polytope. Necessarily, each vertex of it is the incidence vector of an $R-S$ branching. ∎

The box-total dual integrality of (54.16) has as special case the total dual integrality of (54.23), which is equivalent to:

Corollary 54.8b (optimum bibranching theorem)**.** *Let $D = (V, A)$ be a digraph, let V be partitioned into sets R and S, and let $l : A \to \mathbb{Z}_+$ be a length function. Then the minimum length of an $R-S$ bibranching is equal to the maximum size of a family of $R-S$ dicuts, such that each arc a is in at most $l(a)$ of them.*

Proof. This is a reformulation of the total dual integrality of (54.23), which follows from Theorem 54.8. ∎

We also note that Theorem 54.8 implies that for each $k \in \mathbb{Z}_+$ the system

$$\text{(54.24)} \qquad \begin{array}{lll} \text{(i)} & x_a \geq 0 & \text{for each } a \in A, \\ \text{(ii)} & x(C) \geq k & \text{for each } R-S \text{ bicut } C, \end{array}$$

is box-TDI (since if $Ax \leq b$ is box-TDI, then for each $k > 0$, $Ax \leq k \cdot b$ is box-TDI).

Keijsper and Pendavingh [1998] gave an $O(n'(m + n \log n))$ algorithm to find a shortest bibranching, where $n' := \min\{|R|, |S|\}$. The strong polynomial-time solvability follows also from the strong polynomial-time solvability of finding a minimum-length strong connector for a source-sink connected digraph, which by the method of Theorem 57.3 can be reduced to finding a minimum-length directed cut cover, which is a special case of weighted matroid intersection (Section 55.5).

54.6a. Longest bifurcations

Let $D = (V, A)$ be a digraph and let V be partitioned into two sets R and S. Call a subset B of A an $R-S$ *bifurcation* if B contains no undirected circuits, each vertex in R is left by at most one arc in B, each vertex in S is entered by at most one arc in B, and B contains no arcs from S to R. So B is an $R-S$ bifurcation if and only if contracting R gives a branching and contracting S gives a cobranching. (A *cobranching* is a set B of arcs whose reversal B^{-1} is a branching.)

Similarly to maximum $R-S$ biforests, a min-max relation for the maximum size of an $R-S$ bifurcation follows from Kőnig's matching theorem:

Theorem 54.9. *Let $D = (V, A)$ be a graph and let V be partitioned into sets R and S, with $\delta^{\text{in}}(R) = \emptyset$. Then the maximum size of an $R - S$ bifurcation is equal to the minimum size of $|V| - |\mathcal{L}|$, where $\mathcal{L}$ is a collection of strong components K of D with either $K \subseteq R$ and $\delta^{\text{out}}(K) \subseteq \delta^{\text{out}}(R)$, or $K \subseteq S$ and $\delta^{\text{in}}(K) \subseteq \delta^{\text{in}}(S)$, such that no arc connects two components in $\mathcal{L}$.*

Proof. To see that the minimum is not less than the maximum, let B be a maximum-size $R - S$ bifurcation and let $\mathcal{L}$ attain the minimum. Let U be the set of vertices v with $v \in R$ and $\delta^{\text{out}}_B(v) = \emptyset$, or $v \in S$ and $\delta^{\text{in}}_B(v) = \emptyset$. Then

(54.25) $$|B| = |V| - |U| - |B \cap \delta^{\text{out}}(R)| \leq |V| - |\mathcal{L}|,$$

since each $K \in \mathcal{L}$ contains a vertex in U or is entered or left by an arc in $B \cap \delta^{\text{out}}(R)$.

To see equality, consider the following bipartite graph H. H has vertex set the set $\mathcal{K}$ of strong components K of D with either $K \subseteq R$ and $\delta^{\text{out}}(K) \subseteq \delta^{\text{out}}(R)$, or $K \subseteq S$ and $\delta^{\text{in}}(K) \subseteq \delta^{\text{in}}(S)$. Two sets $K, L \in \mathcal{K}$ are adjacent if and only if there is an arc connecting K and L. (This implies that one of K, L is contained in R, the other in S.) Let $\mathcal{L}$ be a maximum-size stable set in H and let B' be a maximum-size matching in H. By Kőnig's matching theorem (Theorem 16.2), $|B'| + |\mathcal{L}| = |\mathcal{K}|$. Now by adding $|V| - |\mathcal{K}|$ arcs to the arc set in D corresponding to B', we can obtain an $R - S$ bifurcation of size $|B'| + |V| - |\mathcal{K}| = |V| - |\mathcal{L}|$. ∎

If each arc of D belongs to $\delta^{\text{out}}(R)$, then Theorem 54.9 reduces to Kőnig's matching theorem (Theorem 16.2).

We next give a min-max relation for the maximum length of an $R - S$ bifurcation, by reduction to Theorem 54.8 on minimum-length bibranching:

Theorem 54.10. *Let $D = (V, A)$ be a digraph and let V be partitioned into R and S such that there are no arcs from S to R. Let $l \in \mathbb{Z}^A_+$ be a length function. Then the maximum length of an $R - S$ bifurcation is equal to the minimum value of*

(54.26) $$\sum_{v \in V} y_v + \sum_{U \in \mathcal{U}} z_U(|U| - 1)$$

where $y \in \mathbb{Z}^V_+$ and $z \in \mathbb{Z}^{\mathcal{U}}_+$, with $\mathcal{U} := \{U \mid U \neq \emptyset, U \subseteq R \text{ or } U \subseteq S\}$, such that

(54.27) $$\sum_{v \in R} y_v \chi^{\delta^{\text{out}}(v)} + \sum_{v \in S} y_v \chi^{\delta^{\text{in}}(v)} + \sum_{U \in \mathcal{U}} z_U \chi^{A[U]} \geq l.$$

Proof. To see that the maximum is not more than the minimum, let B be any $R - S$ bifurcation and let y_v, z_U satisfy (54.27). Then

(54.28) $$\begin{aligned} l(B) &= \sum_{a \in B} l(a) \leq \sum_{a \in B} \Big(\sum_{\substack{v \in R \\ a \in \delta^{\text{out}}(v)}} y_v + \sum_{\substack{v \in S \\ a \in \delta^{\text{in}}(v)}} y_v + \sum_{\substack{U \in \mathcal{U} \\ a \in A[U]}} z_U \Big) \\ &= \sum_{v \in R} y_v |B \cap \delta^{\text{out}}(v)| + \sum_{v \in S} y_v |B \cap \delta^{\text{in}}(v)| + \sum_{U \in \mathcal{U}} z_U |B \cap A[U]| \\ &\leq \sum_{v \in V} y_v + \sum_{U \in \mathcal{U}} z_U(|U| - 1). \end{aligned}$$

To see equality, extend D by two new vertices, r and s, and by arcs (r, v) for each $v \in S \cup \{s\}$ and (v, s) for each $v \in R$. This makes the digraph $D' = (V', A')$. Define $R' := R \cup \{r\}$ and $S' := S \cup \{s\}$. Let $L := \max\{l(a) \mid a \in A\} + 1$. Define $l' \in \mathbb{Z}^{A'}_+$ by:

$$l'(a) := \begin{cases} L - l(a) & \text{for each } a \in A[R] \cup A[S], \\ 2L - l(a) & \text{for each } a \in \delta^{\text{out}}(R), \\ L & \text{for each } a = (r,v) \text{ with } v \in S \text{ and } a = (v,s) \\ & \text{with } v \in R, \\ 0 & \text{for } a = (r,s). \end{cases} \tag{54.29}$$

Let $\mathcal{U}'$ be the collection of nonempty subsets U of R' or S'. By Theorem 54.8, applied to D', there exists an $R'-S'$ bibranching B' in D' and a $z : \mathcal{U}' \to \mathbb{Z}_+$ such that

$$l'(B') = \sum_{U \in \mathcal{U}'} z_U, \tag{54.30}$$

and

$$\sum_{\substack{U \in \mathcal{U}' \\ U \subseteq R'}} z_U \chi^{\delta^{\text{out}}(U)} + \sum_{\substack{U \in \mathcal{U}' \\ U \subseteq S'}} z_U \chi^{\delta^{\text{in}}(U)} \leq l'. \tag{54.31}$$

Since $l'(r,s) = 0$ we know that $z_U = 0$ if r or s belongs to U. That is, $z_U = 0$ if $U \in \mathcal{U}' \setminus \mathcal{U}$.

For each $v \in V$, define

$$y_v := L - \sum_{\substack{U \in \mathcal{U} \\ v \in U}} z_U. \tag{54.32}$$

Then $y_v \geq 0$ for each $v \in V$, as

$$y_v = L - \sum_{\substack{U \in \mathcal{U} \\ v \in U}} z_U \geq L - l'(r,v) = 0 \tag{54.33}$$

if $v \in S$, and similarly $y_v \geq 0$ if $v \in R$.

Also, y and z satisfy (54.27), since for any arc $a = (u,v)$ one has, if $u, v \in R$:

$$\begin{aligned} y_u + \sum_{\substack{U \in \mathcal{U} \\ a \in A[U]}} z_U &= L - \sum_{\substack{U \in \mathcal{U} \\ u \in U}} z_U + \sum_{\substack{U \in \mathcal{U} \\ a \in A[U]}} z_U = L - \sum_{\substack{U \in \mathcal{U} \\ a \in \delta^{\text{out}}(U)}} z_U \\ &\geq L - l'(a) = l(a). \end{aligned} \tag{54.34}$$

Similarly, if $u, v \in S$, then

$$y_v + \sum_{\substack{U \in \mathcal{U} \\ a \in A[U]}} z_U \geq l(a). \tag{54.35}$$

Finally, if $u \in R$ and $v \in S$, then:

$$\begin{aligned} y_u + y_v &= 2L - \sum_{\substack{U \in \mathcal{U} \\ u \in U}} z_U - \sum_{\substack{U \in \mathcal{U} \\ v \in U}} z_U \\ &= 2L - \sum_{\substack{U \in \mathcal{U} \\ a \in \delta^{\text{out}}(U)}} z_U - \sum_{\substack{U \in \mathcal{U} \\ a \in \delta^{\text{in}}(U)}} z_U \geq 2L - l'(a) = l(a). \end{aligned} \tag{54.36}$$

So y and z satisfy (54.27).

Note that each $u \in R$ is left by a unique arc in B', since if there is more than one, all arcs leaving u should have their heads in S' (since if (u, v), $(u', v') \in B'$, $v \neq v'$, $v \notin S'$, then $B' \setminus \{(u, v)\}$ is again an $R' - S'$ bibranching). Then replacing one outgoing arc $(u, v) \in B'$ by the arc (r, v) keeps B' an $R - S$ bibranching, however of smaller length. This contradicts our assumption. So each vertex in R is left by exactly one arc in B', and similarly, each vertex in S is entered by exactly one arc in B'. This implies that $B := B' \cap A$ is an $R - S$ bifurcation.

We finally show that equality holds throughout in (54.28). Indeed, if $a \in B$, then $a \in B'$, and hence we have equality in (54.34), implying that the first inequality in (54.28) is satisfied with equality. Moreover, if $y_v > 0$ and $v \in S$, then we have strict inequality in (54.33), and hence $(r, v) \notin B'$. Therefore $|B \cap \delta^{\text{in}}(v)| = 1$. Similarly, $y_v > 0$ and $v \in R$ implies $|B \cap \delta^{\text{out}}(v)| = 1$. Finally, if $z_U > 0$ and (say) $U \subseteq R$, then $|B' \cap \delta^{\text{out}}(U)| = 1$, and hence $|B' \cap A[U]| = |U| - 1$ (since each $v \in R$ is left by precisely one arc in B'), implying $|B \cap A[U]| = |U| - 1$. This shows that also the second inequality in (54.28) is satisfied with equality. ∎

Theorem 54.10 is equivalent to the total dual integrality of the following system:

(54.37)

(i)	$x_a \geq 0$	for each $a \in A$,
(ii)	$x(\delta^{\text{out}}(v)) \leq 1$	for each $v \in R$,
(iii)	$x(\delta^{\text{in}}(v)) \leq 1$	for each $v \in S$,
(iv)	$x(A[U]) \leq \|U\| - 1$	for each nonempty U with $U \subseteq R$ or $U \subseteq S$.

It yields a description of the $R - S$ *bifurcation polytope* — the convex hull of the incidence vectors of the $R - S$ bifurcations in D.

Corollary 54.10a. *System* (54.37) *is TDI and determines the $R - S$ bifurcation polytope.*

Proof. This is equivalent to Theorem 54.10. ∎

As for the *complexity*, the reduction given in Theorem 54.10 also implies that a maximum-length $R - S$ bifurcation can be found in strongly polynomial time (since a minimum-length $R - S$ bibranching can be found in strongly polynomial time).

54.7. Disjoint bibranchings

Consider the system

(54.38)

(i)	$0 \leq x_a \leq 1$	for each $a \in A$,
(ii)	$x(B) \geq 1$	for each $R - S$ bibranching B.

By the theory of blocking polyhedra, Corollary 54.8a implies:

Corollary 54.10b. *System* (54.38) *determines the convex hull of the incidence vectors of arc sets containing an $R - S$ bicut.*

Proof. Directly from Corollary 54.8a with the theory of blocking polyhedra. ∎

System (54.38) in fact is TDI, which is equivalent to the following statement:

Theorem 54.11 (disjoint bibranchings theorem). *Let $D = (V, A)$ be a digraph and let V be partitioned into sets R and S. Then the maximum number of disjoint $R-S$ bibranchings is equal to the minimum size of an $R-S$ bicut.*

Proof. Let k be the minimum size of an $R - S$ bicut. Clearly, there are at most k disjoint $R - S$ bibranchings. We show equality. For any digraph $D = (V, A)$ and $r \in V$, call a subset B of A an *r-coarborescence* if the set B^{-1} of reverse arcs of B is an r-arborescence.

By Edmonds' disjoint arborescences theorem (Corollary 53.1b), the graph D/R (obtained from D by contracting R to one vertex) has k disjoint R-arborescences $B_1, \ldots, B_k$. Similarly, the graph D/S has k disjoint S-coarborescences $B'_1, \ldots, B'_k$. Choose the B_i and B'_i such that the sum

(54.39) $$\sum_{i=1}^{k} \sum_{\substack{j=1 \\ j \neq i}}^{k} |B_i \cap B'_j|$$

is as small as possible. If the sum is 0, then

(54.40) $$B_1 \cup B'_1, \ldots, B_k \cup B'_k$$

are k disjoint $R - S$ bibranchings in D as required. So we can assume that the sum is positive. Without loss of generality, $B_1 \cap B'_2 \neq \emptyset$.

Define

(54.41) $$X := (B_1 \cup B_2) \cap A[S],\ X' := (B'_1 \cup B'_2) \cap A[R],$$
$$Y := (B_1 \cup B_2) \cap \delta^{\text{out}}(R),\ Y' := (B'_1 \cup B'_2) \cap \delta^{\text{out}}(R).$$

Let $\mathcal{K}$ be the collection of strong components K of the digraph (S, X) with $\delta^{\text{in}}_X(K) = \emptyset$. Similarly, let $\mathcal{K}'$ be the collection of strong components K of the digraph (R, X') with $\delta^{\text{out}}_{X'}(K) = \emptyset$.

Now $d^{\text{in}}_Y(K) = d^{\text{in}}_{B_1 \cup B_2}(K) \geq 2$ for each $K \in \mathcal{K}$, and similarly $d^{\text{out}}_{Y'}(K) \geq 2$ for each $K \in \mathcal{K}'$. Then we can split Y into Y_1 and Y_2 and Y' into Y'_1 and Y'_2 such that

(54.42) $$d^{\text{in}}_{Y_i}(K) \geq 1 \text{ for each } K \in \mathcal{K} \text{ and } i = 1, 2,$$
$$d^{\text{out}}_{Y'_i}(K) \geq 1 \text{ for each } K \in \mathcal{K}' \text{ and } i = 1, 2,$$
$$\text{and } Y_1 \cap Y'_2 = \emptyset \text{ and } Y_2 \cap Y'_1 = \emptyset.$$

This can be seen as follows. Select for each $U \in \mathcal{K}$ a pair e_U from $\delta^{\text{in}}_Y(U)$. Similarly, select for each $U \in \mathcal{K}'$ a pair e_U from $\delta^{\text{out}}_{Y'}(U)$. So the e_U for $U \in \mathcal{K}$ are disjoint, and the e_U for $U \in \mathcal{K}'$ are disjoint. Hence the e_U for $U \in \mathcal{K} \cup \mathcal{K}'$ form a bipartite graph on $Y \cup Y'$ (in fact, a set of vertex-disjoint paths and even circuits). The two colour classes of this bipartite graph give the partitions of Y and Y' as required.

Then by Lemma 53.2α, X can be split into two branchings X_1 and X_2 such that the set of roots of X_i is equal to the set of heads of Y_i ($i = 1, 2$). Similarly, X' can be split into two cobranchings X'_1 and X'_2 such that the set of coroots of X'_i is equal to the set of tails of Y'_i ($i = 1, 2$). (A *cobranching* is a set B of arcs whose reversal B^{-1} is a branching. A *coroot* of B is a root of B^{-1}.)

Define

(54.43) $\qquad \widetilde{B}_i := X_i \cup Y_i$ and $\widetilde{B}'_i := X'_i \cup Y'_i$

for $i = 1, 2$. Since $\widetilde{B}_1 \cap \widetilde{B}'_2 = \emptyset$ and $\widetilde{B}_2 \cap \widetilde{B}'_1 = \emptyset$, replacing B_1, B_2, B'_1, B'_2 by $\widetilde{B}_1, \widetilde{B}_2, \widetilde{B}'_1, \widetilde{B}'_2$ decreases sum (54.39), contradicting the minimality assumption. ∎

The capacitated case can be derived as a consequence:

Corollary 54.11a. *Let $D = (V, A)$ be a digraph, let V be partitioned into sets R and S, and let $c \in \mathbb{Z}_+^A$ be a capacity function. Then the maximum number of $R - S$ bibranchings such that no arc a is in more than $c(a)$ of these bibranchings is equal to the minimum capacity of an $R - S$ bicut.*

Proof. This follows from Theorem 54.11 by replacing any arc a by $c(a)$ parallel arcs. ∎

Equivalently, in TDI terms:

Corollary 54.11b. *System* (54.38) *is totally dual integral.*

Proof. This is a reformulation of Corollary 54.11a. ∎

Another consequence is:

(54.44) For any digraph $D = (V, A)$ and any partition of V into R and S, the $R - S$ bibranching polytope has the integer decomposition property.

As for the *complexity*, the proof of Theorem 54.11 gives a polynomial-time algorithm for finding a maximum number of disjoint $R - S$ bibranchings. For the capacitated case there is a semi-strongly polynomial-time algorithm (that is, where rounding takes one arithmetic step): first find a fractional dual solution, then round (Grötschel, Lovász, and Schrijver [1988]). A combinatorial semi-strongly polynomial-time algorithm follows from the results in Section 57.5.

54.7a. Proof using supermodular colourings

We show how to derive Theorem 54.11 on disjoint bibranchings from Edmonds' disjoint branchings theorem (Theorem 53.1) and Theorem 49.14 on supermodular colourings.

Let $D = (V, A)$ be a digraph and let V be partitioned into R and S. Let $k \in \mathbb{Z}_+$. Define $H := \delta^{\text{out}}(R)$, and define the following collections of subsets of H:

(54.45) $$\mathcal{C}_1 := \{\delta^{\text{in}}_H(U) \mid \emptyset \neq U \subseteq S\} \text{ and } \mathcal{C}_2 := \{\delta^{\text{out}}_H(U) \mid \emptyset \neq U \subseteq R\}.$$

Then $\mathcal{C}_1$ and $\mathcal{C}_2$ are intersecting families on H. Define $g_j : \mathcal{C}_j \to \mathbb{Z}$ for $j = 1, 2$ by:

(54.46) $$g_1(B) := \max\{k - d^{\text{in}}_{A[S]}(U) \mid \emptyset \neq U \subseteq S, B = \delta^{\text{in}}_H(U)\} \text{ for } B \in \mathcal{C}_1,$$
$$g_2(B) := \max\{k - d^{\text{out}}_{A[R]}(U) \mid \emptyset \neq U \subseteq R, B = \delta^{\text{out}}_H(U)\} \text{ for } B \in \mathcal{C}_2.$$

Then g_1 and g_2 are intersecting supermodular. Moreover, if U attains the maximum in (54.46), then

(54.47) $$g_1(B) = k - d^{\text{in}}_{A[S]}(U) \leq d^{\text{in}}_A(U) - d^{\text{in}}_{A[S]}(U) = d^{\text{in}}_H(U) = |B| \text{ if } U \subseteq S$$
and
$$g_2(B) = k - d^{\text{out}}_{A[R]}(U) \leq d^{\text{out}}_A(U) - d^{\text{out}}_{A[R]}(U) = d^{\text{out}}_H(U) = |B| \text{ if } U \subseteq R.$$

Since $g_j(B) \leq k$ for $j = 1, 2$ and $B \in \mathcal{C}_j$, by Theorem 49.14 we can partition H into classes $H_1, \ldots, H_k$ such that:

(54.48)
(i) if $\emptyset \neq U \subseteq S$, then U is entered by at least $k - d^{\text{in}}_{A[S]}(U)$ of the classes H_i, and
(ii) if $\emptyset \neq U \subseteq R$, then U is left by at least $k - d^{\text{out}}_{A[R]}(U)$ of the classes H_i.

By Edmonds' disjoint branchings theorem, (i) implies that $A[S]$ contains disjoint branchings $B_1, \ldots, B_k$ such that, for each $i = 1, \ldots, k$, the root set of B_i is equal to the set of heads of the arcs in H_i; that is, each vertex in S is entered by at least one arc in $B_i \cup H_i$. Similarly, $A[R]$ contains disjoint cobranchings (= branchings if all orientations are reversed) $B'_1, \ldots, B'_k$ such that, for each $i = 1, \ldots, k$, each vertex in R is left by at least one arc in $B'_i \cup H_i$. Then the $B_i \cup H_i \cup B'_i$ form disjoint $R - S$ bibranchings.

54.7b. Covering by bifurcations

Theorem 54.11 also implies the following characterization of the minimum number of $R - S$ bifurcations needed to cover all arcs (Keijsper [1998b]):

Corollary 54.11c. *Let $D = (V, A)$ be a digraph and let V be partitioned into sets R and S, with no arc from S to R. Then A can be covered by k $R - S$ bifurcations if and only if*

(54.49)
(i) $\deg^{\text{out}}(v) \leq k$ *for each* $v \in R$;
(ii) $\deg^{\text{in}}(v) \leq k$ *for each* $v \in S$;
(iii) $|A[U]| \leq k(|U| - 1)$ *for each nonempty subset U of R or S.*

Proof. Necessity being easy, we show sufficiency. Extend D by two new vertices r and s, for each $v \in S$ by $k - \deg^{\text{in}}(v)$ parallel arcs from r to v, for each $v \in R$ by $k - \deg^{\text{out}}(v)$ parallel arcs from v to s, and by k parallel arcs from r to s. Let D' be the graph arising in this way. So in D', each $v \in R$ has outdegree k, and each $v \in S$ has indegree k. Define $R' := R \cup \{r\}$ and $S' := S \cup \{s\}$.

Then by Theorem 54.11, D' has k disjoint $R' - S'$ bibranchings. Indeed, any nonempty subset U of R' is left by $k|U| - |A[U]| \geq k$ arcs of D' if $r \notin U$ (since each vertex in R has outdegree k in D'), and by at least k arcs of D' if $r \in U$. Similarly, any nonempty subset of S' is entered by at least k arcs of D'.

Now each of these bibranchings leaves any $v \in R$ exactly once (as v has outdegree k in D'), and (similarly) enters any $v \in S$ exactly once. Moreover, these bibranchings cover A. Hence restricted to A we obtain a covering of A by k $R - S$ bifurcations. ∎

An equivalent way of saying this is (using Corollary 54.10a):

(54.50) For any digraph $D = (V, A)$ and any partition of V into R and S, the $R - S$ bifurcation polytope has the integer decomposition property.

As for the *complexity*, the reduction given in the proof of Corollary 54.11c implies a polynomial-time algorithm to find a minimum number of $R - S$ bifurcations covering the arc set (by reduction to finding a maximum number of disjoint bibranchings). The capacitated version can be solved in semi-strongly polynomial time, with the help of the ellipsoid method, by first finding a fractional packing, and next round (like in Section 51.4).

54.7c. Disjoint $R - S$ biconnectors and $R - S$ bibranchings

As in Keijsper and Schrijver [1998], one can derive Theorem 54.5 on disjoint $R{-}S$ biconnectors (in an undirected graph) from Theorem 54.11 on disjoint $R{-}S$ bibranchings (in a directed graph), with the help of the Tutte-Nash-Williams disjoint trees theorem (Corollary 51.1a).

Indeed, the condition in Theorem 54.5 gives, with the Tutte-Nash-Williams disjoint trees theorem, that the graph G/R obtained from G by contracting R to one vertex, has k edge-disjoint spanning trees.

By orienting the edges in these trees appropriately, we see that G/R has an orientation such that any nonempty $U \subseteq S$ is entered by at least k arcs, and such that each edge incident with R is oriented away from R. Similarly, G/S has an orientation such that any nonempty $U \subseteq R$ is left by at least k arcs, and such that each edge incident with S is oriented towards S.

Combining the two orientations, we obtain an orientation $D = (V, A)$ of G such that each $R{-}S$ bicut has size at least k. Hence, by Theorem 54.11, D has k disjoint $R - S$ bibranchings, and hence, G has k disjoint $R - S$ biconnectors.

54.7d. Covering by $R - S$ biforests and by $R - S$ bifurcations

Similarly, one can derive Theorem 54.6 on covering $R - S$ biforests from Corollary 54.11c on covering $R - S$ bifurcations, with the help of Nash-Williams' covering forests theorem (Corollary 51.1c). Indeed, the condition in Theorem 54.6 gives, with Nash-Williams' covering forests theorem, that the edges of the graph G/R obtained from G by contracting R to one vertex, can be covered by k forests. Hence G/R has an orientation such that any vertex in S is entered by at most k arcs, and such that R is only left by arcs. Similarly, G/S has an orientation such that any vertex in R is left by at most k arcs, and such that S is only entered by arcs.

Combining the two orientations, we obtain an orientation $D = (V, A)$ of G satisfying the condition in Corollary 54.11c. Hence the arcs of D can be covered by k $R - S$ bifurcations, and hence the edges of G can be covered by k $R - S$ biforests.

Chapter 55

Minimum directed cut covers and packing directed cuts

A *directed cut* in a directed graph $D = (V, A)$ is a set of arcs $\delta^{\text{in}}(U)$ for some nonempty proper subset U of V with $\delta^{\text{out}}(U) = \emptyset$. A *directed cut cover* is a set of arcs intersecting each directed cut — equivalent, it is a set of arcs such that their contraction makes the graph strongly connected. For planar digraphs, a directed cut cover corresponds to a *feedback arc set* in the dual digraph — a set of arcs whose removal makes the digraph acyclic. Lucchesi and Younger showed that the minimum size of a directed cut cover is equal to the maximum number of disjoint directed cuts. This min-max relation is the basis for several other results on *shortest* directed cut covers, which we survey in this chapter. In the next chapter we consider the, less tractable, *disjoint* directed cut covers.

55.1. Minimum directed cut covers and packing directed cuts

Let $D = (V, A)$ be a digraph. A subset C of A is called a *directed cut* if there exists a nonempty proper subset U of V with $\delta^{\text{in}}(U) = C$ and $\delta^{\text{out}}(U) = \emptyset$. A *directed cut cover* is a set of arcs intersecting each directed cut.

It is easy to show that for any subset B of A the following are equivalent:

(55.1)
(i) B is a directed cut cover;
(ii) adding to D all arcs (u, v) with $(v, u) \in B$ makes the digraph strongly connected;
(iii) contracting all arcs in B makes the digraph strongly connected.

So a minimum directed cut cover gives a minimum number of arcs in D such that making them two-way we obtain a strongly connected digraph.

Moreover, A. Frank (cf. Lovász [1979a] p. 271) showed:

Theorem 55.1. *Let $D = (V, A)$ be a weakly connected digraph without cut arcs and let $B \subseteq A$. Then B is an inclusionwise minimal directed cut cover if and only if B is an inclusionwise minimal set such that if we invert the orientations of all arcs in B, the digraph becomes strongly connected.*

Proof. Define $\widetilde{A} := (A \setminus B) \cup B^{-1}$, where $B^{-1} := \{a^{-1} \mid a \in B\}$, and where a^{-1} is the arc arising from a by inverting its orientation.

Trivially, if $(V, \widetilde{A})$ is strongly connected, then B is a directed cut cover. Hence it suffices to show that if B is an inclusionwise minimal directed cut cover, then $\widetilde{D} = (V, \widetilde{A})$ is strongly connected.

Suppose that $\widetilde{D}$ is not strongly connected. Let K be a strong component of $\widetilde{D}$ with $\delta^{\text{in}}_{\widetilde{A}}(K) = \emptyset$. Let $\delta^{\text{in}}_{A}(K) = \{a_1, \ldots, a_t\}$. So $a_1, \ldots, a_t$ belong to B. Hence, as B is an inclusionwise minimal directed cut cover, for each $i = 1, \ldots, t$ there exists a subset U_i of V with $\delta^{\text{in}}_{A}(U_i) = \emptyset$ and $\delta^{\text{out}}_{B}(U_i) = \{a_i\}$.

Then for each i, $U_i \cap K = \emptyset$. For suppose that $U_i \cap K \neq \emptyset$. As the head of a_i does not belong to U_i, U_i splits K. Hence some arc $a \in \widetilde{A}$ enters U_i, with a spanned by K. As $\delta^{\text{in}}_{A}(U_i) = \emptyset$, we know $a \in B^{-1}$, and therefore $a^{-1} \in \delta^{\text{out}}_{B}(U_i)$ while $a \neq a_i$, a contradiction.

Also, $U_i \cap U_j = \emptyset$ for $i \neq j$, as $\delta^{\text{in}}_{A}(U_i \cap U_j) = \emptyset$ and

$$d^{\text{out}}_{B}(U_i \cap U_j) \leq d^{\text{out}}_{B}(U_i) + d^{\text{out}}_{B}(U_j) - d^{\text{out}}_{B}(U_i \cup U_j) = 0, \tag{55.2}$$

since both a_i and a_j leave $U_i \cup U_j$.

So $U_1, \ldots, U_t$ are disjoint subsets of $V \setminus K$. As D has no cut arcs, $d^{\text{out}}_{A}(U_i) \geq 2$ for each i. Hence, as no arc in A enters any U_i, and only one arc (namely a_i) leaves U_i to enter K, the set $W := V \setminus (K \cup U_1 \cup \cdots \cup U_t)$ is nonempty. Also, $\delta^{\text{out}}_{A}(W) = \emptyset$, and so $\delta^{\text{in}}_{B}(W) \neq \emptyset$, that is $\delta^{\text{out}}_{B}(K \cup U_1 \cup \cdots \cup U_t) \neq \emptyset$. However, $\delta^{\text{out}}_{B}(K) = \emptyset$ (since $\delta^{\text{in}}_{\widetilde{A}}(K) = \emptyset$) and $\delta^{\text{out}}_{B}(U_i) = \{a_i\}$, implying $\delta^{\text{out}}_{B}(K \cup U_i) = \emptyset$ for each i, a contradiction. ∎

55.2. The Lucchesi-Younger theorem

Lucchesi and Younger [1978] proved the following min-max relation for the minimum size of a directed cut cover, which was conjectured by N. Robertson and by Younger [1965,1969] (for planar graphs by Younger [1963a], inspired by a question suggested by J.P. Runyan to Seshu and Reed [1961]).

The proof below is a variant of the proof of Lovász [1976c] (cf. Lovász [1979b]).

Theorem 55.2 (Lucchesi-Younger theorem)**.** *Let $D = (V, A)$ be a weakly connected digraph. Then the minimum size of a directed cut cover is equal to the maximum number of disjoint directed cuts.*

Proof. For any digraph D, let $\nu(D)$ be the maximum number of disjoint directed cuts in D and let $\tau(D)$ be the minimum size of a directed cut cover. Choose a counterexample $D = (V, A)$ with a minimum number of arcs.

For any $B \subseteq A$, let D_B be the graph obtained from D by replacing each arc (u, v) in B by a directed $u-v$ path of length 2 (the intermediate vertex being new). Choose an inclusionwise maximal subset B of A with $\nu(D_B) = \nu(D)$. Then $B \neq A$, as $\nu(D_A) \geq 2\nu(D) > \nu(D)$.

Choose $b \in A \setminus B$. So $\nu(D_{B\cup\{b\}}) > \nu(D)$. Moreover, as D is a smallest counterexample, the graph D' obtained from D by contracting b satisfies $\nu(D') = \tau(D') \geq \tau(D) - 1 \geq \nu(D)$. Combining a maximum-size packing of directed cuts in D' and one in $D_{B\cup\{b\}}$, we obtain a family $\mathcal{F}$ of nonempty proper subsets of the vertex set V' of D_B with the property that

(55.3) $|\mathcal{F}| = 2\nu(D) + 1$, and the $\delta^{\text{in}}(U)$ for $U \in \mathcal{F}$ are directed cuts in D_B covering any arc of D_B at most twice.

Now we choose $\mathcal{F}$ satisfying (55.3) such that

(55.4) $$\sum_{U\in\mathcal{F}} |U||V' \setminus U|$$

is minimized. Then $\mathcal{F}$ is a cross-free family. Indeed, if $X, Y \in \mathcal{F}$ with $X \not\subseteq Y \not\subseteq X$, $X \cap Y \neq \emptyset$ and $X \cup Y \neq V'$, we can replace X and Y by $X \cap Y$ and $X \cup Y$, while not violating (55.3) but decreasing sum (55.4) (by Theorem 2.1), contradicting its minimality.

So $\mathcal{F}$ is cross-free. For each $X \in \mathcal{F}$, define

(55.5) $\beta(X) := \{U \in \mathcal{F} \mid U \subseteq X \text{ or } U \cap X = \emptyset\}$.

Let $\mathcal{F}_2$ be the collection of sets occurring twice in $\mathcal{F}$ and let $\mathcal{F}_1$ be the collection of sets occurring precisely once in $\mathcal{F}$. Then

(55.6) if X and Y are distinct sets in $\mathcal{F}_1$ with $|\beta(X)| \equiv |\beta(Y)| \pmod 2$, then no arc of D enters both X and Y.

Suppose that to the contrary arc a enters both X and Y. As $\mathcal{F}$ is cross-free, we can assume that $X \subset Y$.

If $|\beta(Y)| \leq |\beta(X)|$, then (as $Y \in \beta(Y) \setminus \beta(X)$) there exists a Z in $\beta(X) \setminus \beta(Y)$. So $Z \not\subseteq Y$ and $Z \cap Y \neq \emptyset$. Hence $Z \not\subseteq X$, and so $Z \cap X = \emptyset$. So $Y \not\subseteq Z$, and hence (as $\mathcal{F}$ is cross-free) $Z \cup Y = V'$. So a leaves Z, a contradiction (since no arc leaves any set in $\mathcal{F}$).

If $|\beta(Y)| \geq |\beta(X)|+2$, then there exists a $Z \neq Y$ with $Z \in \beta(Y)\setminus\beta(X)$. So $Z \not\subseteq X$ and $Z \cap X \neq \emptyset$. Hence $Z \cap Y \neq \emptyset$, and so $Z \subseteq Y$. So $Z \cup X \neq V'$, and hence (as $\mathcal{F}$ is cross-free) $X \subset Z$. So a enters X, Y, and Z, a contradiction. This proves (55.6).

It follows that for some $j \in \{0, 1\}$, the collection

(55.7) $\mathcal{F}_2 \cup \{X \in \mathcal{F}_1 \bigm| |\beta(X)| \equiv j \pmod 2\}$

has size at least $\nu(D) + 1$. By (55.6), it gives $\nu(D) + 1$ disjoint directed cuts in D_B, contradicting our assumption. ∎

Equivalent to the Lucchesi-Younger theorem is the following weighted version of it:

Corollary 55.2a. *Let $D = (V, A)$ be a digraph and let $l : A \to \mathbb{Z}_+$ be a length function. Then the minimum length of a directed cut cover is equal to* *the maximum number of directed cuts such that each arc a is in at most $l(a)$ of them.*

Proof. Replace any arc a by a path of length $l(a)$ (contracting a if $l(a) = 0$). Then the Lucchesi-Younger theorem applied to the new graph gives the present corollary. ∎

This can be formulated in terms of the total dual integrality of the following system:

$$\text{(55.8)}\qquad \begin{array}{rll} \text{(i)} & 0 \leq x_a \leq 1 & \text{for each } a \in A, \\ \text{(ii)} & x(C) \geq 1 & \text{for each directed cut } C. \end{array}$$

Define the *directed cut cover polytope* of D as the convex hull of the incidence vectors of directed cut covers. Then:

Corollary 55.2b. *System* (55.8) *is TDI and determines the directed cut cover polytope of D.*

Proof. The total dual integrality is a reformulation of Corollary 55.2a. The total dual integrality of (55.8) implies that it determines an integer polytope. Hence the second part of the corollary follows. ∎

55.3. Directed cut k-covers

In fact, system (55.8) is box-TDI, and more generally, the following system is box-TDI, as was shown by Edmonds and Giles [1977]:

$$\text{(55.9)}\qquad x(C) \geq 1 \quad \text{for each directed cut } C.$$

Edmonds and Giles' proof gives the following alternative way of proving the Lucchesi-Younger theorem.

Theorem 55.3. *System* (55.9) *is box-TDI.*

Proof. Let $\mathcal{U}$ be the collection of nonempty proper subsets U of V with $\delta^{\text{out}}(U) = \emptyset$. So $\{\delta^{\text{in}}(U) \mid U \in \mathcal{U}\}$ is the collection of all directed cuts.

Choose $w \in \mathbb{R}^A$, and let y achieve the maximum in the dual of minimizing $w^{\mathsf{T}}x$ over (55.9), that is, in:

$$\text{(55.10)}\qquad \max\{\sum_{U\in\mathcal{U}} y_U \mid y \in \mathbb{R}^{\mathcal{U}}_+, \sum_{U\in\mathcal{U}} y_U \chi^{\delta^{\text{in}}(U)} = w\},$$

such that

$$\text{(55.11)}\qquad \sum_{U\in\mathcal{U}} y_U |U||V \setminus U|$$

is as small as possible. Let $\mathcal{F} := \{U \in \mathcal{U} \mid y_U > 0\}$. Then $\mathcal{F}$ is cross-free. Suppose to the contrary that $T, U \in \mathcal{F}$ with $T \not\subseteq U \not\subseteq T$, $T \cap U \neq \emptyset$, $T \cup U \neq V$. Let $\alpha := \min\{y_T, y_U\} > 0$. Then decreasing y_T and y_U by α, and increasing $y_{T\cap U}$ and $y_{T\cup U}$ by α, maintains feasibility of y, while its value is not changed; so it remains an optimum solution. However, sum (55.11) decreases (by Theorem 2.1). This contradicts the minimality of (55.11).

So $\mathcal{F}$ is cross-free, and hence the constraints corresponding to $\mathcal{F}$ form a totally unimodular matrix (Corollary 13.21a). Hence, by Theorem 5.35, system (55.9) is box-TDI. ∎

This implies the box-total dual integrality of (for $k \geq 0$):

(55.12) $\quad x(C) \geq k \quad$ for each directed cut C.

Corollary 55.3a. *For each $k \in \mathbb{R}_+$, system* (55.12) *is box-TDI.*

Proof. Directly from Theorem 55.3, since if a system $Ax \leq b$ is box-TDI, then also $Ax \leq k \cdot b$ is box-TDI. ∎

This has the following consequences. Call a subset C of the arc set A of a digraph $D = (V, A)$ a *directed cut k-cover* if C intersects each directed cut in at least k arcs. Consider the system:

(55.13) $\quad 0 \leq x_a \leq 1 \quad$ for $a \in A$,
$\quad x(C) \geq k \quad$ for each directed cut C.

Then:

Corollary 55.3b. *System* (55.13) *is TDI and determines the convex hull of the incidence vectors of the directed cut k-covers.*

Proof. Directly from Corollary 55.3a. ∎

From this, a min-max relation for the minimum size of a directed cut k-cover can be derived:

Corollary 55.3c. *Let $D = (V, A)$ be a digraph and let $k \in \mathbb{Z}_+$, such that each directed cut has size at least k. Then the minimum size of a directed cut k-cover is equal to the maximum value of*

(55.14) $$\left|\bigcup \mathcal{C}\right| + k|\mathcal{C}| - \sum_{C \in \mathcal{C}} |C|$$

taken over all collections $\mathcal{C}$ of directed cuts.

Proof. By Corollary 55.3b, the minimum size of a directed cut k-cover is equal to the minimum value of $\mathbf{1}^{\mathsf{T}} x$ over (55.13). Hence, as (55.12) is TDI, the minimum size of a directed cut k-cover is equal to the maximum value of

(55.15) $$k \sum_{C} y_C - z(A),$$

where $y_C \in \mathbb{Z}_+$ for each directed cut C and where $z \in \mathbb{Z}_+^A$ such that

(55.16) $$\sum_{C} y_C \chi^C - z \leq \mathbf{1}.$$

Now we can assume that $y_C \in \{0, 1\}$ for each C, since if $y_C \geq 2$, then $z_a \geq 1$ for each $a \in C$ (by (55.16)). Hence decreasing y_C by 1 and decreasing z_a by 1 for each $a \in C$, maintains (55.16) while (55.15) is not decreased (as $|C| \geq k$ by assumption).

Let $\mathcal{C} := \{C \mid y_C = 1\}$. As $z(A)$ is minimized, we have

(55.17) $$z = \sum_{C \in \mathcal{C}} \chi^C - \chi^{\bigcup \mathcal{C}},$$

and hence that $z(A)$ is equal to $\sum_{C \in \mathcal{C}} |C| - \left|\bigcup \mathcal{C}\right|$. This proves the corollary. ∎

55.4. Feedback arc sets

The Lucchesi-Younger theorem implies a min-max relation for the minimum size of a feedback arc set in a planar digraph. A *feedback arc set* in a digraph $D = (V, A)$ is a set of arcs intersecting every directed circuit.

In fact, if D has no loops, then a set A' is an inclusionwise minimal feedback arc set if and only if A' is an inclusionwise minimal set of arcs such that inverting all arcs in A' makes the digraph acyclic (Grinberg and Dambit [1966], Gallai [1968a]).

E.L. Lawler and R.M. Karp (see Karp [1972b]) showed that finding a minimum-size feedback arc set in a digraph, is NP-complete. For planar digraphs one has however:

Theorem 55.4. *Let $D = (V, A)$ be a planar digraph. Then the minimum size of a feedback arc set is equal to the maximum number of arc-disjoint directed circuits.*

Proof. Consider the dual digraph D^* of D. Then a set of arcs of D forms a directed circuit if and only if the set of dual arcs forms a directed cut in D^*. Hence the corollary follows immediately from the Lucchesi-Younger theorem (Theorem 55.2). ∎

Notes. Figure 55.1 (from Younger [1965]) shows that we cannot drop the planarity condition. This is a counterexample with a smallest number of vertices, since Barahona, Fonlupt, and Mahjoub [1994] showed that in a digraph with no $K_{3,3}$ minor, the minimum size of a feedback arc set is equal to the maximum number of disjoint

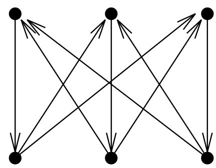

Figure 55.1
The minimum size of a feedback arc set equals 2, while there are no two disjoint directed cuts.

directed circuits. The proof is based on a theorem of Wagner [1937b] on decomposing graphs without $K_{3,3}$ minor into planar graphs and copies of K_5. (Nutov and Penn [1995] gave a similar proof. Related work is done is reported in Nutov and Penn [2000].)

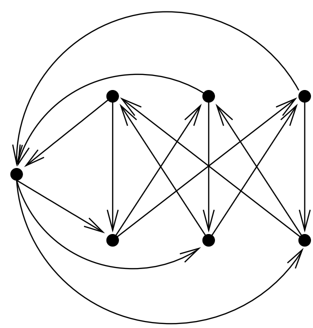

Figure 55.2
An Eulerian digraph where the minimum size of a feedback arc set equals 5, while there are no 5 disjoint directed cuts.

Moreover, Borobia, Nutov, and Penn [1996] showed that in an Eulerian digraph with at most 6 vertices, the minimum size of a feedback arc set is equal to the maximum value of a *fractional* packing of directed circuits. This is not the case if there are more than 6 vertices, as is shown by the graph in Figure 55.2.

Guenin and Thomas [2001] characterized the digraphs D that have the property that for every subhypergraph D' of D, the maximum number of disjoint circuits in D' is equal to the minimum size of a feedback arc set in D'.

More on the polytope determined by the feedback arc sets, equivalently on the *acyclic subgraph polytope* (the convex hull of the incidence vectors of arc sets containing no directed circuit) is presented in Young [1978], Grötschel, Jünger, and Reinelt [1984,1985a,1985b], Reinelt [1993], Leung and Lee [1994], Goemans and Hall [1996], and Bolotashvili, Kovalev, and Girlich [1999]. (Bowman [1972] wrongly claimed to give a system determining the acyclic subgraph polytope.)

The problem of finding a minimum-weight feedback arc set is equivalent to the *linear ordering problem*: given a matrix M, find a permutation matrix P such that the sum of the elements below the main diagonal of $P^{\mathsf{T}}MP$ is minimized. More on this can be found in Younger [1963b], Jünger [1985], Reinelt [1985], Berger and Shor [1990,1997], Arora, Frieze, and Kaplan [1996,2002], Fernandez de la Vega [1996], Frieze and Kannan [1996,1999], and Newman and Vempala [2001].

For feedback arc sets in linklessly embeddable graphs, see Section 55.6b. For feedback vertex sets, see Section 55.6c.

55.5. Complexity

It was shown by Lucchesi [1976], Karzanov [1979c,1981], and Frank [1981b] that a minimum-size directed cut cover and a maximum packing of directed cuts can be found in polynomial time. Lucchesi [1976] also gave a weakly polynomial-time algorithm for the weighted versions of these problems, and Frank [1981b] gave a strongly polynomial-time algorithm for these problems.

Frank and Tardos [1984b] showed that finding a minimum-length directed cut k-cover in fact can be reduced to a weighted matroid intersection problem. Thus all ingredients for a strongly polynomial-time algorithm are ready at hand.

We describe the reduction. Let $D = (V, A)$ be a digraph, let $l : A \to \mathbb{Q}_+$ be a length function, and let $k \in \mathbb{Z}_+$. We want to find a directed cut k-cover of minimum length.

Let $D^{-1} = (V, A^{-1})$ be the reverse digraph of D, where $A^{-1} := \{a^{-1} \mid a \in A\}$ and $a^{-1} = (v, u)$ if $a = (u, v)$. We will define matroids M_1 and M_2 on $A \cup A^{-1}$.

M_1 is easy: it is the partition matroid induced by the sets $\{a, a^{-1}\}$ for $a \in A$. To define M_2, let $\mathcal{U}$ be the collection of nonempty proper subsets U of V with $\delta^{\text{in}}_A(U) = \emptyset$. Define

(55.18) $P := \{x \in \mathbb{Z}^V_+ \mid x(V) = |A| \text{ and } x(U) \geq |A[U]| + k \text{ for each } U \in \mathcal{U}\}$.

Then:

(55.19) for $x, y \in P$ and $u \in V$ with $x_u < y_u$, there exists a $v \in V$ with $x_v > y_v$ and $x + \chi^u - \chi^v \in P$.

Indeed, let $\mathcal{K}$ be the collection of inclusionwise maximal subsets U of $V \setminus \{u\}$ with $U \in \mathcal{U}$ and $x(U) = |A[U]| + k$. As sets with this property are closed under unions of intersecting sets, $\mathcal{K}$ consists of disjoint sets, and no two of them are connected by an arc. Hence for $W := V \setminus \bigcup \mathcal{K}$, we have

(55.20) $$y(W) = y(V) - \sum_{U \in \mathcal{K}} y(U) \leq |A| - \sum_{U \in \mathcal{K}} (|A[U]| + k) = x(W).$$

As $x_u < y_u$ and $u \in W$, we know that $x_v > y_v$ for some $v \in W$. Also, $x + \chi^u - \chi^v \in P$, since there is no subset U of $V \setminus \{u\}$ with $\delta^{\text{in}}(U) = \emptyset$, $x(U) = |A[U]| + k$, and $v \in U$.

This shows (55.19), which implies that

(55.21) $\mathcal{B} := \{B \subseteq A \cup A^{-1} \mid \deg_B^{\text{in}} \in P\}$

forms the collection of bases of a matroid M_2 on $A \cup A^{-1}$, provided that $\mathcal{B}$ is nonempty; equivalently, provided that each directed cut in D has size at least k. (That M_2 is a matroid can also be derived from Corollary 49.7a.)

To test independence in M_2, it suffices to have one base of M_2 (which we have: A^{-1}), and to have a test of being a base. Equivalently, we should be able to test membership of P. Let $x \in \mathbb{Z}_+^V$ with $x(V) = |A|$. By Theorem 51.3, we can find a nonempty proper subset U of V minimizing

(55.22) $$x(U) - |A[U]| + (k + |A|)d^{\text{in}}(U)$$
$$= x(U) - \sum_{v \in U} \deg^{\text{out}}(v) + d^{\text{out}}(U) + (k + |A|)d^{\text{in}}(U),$$

in strongly polynomial time. If this minimum is at least k, then x belongs to P. If this minimum is less than k, then $d^{\text{in}}(U) = 0$, and hence $x(U) < |A[U]| + k$, implying that x does not belong to P.

Now a subset C of A is a directed cut k-cover if and only if $B := (A \setminus C) \cup C^{-1}$ is a common base of M_1 and M_2. Hence:

Theorem 55.5. *Given a digraph $D = (V, A)$, a length function $l : A \to \mathbb{Q}_+$, and $k \in \mathbb{Z}_+$, a minimum-length directed cut k-cover can be found in strongly polynomial time.*

Proof. Directly from the above, with Theorem 41.8. We apply the weighted matroid intersection algorithm to find a maximum-length common base B in the matroids M_1 and M_2 on $A \cup A^{-1}$, defining $l(a^{-1}) := 0$ for $a \in A$. Then $A \setminus B$ is a minimum-length directed cut cover. ∎

55.5a. Finding a dual solution

Also a maximum packing of directed cuts can be found in polynomial time. Let B be the maximum-length base found and let C be the directed cut k-cover with $B = (A \setminus C) \cup C^{-1}$.

The weighted matroid intersection algorithm also yields a dual solution. Indeed, if l is integer-valued, it gives length functions $l_1, l_2 : A \cup A^{-1} \to \mathbb{Z}$ such that $l = l_1 + l_2$ and such that B is an l_i-maximal base of M_i, for $i = 1, 2$ (cf. Section 41.3a).

Define

(55.23) $\mathcal{F} := \{U \subseteq V \mid d_A^{\text{in}}(U) = 0, d_C^{\text{out}}(U) = k\}$,

and define a pre-order $\preceq$ on V by:

(55.24) $u \preceq v \iff$ each $U \in \mathcal{F}$ containing u also contains v, for $u, v \in V$. It can be checked in polynomial time whether $u \preceq v$ holds, since it is equivalent to: $\deg_B^{\text{in}} - \chi^u + \chi^v \in P$. Indeed, $\deg_B^{\text{in}} - \chi^u + \chi^v$ belongs to P if and only if $v \in U$ for each $U \in \mathcal{U}$ satisfying $u \in U$ and $\sum_{s \in U} \deg_B^{\text{in}}(s) = |A[U]| + k$. Now $\sum_{s \in U} \deg_B^{\text{in}}(s) = |A[U]| + d_C^{\text{out}}(U)$. So it is equivalent to: $u \preceq v$.

Next define for each $u \in V$:

(55.25) $$p(u) := \max\{l_2(a) \mid \exists v \succeq u : a^{-1} \in \delta_B^{\text{out}}(v)\}.$$

Let $h_0 < \cdots < h_t$ be the elements of the set $\{p(u) \mid u \in V\}$. For $j = 1, \ldots, t$, define $V_j := \{u \mid p(u) \geq h_j\}$. Let $\mathcal{K}$ be the collection of all weak components of $D - V_j$, over all $j = 1, \ldots, t$, and for each $K \in \mathcal{K}$, let

(55.26) $$y_K := \sum(h_j - h_{j-1} \mid j = 1, \ldots, t;\ K \text{ is a weak component of } D - V_j).$$

So

(55.27) $$P = h_0 \chi^V + \sum_{K \in \mathcal{K}} y_K \chi^K.$$

Then:

Theorem 55.6. *Each $K \in \mathcal{K}$ belongs to $\mathcal{F}$. Moreover, for each $a = (u, v) \in A$:*

(55.28) $$\begin{array}{lll} \text{(i)} & \sum(y_K \mid K \in \mathcal{K}, a \in \delta^{\text{out}}(K)) \leq l(a) & \text{if } a \in A \setminus C, \\ \text{(ii)} & \sum(y_K \mid K \in \mathcal{K}, a \in \delta^{\text{out}}(K)) \geq l(a) & \text{if } a \in C. \end{array}$$

Proof. Consider any $j = 1, \ldots, t$. By definition of $p(u)$, we know that V_j is a lower ideal with respect to $\preceq$. That is, if $v \in V_j$ and $u \preceq v$, then $u \in V_j$. (Indeed, if $v \in V_j$, then $p(v) \geq h_j$, hence $l_2(a) \geq h_j$ for some a with $a^{-1} \in \delta_B^{\text{out}}(w)$ for some $w \succeq v$. Since $w \succeq u$ we have $p(u) \geq l_2(a) \geq h_j$.)

Hence, for each $v \in V_j$ and $u \notin V_j$ we have $u \not\preceq v$. Therefore, there is a $U \in \mathcal{F}$ with $u \in U$ and $v \notin U$. This implies, as $\mathcal{F}$ is a crossing family, that there is a partition of $V \setminus V_j$ into sets in $\mathcal{F}$. As $d_A^{\text{in}}(U) = 0$ and $d_C^{\text{out}}(U) = k$, it follows that this partition is equal to the collection of weak components of the digraph $D - V_j$. So each weak component K of $D - V_j$ satisfies $d_A^{\text{in}}(K) = 0$ and $d_C^{\text{out}}(K) = k$; that is, K belongs to $\mathcal{F}$.

Consider any arc $a = (v, u) \in B$. As B is an l_1-maximal base of M_1, we have $l_1(a^{-1}) \leq l_1(a)$. Let $p(u) = l_2(b)$ for some $b^{-1} \in \delta_B^{\text{out}}(w)$ and some $w \succeq u$. Since $u \preceq w$, we know that $\deg_B^{\text{in}} - \chi^u + \chi^w \in P$. So $(B \cup \{b\}) \setminus \{a\}$ is again a base of M_2. Hence we have (as B is an l_2-maximal base of M_2) $l_2(b) \leq l_2(a)$. So $l_2(a) \geq l_2(b) \geq p(u)$. Also $p(v) \geq l_2(a^{-1})$, by definition of $p(v)$. Hence

(55.29) $$\begin{aligned} l(a) - l(a^{-1}) &= l_1(a) + l_2(a) - l_1(a^{-1}) - l_2(a^{-1}) \geq l_2(a) - l_2(a^{-1}) \\ &\geq p(u) - p(v). \end{aligned}$$

If $a \in A \setminus C$, we have $l(a^{-1}) = 0$, and obtain (55.28)(i), since a enters no $K \in \mathcal{K}$ and so $p(u) \geq p(v)$. Hence

(55.30) $$l(a) \geq p(u) - p(v) = \sum(y_K \mid K \in \mathcal{K}, a \in \delta^{\text{out}}(K)).$$

If $a \in C^{-1}$, we have $l(a) = 0$ and obtain (55.28)(ii), since a^{-1} enters no $K \in \mathcal{K}$, and so $p(u) \leq p(v)$. Hence

(55.31) $$l(a^{-1}) \leq p(v) - p(u) = \sum(y_K \mid K \in \mathcal{K}, a^{-1} \in \delta^{\text{out}}(K)).$$ ∎

For each $a \in C$, let $s(a)$ be the difference of the two terms in (55.28)(ii), and for $a \in A \setminus C$ let $s(a) := 0$. Then

(55.32) $$\sum_{K \in \mathcal{K}} y_K \chi^{\delta_A^{\text{out}}(K)} - s \leq l$$

and

(55.33) $$\begin{aligned} k \sum_{K \in \mathcal{K}} y_K - s(A) &= \sum_{K \in \mathcal{K}} y_K |\delta_A^{\text{out}}(K) \cap C| - s(A) \\ &= \sum_{a \in C} \sum (y_K \mid K \in \mathcal{K}, a \in \delta^{\text{out}}(K)) - s(A) = l(C). \end{aligned}$$

Thus we have an integer optimum dual solution to maximizing $l^{\mathsf{T}} x$ over the system $\mathbf{0} \leq x \leq \mathbf{1}$, $x(Y) \geq k$ (Y directed cut). If $k = 1$, we can do with $s = \mathbf{0}$, and obtain an integer optimum packing of directed cuts subject to l.

So we have:

Theorem 55.7. *Given a digraph $D = (V, A)$ and a length function $l : A \to \mathbb{Z}_+$, an optimum packing of directed cuts subject to l can be found in strongly polynomial time.*

Proof. See above. ∎

55.6. Further results and notes

55.6a. Complexity survey for minimum-size directed cut cover

	$O(n^5 \log n)$	Lucchesi [1976]
	$O(n^3 m)$	Frank [1981b]
	$O(n^2 M(n))$	Frank [1981b]
*	$O(n^2 m)$	Gabow [1993b,1995c]
*	$O(nM(n))$	Gabow [1993b,1995c]

As before, $*$ indicates an asymptotically best bound in the table. $M(n)$ denotes the time to multiply $n \times n$ matrices. Also Karzanov [1979c,1981] gave a polynomial-time algorithm to find a minimum-size directed cut cover. Lucchesi [1976] gave also a polynomial-time algorithm to find a minimum-weight directed cut cover, and Frank [1981b] and Gabow [1993a,1993b,1995c] gave strongly polynomial-time algorithms for this.

55.6b. Feedback arc sets in linklessly embeddable digraphs

An undirected graph is called *linklessly embeddable* if it can be embedded in $\mathbb{R}^3$ such that any two vertex-disjoint circuits C_1 and C_2 are unlinked (that is, there is a topological sphere S such that C_1 is in the interior of S and C_2 is in the exterior of S). A digraph is called linklessly embeddable if its underlying undirected graph is linklessly embeddable. (Linklessly embeddable graphs are characterized by Robertson, Seymour, and Thomas [1995] in terms of 'forbidden minors'.)

Seymour [1996] showed that in an Eulerian linklessly embeddable directed graph, the minimum-size of a feedback arc set is equal to the maximum number of arc-disjoint directed circuits. We sketch the proof.

The basic combinatorial-topological part of the proof consists of showing:

Theorem 55.8. *Let D be an Eulerian linklessly embeddable digraph. Suppose that there exist $2k+1$ directed circuits such that any arc is in at most two of them. Then there exist $k+1$ arc-disjoint directed circuits.*

Sketch of proof. By a theorem of Robertson, Seymour, and Thomas [1995], D can be embedded in $\mathbb{R}^3$ such that for each undirected circuit C in D there exists an open disk B in $\mathbb{R}^3$ with boundary C and disjoint from D. (We identify D with its embedding.)

Let $C_1, \ldots, C_t$ be a maximum number of directed circuits in D such that any arc of D is in at most two of them. So $t \geq 2k+1$. Moreover, each arc of D is contained in *exactly* two of the C_i. Otherwise, the arcs not covered twice contain a directed circuit (as D is Eulerian). This contradicts the maximality of t.

For each $i = 1, \ldots, t$, let B_i by an open disk with boundary C_i and disjoint from D. We can assume that the B_i are pairwise disjoint, as can be seen as follows. First, we can assume that the B_i are tame and in general position. In particular, no point is in four of the B_i. Any point p in three of the B_i is the intersection point of three of the B_i, pairwise crossing at p. Any point p in two of the B_i is the intersection point of two of the B_i, crossing at p. Moreover, any two distinct B_i and B_j intersect each other in a finite number of closed and open curves, each representing crossings of B_i and B_j. Let $c(B_i, B_j)$ denote the number of such components.

We choose the C_i and B_i such that the sum of the $c(B_i, B_j)$ for $i \neq j$ is minimized.

Now it is elementary combinatorial topology to prove that there exist for any distinct i, j, with $B_i \cap B_j \neq \emptyset$, directed circuits C'_i and C'_j in D with

(55.34) $$\chi^{AC'_i} + \chi^{AC'_j} = \chi^{AC_i} + \chi^{AC_j}$$

and open disks B'_i and B'_j with boundaries C'_i and C'_j respectively, such that $B'_i \cap B'_j = \emptyset$ and $c(B'_i, B_h) + c(B'_j, B_h) \leq c(B_i, B_h) + c(B_j, B_h)$ for all $h \neq i, j$.

Hence, by the minimality of the sum of the $c(B_i, B_j)$, it follows that the B_i are disjoint. So D, together with the B_i forms the union of a number of compact surfaces, certain points of which are identified. As these surfaces are orientable (since they are embedded in $\mathbb{R}^3$), the B_i fall apart into two classes: those with boundary oriented clockwise, and those with boundary oriented counter-clockwise. Each of these classes have arc-disjoint boundaries, and at least one of these classes has size at least $k+1$. This proves the theorem. ∎

Seymour [1996] next continues by deriving (for linklessly embeddable graphs) the total dual integrality of the following system in $x \in \mathbb{R}^A$:

(55.35) $x(C) \geq 1$ for each directed circuit C in D.

Note that nonnegativity of x is not required here.

Corollary 55.8a. *For any linklessly embeddable digraph $D = (V, A)$, system* (55.35) *is totally dual integral.*

Proof. Let $w \in \mathbb{Z}^A$ be such that the minimum of $w^{\mathsf{T}} x$ over (55.35) is finite. Let $\mathcal{C}$ be the collection of directed circuits in D. By Theorem 5.29, it suffices to show that the maximum value μ of $\sum_{C\in\mathcal{C}} y(C)$ taken over $y : \mathcal{C} \to \frac{1}{2}\mathbb{Z}_+$ satisfying

$$(55.36) \qquad \sum_{C\in\mathcal{C}} y_C \chi^{AC} \leq w$$

is attained by an integer-valued y.

Now (as the minimum is finite) w belongs to the cone generated by the incidence vectors of directed circuits, and hence w is a nonnegative circulation. Replace any arc $a = (u, v)$ by $w(a)$ parallel arcs from u to v, giving the Eulerian digraph $D' = (V, A')$. Then μ is equal to half of the maximum number μ' of directed circuits in D' such that any arc of D' is in at most two of these circuits. By Theorem 55.8, D' contains at least $\lceil \frac{1}{2}\mu' \rceil$ arc-disjoint directed circuits. Since $\lceil \frac{1}{2}\mu' \rceil \geq \mu$, this gives in D an integer vector $y : \mathcal{C} \to \mathbb{Z}_+$ as required. ∎

This finally gives:

Theorem 55.9. *The minimum size of a feedback arc set in an Eulerian linklessly embeddable digraph $D = (V, A)$ is equal to the maximum number of arc-disjoint directed circuits.*

Proof. Consider the LP-duality relation for maximizing $x(U)$ over (55.35):

$$(55.37) \qquad \begin{aligned} &\min\{x(A) \mid x(C) \geq 1 \text{ for each directed circuit } C\} \\ &= \max\{\sum_C y_C \mid y_C \geq 0, \sum_C y_C \chi^{AC} = \mathbf{1}\}, \end{aligned}$$

where C ranges over all directed circuits. By Corollary 55.8a and the theory of total dual integrality (Theorem 5.22), both optima have an integer optimum solution. So the maximum is equal to the maximum number of arc-disjoint directed circuits. Let x attain the minimum. By Theorem 8.2, there exists a ('potential') $p : V \to \mathbb{Z}$ with $x_a \geq p(v) - p(u)$ for each arc $a = (u, v)$ of D. Define $x'(a) := x_a - p(v) + p(u)$ for each arc $a = (u, v)$. Then $x' \in \mathbb{Z}_+^A$, $x'(C) = x(C) \geq 1$ for each directed circuit C, and $x'(A) = x(A)$ (since D is Eulerian). Hence the set of arcs a with $x'(a) \geq 1$ forms a feedback arc set of size at most $x(A)$, proving the theorem. ∎

System (55.35) can be tested in polynomial time, for any digraph (with the Bellman-Ford method). It implies that in an Eulerian linklessly embeddable digraph, a minimum-size feedback arc set can be found in polynomial time (with the ellipsoid method).

55.6c. Feedback vertex sets

A *feedback vertex set* in a digraph $D = (V, A)$ is a subset U of V with $D - U$ acyclic — that is, U intersects every directed circuit. Reed, Robertson, Seymour, and Thomas [1996] proved:

(55.38) for each integer $k \geq 0$ there exists an integer $n_k \geq 0$ such that each digraph $D = (V, A)$ having no k vertex-disjoint directed circuits, has a feedback vertex set of size at most n_k.

(For $k = 2$ this answers a question of Gallai [1968b] and Younger [1973].)

Reed, Robertson, Seymour, and Thomas also showed that for each fixed integer k, there is a polynomial-time algorithm to find k vertex-disjoint directed circuits in a digraph if they exist.

Earlier, progress on (55.38) was made by McCuaig [1993], who proved it for $k = 2$, where $n_2 = 3$, by Seymour [1995b], who proved a fractional version of it (if there is no fractional packing of k directed circuits, then there is a feedback vertex set of size at most n_k), and by Reed and Shepherd [1996] for planar graphs.

According to Reed, Robertson, Seymour, and Thomas [1996], N. Alon proved that n_k is at least $Ck \log k$ for some constant C.

Cai, Deng, and Zang [1999,2002] characterized for which orientations $D = (V, A)$ of a complete bipartite graph the system

(55.39)
$$\begin{array}{ll} x_v \geq 0 & \text{for } v \in V, \\ x(VC) \geq 1 & \text{for each directed circuit } C, \end{array}$$

is totally dual integral. (Related results can be found in Cai, Deng, and Zang [1998].)

Guenin [2001b] gave a characterization of digraphs $D = (V, A)$ for which the linear system in $\mathbb{R}^{V \cup A}$ for feedback arc and vertex sets:

(55.40)
$$\begin{array}{ll} x_v \geq 0 & \text{for } v \in V, \\ x_a \geq 0 & \text{for } a \in A, \\ x(VC) + x(AC) \geq 1 & \text{for each directed circuit } C, \end{array}$$

is totally dual integral.

The undirected analogue of (55.38) was proved for $k = 2$ by Bollobás [1963], and for general k by Erdős and Pósa [1965]. Ding and Zang [1999] characterized the undirected graphs $G = (V, E)$ for which the system

(55.41)
$$\begin{array}{ll} x_v \geq 0 & \text{for } v \in V, \\ x(VC) \geq 1 & \text{for each circuit } C, \end{array}$$

is totally dual integral. Their characterization implies that (55.41) is totally dual integral if and only if it defines an integer polyhedron.

A polyhedral approach to the feedback vertex set problem was investigated by Funke and Reinelt [1996]. Approximation algorithms for feedback problems were given by Monien and Schulz [1982], Eades, Lin, and Smyth [1993], Bar-Yehuda, Geiger, Naor, and Roth [1994,1998], Becker and Geiger [1994,1996], Bafna, Berman, and Fujito [1995,1999], Even, Naor, Schieber, and Sudan [1995,1998], Even, Naor, and Zosin [1996,2000], Goemans and Williamson [1996,1998], Chudak, Goemans, Hochbaum, and Williamson [1998], Bar-Yehuda [2000], and Cai, Deng, and Zang [2001]. More on the feedback vertex set problem was presented by Smith and Walford [1975], Kevorkian [1980], Rosen [1982], Speckenmeyer [1988], Stamm [1991], Hackbusch [1997], and Pardalos, Qian, and Resende [1999].

55.6d. The bipartite case

McWhirter and Younger [1971] (cf. Younger [1970], Vidyasankar [1978b]) proved the Lucchesi-Younger theorem in case the arcs of D form a directed cut; that is, in case the underlying undirected graph is bipartite, while all arcs are oriented from one colour class to the other. It amounts to the following:

Theorem 55.10. *Let $G = (V, E)$ be a connected bipartite graph and let $\mathcal{F}$ be the collection of subsets $E[U]$ of E for which U is a vertex cover with $E[U]$ nonempty. Then the minimum size of a set of edges intersecting each set in $\mathcal{F}$ is equal to the maximum number of disjoint sets in $\mathcal{F}$.*

Proof. Let U and W be the colour classes of G and let digraph D be obtained from G by orienting each edge from U to W. Then a set of edges belongs to $\mathcal{F}$ if and only if it is a directed cut of D. Hence the theorem follows from the Lucchesi-Younger theorem. ∎

D.H. Younger (cf. Frank [1993b]) showed that the maximum number of disjoint nonempty cuts in a bipartite graph G is equal to the maximum number of disjoint directed cuts in the directed graph obtained from G by orienting all edges from one colour class to the other (cf. Corollary 29.13b). (Vidyasankar [1978b] showed that a set of edges J intersecting each set in $\mathcal{F}$ attains the minimum in Theorem 55.10 if and only if J intersects any circuit C of G in at most $\frac{1}{2}|EC|$ edges; that is, if and only if J is a join — cf. Section 29.11d.)

As noted by Younger [1979], the Lucchesi-Younger theorem, in the form of Corollary 55.2b, implies the Kőnig-Rado edge cover theorem (Theorem 19.4): the minimum size of an edge cover in a bipartite graph $G = (V, E)$ is equal to the maximum size of a stable set in G. To obtain this as a consequence, let U and W be the colour classes of G and let $D = (V, A)$ be the directed graph with vertex set V and arcs all pairs (u, v) with $u \in U$ and $v \in W$. Define a weight function $w : A \to \mathbb{Z}$ by $w(u, v) := 1$ if $uv \in E$, and ∞ otherwise. Then the minimum weight of a directed cut cover in D is equal to the minimum size of an edge cover in G. With this correspondence, Corollary 55.2b gives the Kőnig-Rado edge cover theorem.

55.6e. Further notes

Frank, Tardos, and Sebő [1984] showed that the Lucchesi-Younger theorem implies that in a digraph $D = (V, A)$, the minimum size of a directed cut cover is equal to the maximum value of

$$(55.42) \qquad \sum_{i=1}^{k} \text{number of weak components of } D - V_i,$$

where $\emptyset \neq V_1 \subset V_2 \subset \cdots \subset V_k \subset V$ are such that no arc leaves any V_i and enters at most one of the V_i.

Frank and Tardos [1989] showed that a weakly connected digraph $D = (V, A)$ has a branching that intersects all directed cuts if and only if for each nonempty $U \subseteq V$, the number of weak components K of $D - U$ with $d^{\text{in}}(K) = 0$, is at most $|U|$.

Younger [1965] proved the Lucchesi-Younger theorem for digraphs having an arborescence, and, more generally, Younger [1979] proved it for source-sink connected digraphs (that is, each strong component not left by any arc is reachable by a directed path from each strong component not entered by any arc).

Tuza [1994] showed that for any planar directed graph $D = (V, A)$ and any collection $\mathcal{T}$ of directed triangles in D, the minimum number of arcs intersecting each triangle in $\mathcal{T}$ is equal to the maximum number of arc-disjoint triangles in $\mathcal{T}$.

Chapter 56

Minimum directed cuts and packing directed cut covers

A minimum-capacity directed cut can be found in strongly polynomial time, by applying the minimum-capacity $s-t$ cut algorithm, for all s, t, in some modified digraph.
As for packing directed cut covers it is unknown if it is polynomial-time tractable. Also it is unknown if the maximum number of disjoint directed cut covers is equal to the minimum size of a directed cut — this is Woodall's conjecture. But the capacitated version of it does not hold.
In this chapter we consider a few cases where Woodall's conjecture has been proved, in particular for the *source-sink connected* digraphs.

56.1. Minimum directed cuts and packing directed cut covers

The Lucchesi-Younger theorem states that in a digraph $D = (V, A)$, the minimum size of a directed cut cover is equal to the maximum number of disjoint directed cuts. Woodall [1978a,1978b] ventured the conjecture that this min-max relation would be maintained after interchanging the terms directed cut and directed cut cover:

Conjecture (Woodall's conjecture)**.** In a digraph, the minimum size of a directed cut is equal to the maximum number of disjoint directed cut covers.

This conjecture is open.

A capacitated version of Woodall's conjecture (conjectured by Edmonds and Giles [1977] and D.H. Younger) is however not true. Note that the Lucchesi-Younger theorem is equivalent to its weighted version, by replacing arcs by directed paths of length $l(a)$ if $l(a) \geq 1$, and contracting an arc a if $l(a) = 0$. We could attempt this approach to obtain an equivalent capacitated version from Woodall's conjecture, by replacing any arc a by $c(a)$ parallel arcs, but there is a problem here: if $c(a) = 0$, we delete a and can create new directed cuts.

A capacitated version with capacities 0 and 1 amounts to the statement that each directed cut k-cover can be partitioned into k directed cut covers.

Figure 56.1 gives a counterexample to this for the case $k = 2$ (Schrijver [1980a]). Note that the counterexample is planar, and that therefore the 'planar dual' assertion (on packing feedback arc sets) also does not hold.

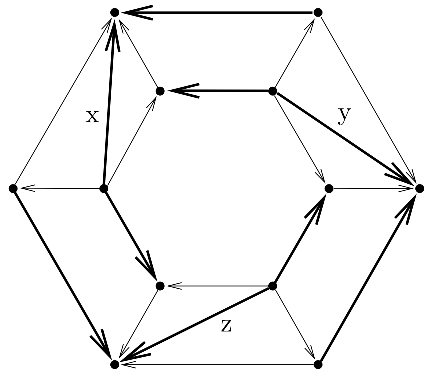

Figure 56.1
A directed cut 2-cover that cannot be split into two directed cut covers. Let C be the set of heavy arcs. Then C is a directed cut 2-cover, since for each arc $c \in C$, the set $C \setminus \{c\}$ is a directed cut cover, which is easy to check since up to symmetry there are only two types of arcs in C.
However, C cannot be split into directed cut covers C_1 and C_2. To see this, observe that each of these C_i must contain exactly one of the two arcs in C meeting any source or sink. Moreover, each C_i must contain at least one of the arcs labeled x, y, z, since the set of arcs from the inner hexagon to the outer hexagon forms a directed cut. Hence we may assume without loss of generality that C_1 contains the arcs x and y, but not z. But then C_1 does not intersect the directed cut of those arcs going from the right half of the figure to the left half.

To interpret this polyhedrally, consider the system:

(56.1)
$$\begin{array}{lll} \text{(i)} & 0 \leq x_a \leq 1 & \text{for each } a \in A, \\ \text{(ii)} & x(B) \geq 1 & \text{for each directed cut cover } B. \end{array}$$

With Corollary 55.2b, the theory of blocking polyhedra gives that system (56.1) determines the convex hull of the incidence vectors of arc sets containing a directed cut. However, by the example in Figure 56.1, system (56.1) generally is not TDI, as total dual integrality amounts to the capacitated version of Woodall's conjecture.

In a number of special cases, Woodall's conjecture, and its capacitated extension, have been proved. In the remainder of this chapter we will consider such cases.

Two more counterexamples to the conjecture of Edmonds and Giles were given by Cornuéjols and Guenin [2002c], and they asked if, together with the example of Figure 56.1, these form all minimal counterexamples to the Edmonds-Giles conjecture.

56.2. Source-sink connected digraphs

Feofiloff and Younger [1987] and Schrijver [1982] showed that for source-sink connected digraphs, the min-max relation for packing directed cut covers does hold. Here a digraph is called *source-sink connected* if each strong component not left by any arc is reachable by a directed path from each strong component not entered by any arc. So an acyclic digraph is source-sink connected if each sink is reachable by a directed path from each source. We follow the proof of Schrijver [1982].

Theorem 56.1. *Let $D = (V, A)$ be a source-sink connected digraph and let $k \in \mathbb{Z}_+$. Then any directed cut k-cover C can be partitioned into k directed cut covers.*

Proof. Choose a counterexample with $|V| + |C|$ as small as possible. Then D is acyclic, since any strong component can be contracted to one vertex.

We may assume that if v is reachable in D from u and $v \neq u$, then $(u, v) \in A$. We first show:

(56.2) for any nonempty proper subset U of V with $\delta^{\text{out}}(U) = \emptyset$ and $|\delta^{\text{in}}_C(U)| = k$, one has $|U| = 1$ or $|U| = |V| - 1$.

Suppose not. Let $D' := D/U$ and $D'' := D/\overline{U}$ be the digraphs obtained from D by contracting U and $\overline{U} := V \setminus U$, respectively. Note that D' and D'' are source-sink connected again. Let C' be the set of arcs in C with tail in $\overline{U}$, and let C'' be the set of arcs in C with head in U.

Now each directed cut in D' intersects C' in at least k arcs, as it is a directed cut in D and hence intersects C in at least k arcs. So by the minimality of $|V|+|C|$, C' can be split into k directed cut covers $B'_1, \ldots, B'_k$ for D'. As $|\delta^{\text{in}}_C(U)| = k$, each B'_i has exactly one arc entering U. Similarly, C'' can be split into k directed cut covers $B''_1, \ldots, B''_k$ for D'', such that each B''_i has exactly one arc entering U. By choosing indices appropriately, we can assume that B'_i and B''_i have an arc entering U in common, for each $i = 1, \ldots, k$ (as $|\delta^{\text{in}}_C(U)| = k$).

Then each $B'_i \cup B''_i$ is a directed cut cover for D. For suppose that there is a nonempty proper subset W of V with $\delta^{\text{out}}(W) = \emptyset$ and $\delta^{\text{in}}(W)$ disjoint from $B'_i \cup B'_i$. Then $U \cap W \neq \emptyset$ and $U \not\subseteq W$, since otherwise $\delta^{\text{in}}(W)$ is a directed cut of D', and hence some arc in B'_i enters W. So some arc in B''_i enters $U \cap W$. Similarly, some arc in B'_i enters $U \cup W$. Since exactly one arc in $B'_i \cup B''_i$ enters U, it follows that at least one arc in $B'_i \cup B''_i$ enters W, contradicting our assumption.

So each $B'_i \cup B''_i$ is a directed cut cover for D. As they are disjoint, this contradicts our assumption, thus proving (56.2).

We next show the following. Let X be the set of sources of D and let Y be the set of sinks of D. Then:

(56.3) for each $a = (u, v) \in C$ we have $u \in X$ or $v \in Y$.

For suppose not. Then by (56.2), each directed cut of D intersects $C \setminus \{a\}$ in at least k arcs (as any directed cut intersecting C in exactly k arcs and containing a is equal to $\delta^{\text{in}}(\{v\})$ or $\delta^{\text{in}}(V \setminus \{u\})$, implying that v is a sink or u is a source). So by the minimality of $|V| + |C|$, we can split $C \setminus \{a\}$ into k directed cut covers. This implies that also C can be split into k directed cut covers, contradicting our assumption. This proves (56.3).

Next:

(56.4) if $a = (u, v) \in C$, $a' = (u', v') \in C$, and v is reachable from u', then $u' \in X$ or $v \in Y$.

For suppose not. By (56.3), $u \in X$ and $v' \in Y$, and hence (since D is source-sink connected), $a'' = (u, v') \in A$. Now $a \neq a'$, as $u \in X$ and $u' \notin X$. So $C' := (C \setminus \{a, a'\}) \cup \{a''\}$ is smaller than C. Moreover, C' is a directed cut k-cover. Indeed, let U be a nonempty proper subset of V with $\delta^{\text{out}}(U) = \emptyset$. If $|U| = 1$ or $|U| = |V| - 1$, then $\delta^{\text{in}}_{C'}(U) = \delta^{\text{in}}_{C}(U)$, since then $U = \{r\}$ for some sink r or $U = V \setminus \{s\}$ for some source s. If $1 < |U| < |V| - 1$, then

(56.5) $|\delta^{\text{in}}_{C'}(U)| \geq |\delta^{\text{in}}_{C}(U)| - 1 \geq k$,

since if both a and a' enter U, then $u \notin U$ and $v' \in U$, and hence a'' enters U.

So C' is a directed cut k-cover, and hence, by the minimality of $|V| + |C|$, C' can be split into k directed cut covers. Let B be the directed cut cover containing a''. Then $B' := (B \setminus \{a''\}) \cup \{a, a'\}$ is a directed cut cover, since any directed cut $\delta^{\text{in}}(W)$ containing a'', contains at least one of a, a'. Indeed, otherwise $u, v \notin W$, $u', v' \in W$, but then $u' \neq v$ and arc (u', v) leaves W, contradicting the fact that W determines a directed cut.

So by replacing B by B' we obtain a splitting of C into k directed cut covers, contradicting our assumption. This proves (56.4).

This implies:

(56.6) V can be partitioned into sets R and S such that $\delta^{\text{in}}(R) = \emptyset$, $X \subseteq R$, $Y \subseteq S$, and if any $(u, v) \in C$ leaves R, then $u \in X$ and $v \in Y$.

For define

(56.7) $C' := \{(u, v) \in C \mid u \notin X \text{ or } v \notin Y\}$,
$R := \{v \in V \mid D' = (V, A \cup C^{-1}) \text{ has a directed } v - X \text{ path}\}$,
$S := V \setminus R$.

Then $X \subseteq R$, $\delta^{\text{in}}_A(R) = \emptyset$, and any $(u, v) \in C$ leaving R satisfies $u \in X$ and $v \in Y$. To see that $Y \subseteq S$, suppose to the contrary that D' has a directed $Y - X$ path P. Choose P shortest. Then by (56.3), P has of at most three arcs. Let (v', u') and (v, u) be the first and last arc of P. So $v' \in Y$ and $u \in X$. These arcs belong to C'^{-1}, and v is reachable from u' in D. So by (56.4), $u' \in X$ or $v \in Y$. This contradicts the definition of C'. This shows (56.6).

Fix R, S as in (56.6). Let $D' = (V, A')$ be the digraph arising from D by replacing any arc (u, v) of D by k parallel arcs from v to u. Then

(56.8) $$|\delta^{\text{in}}_{A' \cup C}(U)| \geq k$$

for each nonempty proper subset U of V. So by Theorem 54.11, $A' \cup C$ can be split into k $R - S$ bibranchings. Let $B_1, \ldots, B_k$ be the intersections of these bibranchings with C. We show that each B_i is a directed cut cover, contradicting our assumption, and therefore finishing the proof.

Suppose that say B_1 is not a directed cut cover. Let U be a nonempty proper subset of V with $\delta^{\text{out}}(U) = \emptyset$, and suppose that no arc in B_1 enters U. Note that if U contains any source, it contains all sinks, since no arc of D leaves U. So U contains no sources or contains all sinks.

First assume that U contains no sources of D. As U contains at least one sink (as $U \neq \emptyset$ and $\delta^{\text{out}}(U) = \emptyset$), we know $U \not\subseteq R$. As $A' \cup B_1$ is an $R - S$ bibranching, we know that

(56.9) $$\delta^{\text{in}}_{A' \cup B_1}(U \cap S) \neq \emptyset.$$

As $\delta^{\text{out}}_A(U \cap S) = \emptyset$ (since $\delta^{\text{out}}_A(U) = \emptyset$ and $\delta^{\text{in}}_A(R) = \emptyset$), we have $\delta^{\text{in}}_{A'}(U \cap S) = \emptyset$. Hence some arc (u, v) in B_1 enters $U \cap S$. As by assumption (u, v) does not enter U, (u, v) enters S, and $u \in U$. However, by (56.6), u belongs to X. This contradicts our assumption that U contains no sources of D.

The case that U contains all sinks is symmetric, and leads again to a contradiction. ∎

A special case of Theorem 56.1 is Woodall's conjecture for source-sink connected digraphs:

Corollary 56.1a. *Let $D = (V, A)$ be a source-sink connected digraph. Then the minimum size of a directed cut is equal to the maximum number of disjoint directed cut covers.*

Proof. This is the case $C = A$ of Theorem 56.1. ∎

Also, a capacitated version can be derived from the theorem:

Corollary 56.1b. *Let $D = (V, A)$ be a source-sink connected digraph and let $c : A \to \mathbb{Z}_+$ be a capacity function. Then the minimum capacity of a directed cut is equal to the maximum number of directed cut covers such that no arc a is in more than $c(a)$ of these directed cut covers.*

Proof. Directly from Theorem 56.1, by adding, for any arc a of D, $c(a)$ arcs parallel to a, and by taking for C the set of newly added arcs. ∎

Equivalently, in TDI terms:

Corollary 56.1c. *If $D = (V, A)$ is a source-sink connected digraph, then system* (56.1) *is totally dual integral.*

Proof. This is a reformulation of Corollary 56.1b. ∎

Feofiloff [1983] gave a polynomial-time algorithm to find a maximum number of disjoint directed cut covers in a source-sink connected digraph. Also the proof above implies a polynomial-time algorithm.

A polynomial-time algorithm for the capacitated case can be derived from the ellipsoid method (cf. Grötschel, Lovász, and Schrijver [1988]). A semi-strongly polynomial-time algorithm also follows from Section 57.5 below.

Notes. Frank [1979b] showed the special case of Woodall's conjecture for digraphs having an arborescence. (Such digraphs are source-sink connected.) J. Edmonds observed that this can be derived from Edmonds' disjoint arborescences theorem (Corollary 53.1b): Let $D = (V, A)$ have an r-arborescence. Let k be the minimum size of a directed cut in D. Add to D, for each arc (u, v) of D, k parallel arcs from v to u. This makes the digraph $D' = (V, A')$ with $|\delta^{\text{in}}_{A'}(U)| \geq k$ for each nonempty $U \subseteq V \setminus \{r\}$. Hence D' has k disjoint r-arborescences (by Edmonds' disjoint arborescences theorem). Now for any r-arborescence B in D', the set $B \cap A$ is a directed cut cover in D, since if U is a nonempty proper subset of V with $\delta^{\text{out}}_A(U) = \emptyset$, then $\delta^{\text{in}}_{A'}(U) = \delta^{\text{in}}_A(U)$, and hence $\delta^{\text{in}}_{B\cap A}(U) = \delta^{\text{in}}_B(U) \neq \emptyset$. So we obtain k disjoint directed cut covers in D.

56.3. Other cases where Woodall's conjecture is true

Another case where Woodall's conjecture holds is given in:

Theorem 56.2. *Let $D = (V, A)$ be a digraph arising from a directed tree $T = (V, A')$ such that $(u, v) \in A$ if and only if v is reachable in T from u. Let $c : A \to \mathbb{Z}_+$ be a capacity function. Then the minimum capacity of a directed cut is equal to the maximum number of directed cut covers such that each arc a is in at most $c(a)$ of them.*

Proof. The proof is by induction on the minimum capacity k of a directed cut. Then it suffices to show that there exists a directed cut cover B with $\chi^B \leq c$ and with $(c - \chi^B)(C) \geq k - 1$ for each directed cut C.

Let M be the $A' \times A$ network matrix generated by T and D (cf. Section 13.3). Then the rows of M are precisely the incidence vectors of inclusionwise minimal directed cuts. So it suffices to show that there exists an integer solution x of

(56.10) $\mathbf{0} \leq x \leq \mathbf{c}, Mx \geq \mathbf{1}, M(c-x) \geq (k-1)\mathbf{1},$

since for any such x there is a directed cut cover B satisfying $\chi^B \leq x$.

Since M is totally unimodular, it suffices to show that (56.10) has any solution. Define $x := \frac{1}{k}c$. Then x satisfies (56.10), since $Mc \geq k\mathbf{1}$ and hence $Mx \geq \mathbf{1}$ and $M(c-x) = \frac{k-1}{k}Mc \geq (k-1)\mathbf{1}$. ∎

The theorem can also be formulated in terms of partitioning directed cut k-covers:

Corollary 56.2a. *Let $D = (V, A)$ be a digraph such that A contains a directed spanning tree T with the property that for each arc (u, v) in A there exists a directed $u-v$ path in T. Then any directed cut k-cover in D can be partitioned into k directed cut covers.*

Proof. This follows from Theorem 56.2 by taking $c(u, v)$ equal to the number of times there is an arc from u to v in the directed cut k-cover. ∎

A. Frank also noted that Woodall's conjecture is true if the minimum size of a directed cut is at most 2:

Theorem 56.3. *Let $D = (V, A)$ be a digraph such that each directed cut has size at least two. Then there are two disjoint directed cut covers.*

Proof. As the underlying undirected graph is 2-edge-connected, it has a strongly connected orientation $D' = (V, A')$ (see Corollary 61.3a). Let B_1 be the set of arcs of D that have the same orientation in D' and let $B_2 := A \setminus B_1$. Then B_1 and B_2 are disjoint directed cut covers. ∎

Figure 56.1 shows that this cannot be generalized to each directed cut 2-cover being partitionable into two directed cut covers.

56.3a. Further notes

Karzanov [1985c] gave a strongly polynomial-time algorithm to find a minimum-*mean* capacity directed cut (cf. McCormick and Ervolina [1994]).

Chapter 57

Strong connectors

A *strong connector* is a set of new arcs whose addition to a given digraph D makes it strongly connected. If each potential new arc has been given a length, then finding a shortest strong connector is NP-complete, even if D has no arcs at all: finding a directed Hamiltonian circuit is a special case. (So even if each length is 0 or 1, the problem is NP-complete.)
However, there are a few cases where finding a shortest strong connector is tractable and where min-max relations and polyhedral characterizations hold — for instance, if D is source-sink connected. For these digraphs, packing strong connectors is similarly tractable. These results follow by reduction to directed cut covers discussed in the previous two chapters.

57.1. Making a directed graph strongly connected

Let (V, A) and (V, B) be digraphs. The set B is called a *strong connector for* D if the digraph $(V, A \cup B)$ is strongly connected.

Consider the following *strong connectivity augmentation problem*:

(57.1) Given a digraph $D = (V, A)$ and a cost function $k : V \times V \to \mathbb{Q}$, find a minimum-cost strong connector for D.

Theorem 57.1. *The strong connectivity augmentation problem is* NP*-complete, even if* $A = \emptyset$.

Proof. The problem of finding a Hamiltonian circuit in a digraph $D' = (V, A')$ is equivalent to the existence of a strong connector for $(V, \emptyset)$ of cost $|V|$, where $k(u, v) := 1$ if $(u, v) \in A'$, and $k(u, v) := 2$ otherwise. ∎

Eswaran and Tarjan [1976] showed that if the cost of each new arc equals 1, then there is an easy solution:

Theorem 57.2. *If* $D = (V, A)$ *is an acyclic digraph with at least* 2 *vertices, and with* ρ *sources and* σ *sinks, then the minimum size of a strong connector for* D *equals* $\max\{\rho, \sigma\}$.

Proof. To see that the minimum is at least $\max\{\rho, \sigma\}$, note that for each source r one should add at least one arc entering r; similarly, for each sink s one should add at least one arc leaving s.

That the bound can be attained is shown by induction on $\max\{\rho, \sigma\}$. If there is a pair of a source r and a sink s such that s is not reachable from r, add an arc (s, r). This reduces both ρ and σ by 1, while maintaining acyclicity, and induction gives the result.

So we can assume that each sink is reachable from each source. We can also assume that $\rho \geq \sigma$ (otherwise, reverse all orientations). Let $r_1, \ldots, r_\rho$ be the sources and let $s_1, \ldots, s_\sigma$ be the sinks. Then adding arcs (s_i, r_i) for $i = 1, \ldots, \sigma$, and arcs (s_i, r_1) for $i = \sigma+1, \ldots, \rho$ makes D strongly connected, proving the theorem. ∎

This implies for not necessarily acyclic digraphs:

Corollary 57.2a. *Let $D = (V, A)$ be a digraph which is not strongly connected, let ρ be the number of strong components K of D with $d^{\text{in}}(K) = 0$ and let σ be the number of strong components K of D with $d^{\text{out}}(K) = 0$. Then the minimum size of a strong connector for D equals* $\max\{\rho, \sigma\}$.

Proof. Apply Theorem 57.2 to the digraph obtained from D by contracting each strong component of D to one vertex. ∎

These proofs also give a polynomial-time algorithm to find a minimum-size strong connector. Eswaran and Tarjan [1976] describe a linear-time implementation.

57.2. Shortest strong connectors

Let $D_0 = (V, A_0)$ and $D = (V, A)$ be digraphs. Call a subset A' of A a *D_0-cut (in D)* if $A' = \delta^{\text{in}}_A(U)$ for some nonempty proper subset U of V with $\delta^{\text{in}}_{A_0}(U) = \emptyset$.

It is easy to see that a set B of arcs of D is a strong connector for D_0 if and only if B intersects each D_0-cut in D. The following consequence of the Lucchesi-Younger theorem was given in Schrijver [1982]. It gives a min-max relation for the minimum length of a strong connector, if the following condition holds for digraphs $D_0 = (V, A_0)$ and $D = (V, A)$:

(57.2) for each $(u, v) \in A$ there exist $u', v' \in V$ such that in D_0, u' is reachable from u and from v', and v from v'.

We mention two special cases where this condition is satisfied:

- A is a subset of A_0^{-1},
- D_0 is source-sink connected.

We derive from the Lucchesi-Younger theorem (Schrijver [1982]):

Theorem 57.3. *Let $D_0 = (V, A_0)$ and $D = (V, A)$ be digraphs satisfying (57.2) and let $l : A \to \mathbb{Z}_+$ be a length function. Then the minimum length of a strong connector in D for D_0 is equal to the maximum number of D_0-cuts in D such that no arc a of D is in more than $l(a)$ of these cuts.*

Proof. We can assume that D_0 is acyclic, and that for any $u, v \in V$, if v is reachable in D_0 from u, then $(u, v) \in A_0$. (So $(v, v) \in A_0$ for each $v \in V$.)

We show the theorem by induction on the number τ of arcs $a = (u, v)$ of D for which $(v, u) \notin A_0$. If $\tau = 0$, the theorem is equivalent to Corollary 55.2a.

If $\tau > 0$, choose $(u, v) \in A$ with $(v, u) \notin A_0$. By assumption, there exist $u', v' \in V$ with $(u, u'), (v', u'), (v', v) \in A_0$. Introduce two new vertices, u'' and v'', and add arcs

(57.3) $\qquad (u, u''), (u'', u'), (v'', u''), (v'', v), (v', v'')$

to A_0. Moreover, replace arc (u, v) of A by (u'', v''), with length equal to that of the original arc (u, v). Let $\widetilde{D}_0 = (\widetilde{V}, \widetilde{A}_0)$ and $\widetilde{D} = (\widetilde{V}, \widetilde{A})$ denote the modified graphs.

This transformation decreases the number τ by 1. Moreover,

(57.4) $\qquad$ any subset C of A is a strong connector for D_0 if and only if the set $\widetilde{C} \subseteq \widetilde{A}$ is a strong connector for $\widetilde{D}_0$.

Here $\widetilde{C}$ arises from C by replacing (u, v) by (u'', v'') if $(u, v) \in C$. Proving (57.4) suffices, since it implies that the two numbers in the theorem are invariant under the transformation.

(57.4) can be seen as follows. Choose $C \subseteq A$. First let C be a strong connector for D_0. If $(u, v) \notin C$, then $\widetilde{C} = C$ is also strong connector for $\widetilde{D}_0$ (since in $\widetilde{D}_0$ the new vertex u'' is on a $u - u'$ path, and the new vertex v'' is on a $v' - v$ path). If $(u, v) \in C$, then $\widetilde{C} = (C \setminus \{(u, v)\}) \cup \{(u'', v'')\}$ is a strong connector for $\widetilde{D}_0$, since $A_0 \cup C$ contains the $u - v$ path (u, u''), (u'', v''), (v'', v).

Conversely, let $\widetilde{C}$ be a strong connector for $\widetilde{D}_0$. If $(u'', v'') \notin \widetilde{C}$, then $C = \widetilde{C}$ is also a strong connector for D_0, since any directed path in $\widetilde{A}_0 \cup \widetilde{C}$ connecting two vertices in V and traversing any of the new vertices u'', v'', can be shortcut to a path avoiding u'' and v''.

If $(u'', v'') \in \widetilde{C}$, then $C = (\widetilde{C} \setminus \{(u'', v'')\}) \cup \{(u, v)\}$ is a strong connector for D_0, since any directed path in $\widetilde{A}_0 \cup \widetilde{C}$ connecting two vertices in V and traversing arc (u'', v''), must traverse (u, u''), (u'', v''), and (v'', v), and hence gives a path in $A_0 \cup C$, by replacing this by (u, v). ∎

The proof gives also an algorithmic reduction to the problem of finding a minimum-length directed cut cover, and hence (by Theorem 55.5) a minimum-length strong connector for D_0 can be found in strongly polynomial time.

Theorem 57.3 includes several theorems considered earlier:

- $s, t \in V$ and $A_0 := \{(u,v) \mid u = t \text{ or } v = s\}$: max-potential min-work theorem (Theorem 8.3);
- V is the disjoint union of U and W, $A_0 := \{(u,w) \mid u \in U, w \in W\}$ and $A \subseteq \{(w,u) \mid w \in W, u \in U\}$: weighted version of the Kőnig-Rado edge cover theorem(Theorem 19.4);
- $A_0 = \{(v,r) \mid v \in V\}$ for some $r \in V$: optimum arborescence theorem(Theorem 52.3);
- V is the disjoint union of U and W and $A_0 := \{(u,w) \mid u \in U, w \in W\}$:optimum bibranching theorem(Corollary 54.8b);
- $A \subseteq \{(u,v) \mid (v,u) \in A_0\}$: Lucchesi-Younger theorem (Theorem 55.2).

A cardinality version of the previous theorem is:

Corollary 57.3a. *Let $D_0 = (V, A_0)$ and $D = (V, A)$ be digraphs satisfying* (57.2). *Then the minimum size of a strong connector in D for D_0 is equal to the maximum number of disjoint D_0-cuts in D.*

Proof. This is the case $l = \mathbf{1}$ of Theorem 57.3. ∎

We formulate this for the special case of source-sink connected digraphs. Recall that a digraph $D = (V, A)$ is called *source-sink connected* if each strong component not left by any arc is reachable by a directed path from each strong component not entered by any arc.

Corollary 57.3b. *Let $D_0 = (V, A_0)$ and $D = (V, A)$ be digraphs, with D_0 source-sink connected. Let $l : A \to \mathbb{Z}_+$ be a length function. Then the minimum length of a strong connector in D for D_0 is equal to the maximum number of D_0-cuts in D such that no arc a of D is in more than $l(a)$ of these cuts.*

Proof. Directly from Theorem 57.3, since condition (57.2) is implied by the fact that D_0 is source-sink connected. ∎

The cardinality version is:

Corollary 57.3c. *Let $D_0 = (V, A_0)$ and $D = (V, A)$ be digraphs, with D_0 source-sink connected. Then the minimum size of a strong connector in D for D_0 is equal to the maximum number of disjoint D_0-cuts in D.*

Proof. This is the case $l = \mathbf{1}$ in Corollary 57.3b. ∎

57.3. Polyhedrally

Theorem 57.3 can be equivalently formulated in TDI terms:

Corollary 57.3d. *Let $D_0 = (V, A_0)$ and $D = (V, A)$ be digraphs satisfying* (57.2). *Then the system*

$$\text{(57.5)} \qquad \begin{array}{rll} \text{(i)} & x_a \geq 0 & a \in A, \\ \text{(ii)} & x(\delta^{\text{in}}_A(U)) \geq 1 & U \subset V, U \neq \emptyset, \delta^{\text{in}}_{A_0}(U) = \emptyset, \end{array}$$

is TDI and determines the convex hull of the strong connectors of D_0.

Proof. This is a reformulation of Theorem 57.3. ∎

In fact, system (57.5) is box-TDI, as will follow from Theorem 60.3.

By the theory of blocking polyhedra, Corollary 57.3d implies:

Corollary 57.3e. *Let $D_0 = (V, A_0)$ and $D = (V, A)$ satisfy* (57.2). *Then the system*

$$\text{(57.6)} \qquad \begin{array}{rll} \text{(i)} & 0 \leq x_a \leq 1 & a \in A, \\ \text{(ii)} & x(B) \geq 1 & B \text{ strong connector for } D_0 \end{array}$$

determines the convex hull of subsets of A containing a D_0-cut.

Proof. System (57.6) determines the blocking polyhedron of the polyhedron determined by (57.5), and hence its vertices are the incidence vectors of subsets of A that intersect all strong connectors for D_0. These are precisely the sets of arcs in A containing a D_0-cut. ∎

System (57.6) generally is not TDI, by Figure 56.1. But if D_0 is source-sink connected, system (57.6) is totally dual integral, as is shown in the following section.

57.4. Disjoint strong connectors

Similarly to the derivation of Theorem 57.3 from the Lucchesi-Younger theorem, the following generalization can be derived as a consequence of Theorem 56.1 (Schrijver [1982]):

Theorem 57.4. *Let $D_0 = (V, A_0)$ and $D = (V, A)$ be digraphs, with D_0 source-sink connected. Then the minimum size of a D_0-cut in D is equal to the maximum number of disjoint strong connectors in D for D_0.*

Proof. The proof is similar to the derivation of Theorem 57.3 from the Lucchesi-Younger theorem. We can assume that for any $u, v \in V$, if v is reachable in D_0 from u, then $(u, v) \in A_0$.

We show the theorem by induction on the number τ of arcs (u,v) of D for which $(v,u) \notin A_0$. If $\tau = 0$, the theorem is equivalent to Theorem 56.1 (by taking $C := \{(u,v) \mid (v,u) \in A\}$).

If $\tau > 0$, choose $(u,v) \in A$ with $(v,u) \notin A_0$. Let u' be a sink of D_0 with $(u,u') \in A_0$ and let v' be a source of D_0 with $(v',v) \in A_0$. As D_0 is source-sink connected we know that $(v',u') \in A_0$. Now introduce two new vertices, u'' and v'', and add arcs

(57.7) $$(u,u''), (u'',u'), (v'',u''), (v'',v), (v',v'')$$

to A_0. Moreover, replace arc (u,v) of A by (u'',v''). Let $\widetilde{D}_0 = (\widetilde{V}, \widetilde{A}_0)$ and $\widetilde{D} = (\widetilde{V}, \widetilde{A})$ denote the modified graphs.

This transformation decreases τ by 1. Again (57.4) holds. This implies that the two numbers in the theorem are invariant under the transformation. Hence the theorem follows by induction. ∎

The condition given in this theorem cannot be relaxed to condition (57.2), as Figure 56.1 shows.

Theorem 57.4 has the following special cases:

- $s, t \in V$ and $A_0 := \{(u,v) \mid u = t \text{ or } v = s\}$: Menger's theorem (Corollary 9.1b);
- V is the disjoint union of U and W, $A_0 = \{(u,w) \mid u \in U, w \in W\}$ and $A \subseteq \{(w,u) \mid w \in W, u \in U\}$: Gupta's edge-colouring theorem (Theorem 20.5);
- $r \in V$ and $A_0 = \{(v,r) \mid v \in V\}$: Edmonds' disjoint arborescences theorem (Corollary 53.1b);
- V is the disjoint union of U and W and $A_0 = \{(u,w) \mid u \in U, w \in W\}$: disjoint bibranchings theorem(Theorem 54.11);
- $D_0 = (V, A_0)$ is source-sink connected and $A \subseteq \{(u,v) \mid (v,u) \in A_0\}$: Corollary 56.1b.

An equivalent capacitated version of Theorem 57.4 reads:

Corollary 57.4a. *Let $D_0 = (V, A_0)$ and $D = (V, A)$ be digraphs, with D_0 source-sink connected, and let $c \in \mathbb{Z}_+^A$ be a capacity function. Then the minimum capacity of a D_0-cut in D is equal to the maximum number of strong connectors in D for D_0 such that any arc a of D is in at most $c(a)$ of them.*

Proof. Directly from Theorem 57.4 by replacing any arc a of D by $c(a)$ parallel arcs. ∎

Equivalently, in TDI terms:

Corollary 57.4b. *Let $D_0 = (V, A_0)$ and $D = (V, A)$ be digraphs, with D_0 source-sink connected. Then system* (57.6) *is totally dual integral.*

Proof. This is a reformulation of Corollary 57.4a. ∎

57.5. Complexity

As for the complexity of finding disjoint strong connectors for a source-sink connected digraph, the proof of Theorem 57.4 gives a polynomial-time reduction to finding a maximum number of disjoint directed cut covers in a subset of the arcs of a source-sink connected graph. The latter problem is solvable in polynomial time by the methods of Section 56.2.

The capacitated case can be solved in semi-strongly polynomial time (that is, where rounding is taken as one arithmetic operation) with the ellipsoid method (cf. Grötschel, Lovász, and Schrijver [1988]). A combinatorial semi-strongly polynomial-time algorithm is as follows.

Let be given a source-sink connected digraph $D_0 = (V, A_0)$, a digraph $D = (V, A)$, and a capacity function $c : A \to \mathbb{Z}_+$. We show that an optimum *fractional* packing of strong connectors subject to c can be found in strongly polynomial time. Then an *integer* packing can be found by rounding (like in Section 51.4), thus yielding a semi-strongly polynomial-time algorithm.

Define $\mathcal{C} := \{U \mid \emptyset \neq U \subset V, d^{\text{in}}_{A_0}(U) = 0\}$. To find an optimum fractional packing, let κ be the minimum of $c(\delta^{\text{in}}_A(U))$ taken over sets $U \in \mathcal{C}$. (κ can be computed with a maximum flow algorithm.) We keep a subcollection $\mathcal{U}$ of $\mathcal{C}$ with $c(\delta^{\text{in}}_A(U)) = \kappa$ for each $U \in \mathcal{U}$.

Choose a strong connector $B \subseteq A$ for A_0 with $d^{\text{in}}_B(U) = 1$ for each $U \in \mathcal{U}$. (This can be found in strongly polynomial time, by finding a minimum-length strong connector for length function $l := \sum_{U \in \mathcal{U}} \chi^{\delta^{\text{in}}_B(U)}$. It exists by Theorem 57.4.)

If $c = \mathbf{0}$, we are done. If $c \neq \mathbf{0}$, determine a rational λ as follows. First set $\lambda := \min\{c(a) \mid a \in B\}$. Next, iteratively, find a $U \in \mathcal{C}$ minimizing

$$(57.8) \qquad (c - \lambda \cdot \chi^B)(\delta^{\text{in}}_A(U)).$$

If this minimum value is less than $\kappa - \lambda$, reset

$$(57.9) \qquad \lambda := \frac{c(\delta^{\text{in}}_A(U)) - \kappa}{d^{\text{in}}_B(U) - 1},$$

and iterate. If the minimum is equal to $\kappa - \lambda$, this ends the inner iterations. Then we reset $c := c - \lambda \cdot \chi^B$, $\kappa := \kappa - \lambda$, and $\mathcal{U} := \mathcal{U} \cup \{U\}$, and (outer) iterate.

In each outer iteration, the number of arcs a with $c(a) > 0$ decreases or the intersecting family generated by $\mathcal{U}$ increases (since for the U added we have $d^{\text{in}}_B(U) > 1$). Hence the number of outer iterations is bounded by $|A| + |V|^3$ (see the argument given in the proof of Theorem 53.9).

In each outer iteration, the number of inner iterations is at most $|B|$. To see this, consider any inner iteration, and denote by λ' and U' the objects λ and U in the next inner iteration. As U minimizes (57.8), we know

$$(57.10) \qquad (c - \lambda \cdot \chi^B)(\delta_A^{\text{in}}(U)) \leq (c - \lambda \cdot \chi^B)(\delta_A^{\text{in}}(U')).$$

Moreover, if the next iteration is not the last iteration, then

$$(57.11) \qquad (c - \lambda' \cdot \chi^B)(\delta_A^{\text{in}}(U')) < \kappa - \lambda' = (c - \lambda' \cdot \chi^B)(\delta_A^{\text{in}}(U))$$

(the equality follows from definition (57.9), replacing λ by λ'). Now (57.10) and (57.11) imply

$$(57.12) \qquad \begin{aligned} &\lambda'(d_B^{\text{in}}(U) - d_B^{\text{in}}(U')) < c(\delta_A^{\text{in}}(U)) - c(\delta_A^{\text{in}}(U')) \\ &\leq \lambda(d_B^{\text{in}}(U) - d_B^{\text{in}}(U')). \end{aligned}$$

Since $\lambda' < \lambda$ (as (57.8) is less than $\kappa - \lambda$), we have $d_B^{\text{in}}(U') < d_B^{\text{in}}(U)$. Hence the number of inner iterations is at most $|B|$.

57.5a. Crossing families

Theorem 57.4 and part of Theorem 57.3 were generalized by Schrijver [1983b]. Let $\mathcal{C}$ be a *crossing family* of subsets of a set V; that is:

(57.13) if $U, W \in \mathcal{C}$ and $U \cap W \neq \emptyset$ and $U \cup W \neq V$, then $U \cap W \in \mathcal{C}$ and $U \cup W \in \mathcal{C}$.

Let $D = (V, A)$ be a digraph. Call $B \subseteq A$ a *$\mathcal{C}$-cut* if $B = \delta^{\text{in}}(U)$ for some $U \in \mathcal{C}$. Call $B \subseteq A$ a *$\mathcal{C}$-cover* if B intersects each $\mathcal{C}$-cut.

Let $\mathcal{C}$ be a crossing family of nonempty proper subsets of a set V. In Schrijver [1983b] it is shown that the following are equivalent:

(57.14)
(i) for each digraph $D = (V, A)$, the minimum size of a $\mathcal{C}$-cut is equal to the maximum number of disjoint $\mathcal{C}$-covers;
(ii) for each digraph $D = (V, A)$ and each length function $l : A \to \mathbb{Z}_+$, the minimum length of a $\mathcal{C}$-cover is equal to the maximum number of $\mathcal{C}$-cuts such that no arc a is in more than $l(a)$ of these cuts;
(iii) there are no V_1, V_2, V_3, V_4, V_5 in $\mathcal{C}$ with $V_1 \subseteq V_3 \subseteq V_5$, $V_1 \subseteq V_2$, $V_2 \cup V_3 = V$, $V_3 \cap V_4 = \emptyset$, and $V_4 \subseteq V_5$.

The configuration described in (iii) is depicted in Figure 57.1. As directed graphs may have parallel arcs, property (57.14)(i) is equivalent to its capacitated version. So condition (57.14)(i) is equivalent to the total dual integrality of

$$(57.15) \qquad \begin{array}{ll} x_a \geq 0 & \text{for } a \in A, \\ x(B) \geq 1 & \text{for each } \mathcal{C}\text{-cover } B \subseteq A, \end{array}$$

for each digraph (V, A). Similarly, condition (57.14)(ii) is equivalent to the total dual integrality of

$$(57.16) \qquad \begin{array}{ll} x_a \geq 0 & \text{for } a \in A, \\ x(B) \geq 1 & \text{for each } \mathcal{C}\text{-cut } B \subseteq A, \end{array}$$

for each digraph (V, A).

Frank [1979b] showed that (57.14)(i) holds if $\mathcal{C}$ is an intersecting family. (For any intersecting family $\mathcal{C}$, (iii) holds if $V \notin \mathcal{C}$, which we may assume without loss of generality.)

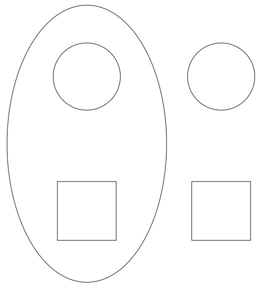

Figure 57.1
The configuration excluded in (57.14)(iii)**.** In this Venn-diagram, the collection is represented by the *interiors* of the ellipses and by the *exteriors* of the rectangles.

In (57.14)(i) and (ii) we require the min-max relation for cuts and covers to hold for *all* directed graphs on V. It is a more general problem to characterize pairs $(\mathcal{C}, D)$ of a crossing family $\mathcal{C}$ on V and a directed graph $D = (V, A)$ having the properties described in (57.14)(i) and (ii), respectively. For example, the Lucchesi-Younger theorem (Theorem 55.2), and its extension by Edmonds and Giles [1977], assert that if $\mathcal{C}$ is a crossing family on V and no arc of D leaves any set $U \in \mathcal{C}$, then $(\mathcal{C}, D)$ has the properties described in (ii). However, the example in Figure 56.1 shows that it generally does not have the property described in (57.14)(i). So for *fixed* graphs D, (57.14)(i) and (ii) are not equivalent.

Theorem 60.3 implies that a pair $(\mathcal{C}, D)$ has property (ii) if $\mathcal{C}$ is a crossing family and D a directed graph such that if $U_1, U_2, U_3 \in \mathcal{C}$ with $U_1 \subseteq V \setminus U_2 \subseteq U_3$, then no arc enters both U_1 and U_3. This generalizes the Lucchesi-Younger theorem.

We show the equivalence of (57.14)(ii) and (iii), for which we show a lemma indicating that condition (57.14)(iii) has a natural characterization in terms of total unimodularity.

For any collection $\mathcal{C}$ of subsets of a set V, let A be the collection of all ordered pairs of elements of V (making the complete directed graph $D = (V, A)$), and let $M_{\mathcal{C}}$ be the $\mathcal{C} \times A$ matrix with

(57.17) $$(M_{\mathcal{C}})_{U,a} := \begin{cases} 1 & \text{if } a \text{ enters } U, \\ 0 & \text{otherwise.} \end{cases}$$

Lemma 57.5α. *Let $\mathcal{C}$ be a cross-free collection of nonempty proper subsets of a set V. Then $M_{\mathcal{C}}$ is totally unimodular if and only if $\mathcal{C}$ satisfies* (57.14)(iii)*.*

Proof. To see necessity, let $M_{\mathcal{C}}$ be totally unimodular. Suppose that condition (57.14)(iii) is violated. So there exist V_1, V_2, V_3, V_4, V_5 in $\mathcal{C}$ with $V_1 \subseteq V_3 \subseteq V_5$, $V_1 \subseteq V_2$, $V_2 \cup V_3 = V$, $V_3 \cap V_4 = \emptyset$, and $V_4 \subseteq V_5$. Choose $v_1 \in V_1$, $v_2 \in V \setminus V_2$, $v_4 \in V_4$, and $v_5 \in V \setminus V_5$. Define

(57.18) $$A_0 := \{(v_2, v_1), (v_4, v_1), (v_2, v_4), (v_5, v_4), (v_5, v_2)\}$$

(cf. Figure 57.2). Consider the submatrix of $M_{\mathcal{C}}$ with rows indexed by $V_1, \ldots, V_5$, and columns indexed by the arcs in A_0. Then, as one easily checks:

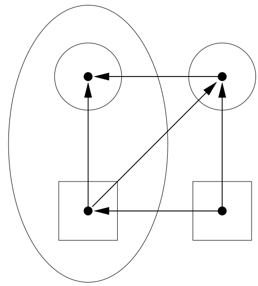

Figure 57.2

(57.19) each set in $\mathcal{C}_0$ is entered by exactly two arcs from A_0, and each arc in A_0 enters exactly two sets in $\mathcal{C}_0$.

So this submatrix has exactly two 1's in each row and each column, and hence is not totally unimodular.

To see sufficiency, let $\mathcal{C}$ satisfy (57.14)(iii). To prove that $M_\mathcal{C}$ is totally unimodular, we use the following characterization of Ghouila-Houri [1962b] (cf. Theorem 19.3 in Schrijver [1986b]): a matrix M is totally unimodular if and only if each collection R of rows of M can be partitioned into classes R_1 and R_2 such that the sum of the rows in R_1, minus the sum of the rows in R_2, is a vector with entries $0, \pm 1$ only.

To check this condition, we can assume that we have chosen all rows of $M_\mathcal{C}$ (as any subset of the rows gives a matrix of the same type as $M_\mathcal{C}$). Make a digraph $D = (\mathcal{C}, A')$, where A' consists of all pairs (T, U) from $\mathcal{C}$ such that

(57.20) $T \subset U$, and there is no $W \in \mathcal{C}$ with $T \subset W \subset U$.

We show that the undirected graph underlying D' is bipartite, which will verify Ghouila-Houri's criterion: let $\mathcal{C}_1$ and $\mathcal{C}_2$ be the two colour classes; then any arc $a = (u, v)$ of D enters a chain of subsets in $\mathcal{C}$ (as $\mathcal{C}$ is cross-free), which subsets are alternatingly in $\mathcal{C}_1$ and $\mathcal{C}_2$. Hence the sum of the rows with index in $\mathcal{C}_1$ minus the sum of the rows with index in $\mathcal{C}_2$, has an entry 0 or ± 1 in position a.

To show that D' is bipartite, suppose that it has an (undirected) circuit of odd length. Since this circuit is odd, and since D' is acyclic, it follows that there are distinct $U_0, U_1, \ldots, U_k, U_{k+1}$ in $\mathcal{C}$, with $k \geq 3$, such that

(57.21) $(U_1, U_0), (U_1, U_2), (U_2, U_3), \ldots, (U_{k-1}, U_k), (U_{k+1}, U_k)$

belong to A'. So U_0 and U_2 are distinct minimal sets in $\mathcal{C}$ containing U_1 as a subset. As $\mathcal{C}$ is cross-free, $U_0 \cup U_2 = V$. Similarly, U_{k-1} and U_{k+1} are distinct maximal subsets of U_k, and hence $U_{k-1} \cap U_{k+1} = \emptyset$. As $U_2 \subseteq U_{k-1}$, it follows that $U_1 \subseteq U_0 \cap U_2$, $U_0 \cup U_2 = V$, $U_2 \cup U_{k+1} \subseteq U_k$, and $U_2 \cap U_{k+1} = \emptyset$. This contradicts (57.14)(iii). ∎

This gives the box-TDI result:

Theorem 57.5. *Let $\mathcal{C}$ be a crossing family of nonempty proper subsets of a set V satisfying* (57.14)(iii) *and let $D = (V, A)$ be a digraph. Then the system*

(57.22) $\quad x_a \geq 0 \quad$ for $a \in A$,
$\quad x(\delta^{\text{in}}(U)) \geq 1 \quad$ for $U \in \mathcal{C}$,

is box-TDI.

Proof. Let $w : A \to \mathbb{R}_+$. Consider the maximum value of

(57.23) $$\sum_{U \in \mathcal{C}} y_U$$

where $y : \mathcal{C} \to \mathbb{R}_+$ satisfies

(57.24) $$\sum_{U \in \mathcal{C}} y_U \chi^{\delta^{\text{in}}(U)} \leq w.$$

Choose $y : \mathcal{C} \to \mathbb{R}_+$ attaining the maximum, such that

(57.25) $$\sum_{U \in \mathcal{C}} y_U |U||V \setminus U|$$

is minimized. We show that the collection $\mathcal{F} := \{U \in \mathcal{C} \mid y_U > 0\}$ is cross-free; that is, for all $T, U \in \mathcal{F}$ one has

(57.26) $\quad T \subseteq U$ or $U \subseteq T$ or $T \cap U = \emptyset$ or $T \cup U = V$.

Suppose that this is not true. Let $\alpha := \min\{y_T, y_U\}$. Decrease y_T and y_U by α, and increase $y_{T\cap U}$ and $y_{T\cup U}$ by α. Now (57.24) is maintained, and (57.23) did not change. However, (57.25) decreases (Theorem 2.1), contradicting our minimality assumption.

So $\mathcal{F}$ is cross-free. As $M_{\mathcal{F}}$ is totally unimodular by Lemma 57.5α, this gives the box-total dual integrality of (57.22) by Theorem 5.35. ∎

Condition (57.14)(iii) is necessary and sufficient for integrality of the polyhedron:

Corollary 57.5a. *For any crossing family $\mathcal{C}$ of nonempty proper subsets of a set V,* (57.22) *defines an integer polyhedron for each digraph $D = (V, A)$ if and only if condition* (57.14)(iii) *holds.*

Proof. Sufficiency follows from Theorem 57.5. To see necessity, suppose that (57.22)(iii) does not hold. Let $V_1, \ldots, V_5$ in $\mathcal{C}$ with $V_1 \subsetneq V_3 \subsetneq V_5$, $V_1 \subsetneq V_2$, $V_2 \cup V_3 = V$, $V_3 \cap V_4 = \emptyset$, and $V_4 \subsetneq V_5$. Let $\mathcal{C}_0 := \{V_1, \ldots, V_5\}$ and $\mathcal{C}_1 := \mathcal{C} \setminus \mathcal{C}_0$. Choose $v_1 \in V_1$, $v_2 \in V \setminus V_2$, $v_4 \in V_4$, $v_5 \in V \setminus V_5$. Let $D = (V, A)$ be a digraph, with $A = A_0 \cup A_1$, where A_0 is as defined in (57.18) and where

(57.27) $\quad A_1 := \{(u, v) \mid u, v \in V$ such that (u, v) enters no V_i $(i = 1, \ldots, 5)\}$.

Then

(57.28) $\quad$ each set in $\mathcal{C}_1$ is either entered by at least one arc in A_1 or by at least two arcs in A_0.

To see this, by definition of A_1, a subset U of V is entered by no arc in A_1 if and only if U belongs to the lattice generated by $\mathcal{C}_0$ (with respect to inclusion). This lattice consists of the sets

(57.29) $\emptyset, V, V_1, \ldots, V_5, V_1 \cup V_4, V_2 \cap V_3, (V_2 \cap V_3) \cup V_4, V_3 \cup V_4, V_2 \cap V_5,$

as (57.29) is closed under taking unions and intersections, and as each set in (57.29) is generated by taking unions and intersections from $\mathcal{C}_0$. Since each of the sets in (57.29), except $\emptyset$ and V, is entered by at least two arcs in A_0, we have (57.28).

(57.19) and (57.28) give:

(57.30) any $\mathcal{C}$-cover in A contains at least three arcs in A_0, and any $\mathcal{C}$-cut contains at least one arc in A_1 or at least two arcs in A_0.

Define $x : A \to \mathbb{Q}$ be $x := \chi^{A_1} + \frac{1}{2}\chi^{A_0}$ and a length function $l : A \to \mathbb{Z}$ by $l := \chi^{A_0}$. Then x satisfies (57.22) and $l^{\mathsf{T}} x = \frac{5}{2}$. However, $l(C) \geq 3$ for each $\mathcal{C}$-cover C. So (57.22) determines no integer polyhedron. ∎

Theorem 57.5 and Corollary 57.5a imply the equivalence of (57.14)(ii) and (iii). For the proof of the equivalence of (57.14)(i) and (iii), we refer to Schrijver [1983b].

Chapter 58

The traveling salesman problem

The traveling salesman problem (TSP) asks for a shortest Hamiltonian circuit in a graph. It belongs to the most seductive problems in combinatorial optimization, thanks to a blend of complexity, applicability, and appeal to imagination.

The problem shows up in practice not only in routing but also in various other applications like machine scheduling (ordering jobs), clustering, computer wiring, and curve reconstruction.

The traveling salesman problem is an NP-complete problem, and no polynomial-time algorithm is known. As such, the problem would not fit in the scope of the present book. However, the TSP is closely related to several of the problem areas discussed before, like 2-matching, spanning tree, and cutting planes, which areas actually were stimulated by questions prompted by the TSP, and often provide subroutines in solving the TSP.

Being NP-complete, the TSP has served as prototype for the development and improvement of advanced computational methods, to a large extent utilizing polyhedral techniques. The basis of the solution techniques for the TSP is branch-and-bound, for which good bounding techniques are essential. Here 'good' is determined by two, often conflicting, criteria: the bound should be *tight* and *fast* to compute. Polyhedral bounds turn out to be good candidates for such bounds.

58.1. The traveling salesman problem

Given a graph $G = (V, E)$, a *Hamiltonian circuit* in G is a circuit C with $VC = V$. The *symmetric traveling salesman problem* (TSP) is: given a graph $G = (V, E)$ and a length function $l : E \to \mathbb{R}$, find a Hamiltonian circuit C of minimum length.

The directed version is as follows. Given a digraph $D = (V, A)$, a *directed Hamiltonian circuit*, or just a *Hamiltonian circuit*, in D is a directed circuit C with $VC = V$. The *asymmetric traveling salesman problem* (TSP or ATSP) is: given a digraph $D = (V, A)$ and a length function $l : A \to \mathbb{R}$, find a Hamiltonian circuit C of minimum length.

In the context of the traveling salesman problem, vertices are sometimes called *cities*, and a Hamiltonian circuit a *traveling salesman tour*. If the vertices are represented by points in the plane and each pair of vertices is connected by an edge of length equal to the Euclidean distance between the two points, one speaks of the *Euclidean traveling salesman problem*.

58.2. NP-completeness of the TSP

The problem of finding a Hamiltonian circuit and (hence) the traveling salesman problem are NP-complete. Indeed, in Theorem 8.11 and Corollary 8.11b we proved the NP-completeness of the directed and undirected Hamiltonian circuit problem. This implies the NP-completeness of the TSP, both in the undirected and the directed case:

Theorem 58.1. *The symmetric TSP and the asymmetric TSP are* NP-*complete.*

Proof. Given an undirected graph $G = (V, E)$, define $l(e) := 0$ for each edge e. Then G has a Hamiltonian circuit if and only if G has a Hamiltonian circuit of length ≤ 0. This reduces the undirected Hamiltonian circuit problem to the symmetric TSP.

One similarly shows the NP-completeness of the asymmetric TSP. ∎

This method also gives that the symmetric TSP remains NP-complete if the graph is complete and the length function satisfies the *triangle inequality*:

(58.1) $$l(uw) \leq l(uv) + l(vw) \text{ for all } u, v, w \in V.$$

Indeed, to test if a graph $G = (V, E)$ has a Hamiltonian circuit, define $l(uv) := 1$ if u and v are adjacent and $l(uv) := 2$ otherwise (for $u \neq v$). Then G has a Hamiltonian circuit if and only if there exists a traveling salesman tour of length $\leq |V|$.

Garey, Graham, and Johnson [1976] and Papadimitriou [1977a] showed that even the Euclidean traveling salesman problem is NP-complete. (Similarly for several other metrics, like l_1.) More on complexity can be found in Section 58.8b below.

58.3. Branch-and-bound techniques

The traveling salesman problem is NP-complete, and no polynomial-time algorithm is known. Most exact methods known are essentially enumerative, aiming at minimizing the enumeration. A general framework is that of *branch-and-bound.* The idea of branch-and-bound applied to the traveling salesman problem roots in papers of Tompkins [1956], Rossman and Twery [1958], and Eastman [1959]. The term 'branch and bound' was introduced by Little, Murty, Sweeney, and Karel [1963].

A rough, elementary description is as follows. Let $G = (V, E)$ be a graph and let $l : E \to \mathbb{R}$ be a length function. For any set $\mathcal{C}$ of Hamiltonian circuits, let $\mu(\mathcal{C})$ denote the minimum length of the Hamiltonian circuits in $\mathcal{C}$.

Keep a collection Γ of sets of Hamiltonian circuits and a function $\lambda : \Gamma \to \mathbb{R}$ satisfying:

(58.2) (i) $\bigcup \Gamma$ contains a shortest Hamiltonian circuit;
(ii) $\lambda(\mathcal{C}) \leq \mu(\mathcal{C})$ for each $\mathcal{C} \in \Gamma$.

A typical iteration is:

(58.3) Select a collection $\mathcal{C} \in \Gamma$ with $\lambda(\mathcal{C})$ minimal. Either find a circuit $C \in \mathcal{C}$ with $l(C) = \lambda(\mathcal{C})$ or replace $\mathcal{C}$ by (zero or more) smaller sets such that (58.2) is maintained.

Obviously, if we find $C \in \mathcal{C}$ with $l(C) = \lambda(\mathcal{C})$, then C is a shortest Hamiltonian circuit.

This method always terminates, but the method and its efficiency heavily depend on how the details in this framework are filled in: how to bound (that is, how to define and calculate $\lambda(\mathcal{C})$), how to branch (that is, which smaller sets replace $\mathcal{C}$), and how to find the circuit C.

As for branching, the classes $\mathcal{C}$ in Γ can be stored implicitly: for example, by prescribing sets B and F of edges such that $\mathcal{C}$ consists of all Hamiltonian circuits whose edge set contains B and is disjoint from F. Then we can split $\mathcal{C}$ by selecting an edge $e \in E \setminus (B \cup F)$ and replacing $\mathcal{C}$ by the classes determined by $B \cup \{e\}, F$ and by $B, F \cup \{e\}$ respectively.

As for bounding, one should choose $\lambda(\mathcal{C})$ that is fast to compute and close to $\mu(\mathcal{C})$. For this, polyhedral bounds seem good candidates, and in the coming sections we consider a number of them.

For finding the circuit $C \in \mathcal{C}$, a heuristic or exact method can be used. If it returns a circuit C with $l(C) > \lambda(\mathcal{C})$, we can delete all sets $\mathcal{C}'$ from Γ with $\lambda(\mathcal{C}') \geq l(C)$, thus saving computer space.

58.4. The symmetric traveling salesman polytope

The *(symmetric) traveling salesman polytope* of an undirected graph $G = (V, E)$ is the convex hull of the incidence vectors (in $\mathbb{R}^E$) of the Hamiltonian circuits. The TSP is equivalent to minimizing a function $l^{\mathsf{T}}x$ over the traveling salesman polytope. Hence this is NP-complete.

The NP-completeness of the TSP also implies that, unless NP=co-NP, no description in terms of inequalities of the traveling salesman polytope may be expected (Corollary 5.16a). In fact, as deciding if a Hamiltonian circuit exists is NP-complete, it is NP-complete to decide if the traveling salesman polytope is nonempty. Hence, if NP$\neq$co-NP, there exist no inequalities satisfied by the traveling salesman polytope such that their validity can be certified in polynomial time and such that they have no common solution.

58.5. The subtour elimination constraints

Polynomial-time computable lower bounds on the minimum length of a Hamiltonian circuit can be obtained by including the traveling salesman polytope in a larger polytope (a *relaxation*) over which $l^{\mathsf{T}}x$ can be minimized in polynomial time.

Dantzig, Fulkerson, and Johnson [1954a,1954b] proposed the following relaxation:

(58.4)
$$\begin{array}{rll} \text{(i)} & 0 \leq x_e \leq 1 & \text{for each edge } e, \\ \text{(ii)} & x(\delta(v)) = 2 & \text{for each vertex } v, \\ \text{(iii)} & x(\delta(U)) \geq 2 & \text{for each } U \subseteq V \text{ with } \emptyset \neq U \neq V. \end{array}$$

The integer solutions of (58.4) are precisely the incidence vectors of the Hamiltonian circuits. If (ii) holds, then (iii) is equivalent to:

(58.5) (iii') $x(E[U]) \leq |U| - 1$ for each $U \subseteq V$ with $\emptyset \neq U \neq V$.

These conditions are called the *subtour elimination constraints*.

It can be shown with the ellipsoid method that the minimum of $l^{\mathsf{T}}x$ over (58.4) can be found in strongly polynomial time (cf. Theorem 5.10). For this it suffices to show that the conditions (58.4) can be tested in polynomial time. This is easy for (i) and (ii). If (i) and (ii) are satisfied, we can test (iii) by taking x as capacity function, and test if there is a cut $\delta(U)$ of capacity less than 2, with $\emptyset \neq U \neq V$.

No combinatorial polynomial-time algorithm is known to minimize $l^{\mathsf{T}}x$ over (58.4). In practice, one can apply the simplex method to minimize $l^{\mathsf{T}}x$ over the constraints (i) and (ii), test if the solution satisfies (iii) by finding a cut $\delta(U)$ minimizing $x(\delta(U))$. If this cut has capacity at least 2, then x minimizes $l^{\mathsf{T}}x$ over (58.4). Otherwise, we can add the constraint $x(\delta(U)) \geq 2$ to the simplex tableau (a *cutting plane*), and iterate. (This method is implicit in Dantzig, Fulkerson, and Johnson [1954b].)

Branch-and-bound methods that incorporate such a cutting plane method to obtain bounds and that extend the cutting plane found to all other nodes of the branching tree to improve their bounds, are called *branch-and-cut*.

System (58.4) generally is not enough to determine the traveling salesman polytope: for the Petersen graph $G = (V, E)$, the vector x with $x_e = \frac{2}{3}$ for each $e \in E$ satisfies (58.4) but is not in the traveling salesman polytope of G (as it is empty).

Wolsey [1980] (also Shmoys and Williamson [1990]) showed that if G is complete and the length function l satisfies the triangle inequality, then the minimum of $l^{\mathsf{T}}x$ over (58.4) is at least $\frac{2}{3}$ times the minimum length of a Hamiltonian circuit. It is conjectured (cf. Carr and Vempala [2000]) that for any length function, a lower bound of $\frac{3}{4}$ holds (which is best possible). Related results are given by Papadimitriou and Vempala [2000] and Boyd and Labonté [2002] (who verified the conjecture for $n \leq 10$).

Maurras [1975] and Grötschel and Padberg [1979b] showed that, if G is the complete graph on V and $2 \leq |U| \leq |V|-2$, then the subtour elimination constraint (58.4)(iii) determines a facet of the traveling salesman polytope.

Chvátal [1989] showed the NP-completeness of recognizing if the bound given by the subtour elimination constraints is equal to the length of a shortest tour. He also showed that there is no nontrivial upper bound on the relative error of this bound.

58.6. 1-trees and Lagrangean relaxation

Held and Karp [1971] gave a method to find the minimum value of $l^{\mathsf{T}}x$ over (58.4), with the help of 1-*trees* and *Lagrangean relaxation*.

Let $G = (V, E)$ be a graph and fix a vertex, say 1, of G. A 1-*tree* is a subset F of E such that $|F \cap \delta(1)| = 2$ and such that $F \setminus \delta(1)$ forms a spanning tree on $V \setminus \{1\}$. So each Hamiltonian circuit is a 1-tree with all degrees equal to 2.

It is easy to find a shortest 1-tree F, as it consists of a shortest spanning tree of the graph $G - 1$, joined with the two shortest edges incident with vertex 1. Corollary 50.7c implies that the convex hull of the incidence vectors of 1-trees is given by:

(58.6)
$$\begin{array}{lll} \text{(i)} & 0 \leq x_e \leq 1 & \text{for each } e \in E, \\ \text{(ii)} & x(\delta(1)) = 2, & \\ \text{(iii)} & x(E[U]) \leq |U| - 1 & \text{for each nonempty } U \subseteq V \setminus \{1\}, \\ \text{(iv)} & x(E) = |V|. & \end{array}$$

Then (58.4) is equivalent to (58.6) added with (58.4)(ii).

The Lagrangean relaxation approach to find the minimum of $l^{\mathsf{T}}x$ over (58.4) is based on the following result. For any $y \in \mathbb{R}^V$ define

(58.7)
$$l_y(e) := l(e) - y_u - y_v$$

for $e = uv \in E$, and define

(58.8)
$$f(y) := 2y(V) + \min_F l_y(F),$$

where F ranges over all 1-trees. Christofides [1970] and Held and Karp [1970] observed that for each $y \in \mathbb{R}^V$:

(58.9)
$$f(y) \leq \text{the minimum length of a Hamiltonian circuit,}$$

since if C is a shortest Hamiltonian circuit, then $f(y) \leq 2y(V) + l_y(C) = l(C)$.

The function f is concave. Since a shortest 1-tree can be found fast, also $f(y)$ can be computed fast. Held and Karp [1970] showed:

Theorem 58.2. *The minimum value of* $l^{\mathsf{T}}x$ *over* (58.4) *is equal to the maximum value of* $f(y)$ *over* $y \in \mathbb{R}^V$.

Proof. This follows from general linear programming theory. Let $Ax = b$ be system (58.4)(ii) and let $Cx \geq d$ be system (58.6). As (58.4) is equivalent to $Ax = b$, $Cx \geq d$, we have, using LP-duality:

(58.10)
$$\begin{aligned}\min_{\substack{Ax=b\\ Cx\geq d}} l^{\mathsf{T}}x &= \max_{\substack{y,z\\ z\geq\mathbf{0}\\ y^{\mathsf{T}}A+z^{\mathsf{T}}C=l^{\mathsf{T}}}} y^{\mathsf{T}}b + z^{\mathsf{T}}d \\ &= \max_{y}(y^{\mathsf{T}}b + \max_{\substack{z\geq\mathbf{0}\\ z^{\mathsf{T}}C=l^{\mathsf{T}}-y^{\mathsf{T}}A}} z^{\mathsf{T}}d) = \max_{y}\left(y^{\mathsf{T}}b + \min_{Cx\geq d}(l^{\mathsf{T}}-y^{\mathsf{T}}A)x\right) \\ &= \max_{y} f(y).\end{aligned}$$

The last inequality holds as $Cx \geq d$ determines the convex hull of the incidence vectors of 1-trees. ∎

This translates the problem of minimizing $l^{\mathsf{T}}x$ over (58.4) to finding the maximum of the concave function f. We can find this maximum with a subgradient method (cf. Chapter 24.3 of Schrijver [1986b]). The vector y (the *Lagrangean multipliers*) can be used as a correction mechanism to urge the 1-tree to have degree 2 at each vertex. That is, if we calculate $f(y)$, and see that the 1-tree F minimizing $l_y(F)$ has degree more than 2 at a vertex v, we can increase l_y on $\delta(v)$ by decreasing y_v. Similarly, if the degree is less than 2, we can increase y_v. This method was proposed by Held and Karp [1970,1971].

The advantage of this approach is that one need not implement a linear programming algorithm with a constraint generation technique, but that instead it suffices to apply the more elementary tools of finding a shortest 1-tree and updating y. More can be found in Jünger, Reinelt, and Rinaldi [1995].

58.7. The 2-factor constraints

A strengthening of relaxation (58.4) is obtained by using the facts that each Hamiltonian circuit is a 2-factor and that the convex hull of the incidence vectors of 2-factors is known (Corollary 30.8a) (this idea goes back to Robinson [1949] for the asymmetric TSP and Bellmore and Malone [1971] for the symmetric TSP, and was used for the symmetric TSP by Grötschel [1977a] and Pulleyblank [1979b]):

(58.11)
(i) $0 \leq x_e \leq 1$ for each edge e,
(ii) $x(\delta(v)) = 2$ for each vertex v,
(iii) $x(\delta(U)) \geq 2$ for each $U \subseteq V$ with $\emptyset \neq U \neq V$,
(iv) $x(\delta(U) \setminus F) - x(F) \geq 1 - |F|$
for $U \subseteq V$, $F \subseteq \delta(U)$, F matching, $|F|$ odd.

Since a minimum-length 2-factor can be found in polynomial time, the inequalities (i), (ii), and (iv) can be tested in polynomial time (cf. Theorem 32.5). Hence the minimum of $l^{\mathsf{T}}x$ over (58.11) can be found in strongly polynomial time.

System (58.11) generally is not enough to determine the traveling salesman polytope, as can be seen, by taking the Petersen graph $G = (V, E)$ and $x_e := \frac{2}{3}$ for each edge e.

Grötschel and Padberg [1979b] showed that, for complete graphs, each of the inequalities (58.11)(iv) determines a facet of the traveling salesman polytope (if $|F| \geq 3$). Boyd and Pulleyblank [1991] studied optimization over (58.11).

58.8. The clique tree inequalities

Grötschel and Pulleyblank [1986] found a large class of facet-inducing inequalities, the 'clique tree inequalities', that generalize the 'comb inequalities' (see below), which generalize both the subtour elimination constraints (58.4)(iii) and the 2-factor constraints (58.11)(iv). However, no polynomial-time test of clique tree inequalities is known.

A *clique tree inequality* is given by:

(58.12) $$\sum_{i=1}^{r} x(\delta(H_i)) + \sum_{j=1}^{s} x(\delta(T_j)) \geq 2r + 3s - 1,$$

where $H_1, \ldots, H_r$ are pairwise disjoint subsets of V and $T_1, \ldots, T_s$ are pairwise disjoint proper subsets of V such that

(58.13)
(i) no T_j is contained in $H_1 \cup \cdots \cup H_r$,
(ii) each H_i intersects an odd number of the T_j,
(iii) the intersection graph of $H_1, \ldots, H_r, T_1, \ldots, T_s$ is a tree.

(Here, the *intersection graph* is the graph with vertices $H_1, \ldots, H_r, T_1, \ldots, T_s$, two of them being adjacent if and only if they intersect. Each H_i is called a *handle* and each T_j a *tooth*.)

Theorem 58.3. *The clique tree inequality* (58.12) *is valid for the traveling salesman polytope.*

Proof. It suffices to show that each Hamiltonian circuit C satisfies:

(58.14) $$\sum_{i=1}^{r} d_C(H_i) + \sum_{j=1}^{s} d_C(T_j) \geq 2r + 3s - 1.$$

We apply induction on r, the case $r = 0$ being easy (as it implies $s = 1$). For each $i = 1, \ldots, r$, let β_i be the number of T_j intersecting H_i.

If there is an i with $d_C(H_i) \geq \beta_i$, say $i = 1$, then, by parity, $d_C(H_1) \geq \beta_1 + 1$. The sets $H_2, \ldots, H_r, T_1, \ldots, T_s$ fall apart into β_1 collections of type (58.13), to which we can apply induction. Adding up the inequalities obtained, we get:

$$(58.15) \qquad \sum_{i=2}^{r} d_C(H_i) + \sum_{j=1}^{s} d_C(T_j) \geq 2(r-1) + 3s - \beta_1.$$

Then (58.14) follows, as $d_C(H_1) \geq \beta_1 + 1$.

So we can assume that $d_C(H_i) \leq \beta_i - 1$ for each i. For all i, j, let $\alpha_{i,j} := 1$ if $T_j \cap H_i \neq \emptyset$ and C has no edge connecting $T_j \cap H_i$ and $T_j \setminus H_i$, and let $\alpha_{i,j} := 0$ otherwise. Then

$$(58.16) \qquad d_C(T_j) \geq 2 + 2\sum_{i=1}^{r} \alpha_{i,j},$$

since C restricted to T_j falls apart into at least $1 + \sum_{i=1}^{r} \alpha_{i,j}$ components (using (58.13)(i)).

Moreover, for each $i = 1, \ldots, r$, there exist at least $\beta_i - d_C(H_i)$ indices j with $\alpha_{i,j} = 1$. Hence

$$(58.17) \qquad \begin{aligned} \sum_{j=1}^{s} d_C(T_j) &\geq 2s + 2\sum_{i=1}^{r}\sum_{j=1}^{s} \alpha_{i,j} \geq 2s + 2\sum_{i=1}^{r}(\beta_i - d_C(H_i)) \\ &\geq 2s + r + \sum_{i=1}^{r}(\beta_i - d_C(H_i)) = 2r + 3s - 1 - \sum_{i=1}^{r} d_C(H_i), \end{aligned}$$

since $\sum_{i=1}^{r} \beta_i = r + s - 1$, as the intersection graph of the H_i and the T_j is a tree with $r + s$ vertices, and hence with $r + s - 1$ edges.

(58.17) implies (58.14). ∎

Notes. Grötschel and Pulleyblank [1986] also showed that, if G is a complete graph, then any clique tree inequality determines a facet if and only if each H_i intersects at least three of the T_j.

The clique tree inequalities are not enough to determine the traveling salesman polytope, as is shown again by taking the Petersen graph $G = (V, E)$ and $x_e := \frac{2}{3}$ for all $e \in E$.

The special case $r = 1$ of the clique tree inequality is called a *comb inequality*, and was introduced by Grötschel and Padberg [1979a] and proved to be facet-inducing (if G is complete and $s \geq 3$) by Grötschel and Padberg [1979b].

The special case of the comb inequality with $|H_1 \cap T_j| = 1$ for all $j = 1, \ldots, s$ is called a *Chvátal comb inequality*, introduced by Chvátal [1973b]. The special case of the Chvátal comb inequalities with $|T_j| = 2$ for each $j = 1, \ldots, s$ gives the 2-factor constraints (58.11)(iv) (since $2x(F) + \sum_{f \in F} x(\delta(f)) = 4|F|$).

No polynomial-time algorithm is know to test the clique tree inequalities, or the comb inequalities, or the Chvátal comb inequalities. Carr [1995,1997] showed that for each constant K, there is a polynomial-time algorithm to test the clique tree inequalities with at most K teeth and handles. (This can be done by first fixing intersection points of the $H_i \cap T_j$ (if nonempty) and points in $T_j \setminus (H_1 \cup \cdots \cup H_r)$, and next finding minimum-capacity cuts separating the appropriate sets of these points (taking x as capacity function). We can make them disjoint where necessary by the usual uncrossing techniques. As K is fixed, the number of vertices to be chosen is also bounded by a polynomial in $|V|$.)

Letchford [2000] gave a polynomial-time algorithm for testing a superclass of the comb inequalities in planar graphs. Related results are given in Carr [1996], Fleischer and Tardos [1996,1999], Letchford and Lodi [2002], and Naddef and Thienel [2002a,2002b].

58.8a. Christofides' heuristic for the TSP

Christofides [1976] designed the following algorithm to find a short Hamiltonian circuit in a complete graph $G = (V, E)$ (generally not the shortest however). It assumes a nonnegative length function l satisfying the following *triangle inequality*:

(58.18) $$l(uw) \leq l(uv) + l(vw)$$

for all $u, v, w \in V$.

First determine a shortest spanning tree T (with the greedy algorithm). Next, let U be the set of vertices that have odd degree in T. Find a shortest perfect matching M on U. Now $ET \cup M$ forms a set of edges such that each vertex has even degree. (If an edge occurs both in ET and in M, we take it as two parallel edges.) So we can make a closed path C such that each edge in $ET \cup M$ is traversed exactly once. Then C traverses each vertex at least once. By shortcutting we obtain a Hamiltonian circuit C' with $l(C') \leq l(C)$.

How far away is the length of C' from the minimum length μ of a Hamiltonian circuit?

Theorem 58.4. *$l(C') \leq \frac{3}{2}\mu$.*

Proof. Let C'' be a shortest Hamiltonian circuit. Then $l(T) \leq l(C'') = \mu$, since C'' contains a spanning tree. Also, $l(M) \leq \frac{1}{2}l(C'') = \frac{1}{2}\mu$, since we can split C'' into two collections of paths, each having U as set of end vertices. They give two perfect matchings on U, of total length at most $l(C'')$ (by the triangle inequality (58.18)). Hence one of these matchings has length at most $\frac{1}{2}l(C'')$. So $l(M) \leq \frac{1}{2}l(C'') = \frac{1}{2}\mu$.

Combining the two inequalities, we obtain

(58.19) $$l(C') \leq l(C) = l(T) + l(M) \leq \tfrac{3}{2}\mu,$$

which proves the theorem. ∎

The factor $\frac{3}{2}$ seems quite large, but it is the smallest factor for which a polynomial-time method is known. Don't forget moreover that it is a *worst-case* bound, and that in practice (or on average) the algorithm might have a much better performance.

Wolsey [1980] showed more strongly that (if l satisfies the triangle inequality) the length of the tour found by Christofides' algorithm, is at most $\frac{3}{2}$ times the lower bound based on the subtour elimination constraints (58.4). If all distances are 1 or 2, Papadimitriou and Yannakakis [1993] gave a polynomial-time algorithm with worst-case factor $\frac{7}{6}$. Hoogeveen [1991] analyzed the behaviour of Christofides' heuristic when applied to finding shortest Hamiltonian paths.

58.8b. Further notes on the symmetric traveling salesman problem

Adjacency of vertices of the symmetric traveling salesman polytope of a graph $G = (V, E)$ is co-NP-complete, as was shown by Papadimitriou [1978].

Norman [1955] remarked that the symmetric traveling salesman polytope of the complete graph K_n has dimension $\frac{1}{2}n(n-3) = \binom{n}{2} - n$ (if $n \geq 3$). Proofs were given by Maurras [1975] and Grötschel and Padberg [1979a].

The symmetric traveling salesman polytopes of K_n for small n were studied by Norman [1955], Boyd and Cunningham [1991], Christof, Jünger, and Reinelt [1991] ($n = 8$), and Naddef and Rinaldi [1992,1993]. Weinberger [1974a] showed that the up hull of the symmetric traveling salesman polytope of K_6 is not determined by inequalities with $0, 1$ coefficients only.

Rispoli and Cosares [1998] showed that the diameter of the symmetric traveling salesman polytope of a complete graph is at most 4. Grötschel and Padberg [1985] conjecture that it is at most 2. (See Sierksma and Tijssen [1992] and Sierksma, Teunter, and Tijssen [1995] for supporting results.) Further work on the symmetric traveling salesman polytope includes Naddef and Rinaldi [1993], Queyranne and Wang [1993], Carr [2000], Cook and Dash [2001], and Naddef and Pochet [2001].

Rispoli [1998] showed that the monotonic diameter of the symmetric traveling salesman polytope of K_n is $\lfloor n/2 \rfloor - 1$ if $n \geq 6$. (The *monotonic diameter* of a polytope is the minimum λ such that for each linear function $l^{\mathsf{T}}x$ and each pair of vertices y, z such that $l^{\mathsf{T}}x$ is maximized over P at z, there is a $y - z$ path along vertices and edges of the polytope such that the function $l^{\mathsf{T}}x$ is monotonically nondecreasing and such that the number of edges in the path is at most λ.)

Sahni and Gonzalez [1976] showed that for any constant c, unless P=NP, there is no polynomial-time algorithm finding a Hamiltonian circuit of length at most c times the minimum length of a Hamiltonian circuit. Johnson and Papadimitriou [1985a] showed that unless P=NP there is no *fully polynomial approximation scheme* for the Euclidean traveling salesman problem (that is, there is no algorithm that gives for any $\varepsilon > 0$, a Hamiltonian circuit of length at most $1+\varepsilon$ times the minimum length of a Hamiltonian circuit, with running time bounded by a polynomial in the size of the problem and in $1/\varepsilon$).

However, Arora [1996,1997,1998] showed that for the Euclidean TSP there is a polynomial approximation scheme: there is an algorithm that gives, for any n vertices in the plane and any $\varepsilon > 0$, a Hamiltonian circuit of length at most $1 + \varepsilon$ times the minimum length of a Hamiltonian circuit, in $n^{O(1/\varepsilon)}$ time. The method also applies to several other metrics. Mitchell [1999] noticed that the methods of Mitchell [1996] imply similar results. Related work is reported in Trevisan [1997, 2000], Rao and Smith [1998], and Dumitrescu and Mitchell [2001]. Earlier work on plane TSP includes Karp [1977], Steele [1981], Moran [1984], Karloff [1989], and Clarkson [1991].

A polynomial-time approximation scheme for the traveling salesman problem where the length is determined by the shortest path metric in a weighted planar graph was given by Arora, Grigni, Karger, Klein, and Woloszyn [1998] (extending the unweighted case proved by Grigni, Koutsoupias, and Papadimitriou [1995]).

Yannakakis [1988,1991] showed that the traveling salesman problem on K_n cannot be expressed by a linear program of polynomial size that is invariant under the symmetric group on K_n. (A similar negative result was proved by Yannakakis for the perfect matching polytope.)

More valid inequalities for the symmetric traveling salesman polytope were given by Grötschel [1980a], Papadimitriou and Yannakakis [1984], Fleischmann [1988], Boyd and Cunningham [1991], Naddef [1992], Naddef and Rinaldi [1992], and Boyd, Cunningham, Queyranne, and Wang [1995].

Jünger, Reinelt, and Rinaldi [1995] gave a comparison of the values of various relaxations for several instances of the symmetric traveling salesman problem. Johnson, McGeoch, and Rothberg [1996] report on an 'asymptotic experimental analysis' of the Held-Karp bound. A probabilistic analysis of the Held-Karp bound for the Euclidean TSP was presented by Goemans and Bertsimas [1991].

A worst-case comparison of several classes of valid inequalities for the traveling salesman polytope was given by Goemans [1995]. Several integer programming formulations for the TSP were compared by Langevin, Soumis, and Desrosiers [1990]. Althaus and Mehlhorn [2000,2001] showed that the subtour elimination constraints solve traveling salesman problems coming from curve reconstruction, under appropriate sampling conditions.

Semidefinite programming was applied to the symmetric TSP by Cvetković, Čangalović, and Kovačević-Vujčić [1999a,1999b] and Iyengar and Çezik [2001].

Let $G = (V, E)$ be an undirected graph. The symmetric traveling salesman polytope of G is a face of the convex hull of all integer solutions of

$$\text{(58.20)} \qquad \begin{array}{rll} \text{(i)} & x_e \geq 0 & \text{for each } e \in E, \\ \text{(ii)} & x(\delta(U)) \geq 2 & \text{for each } U \subseteq V \text{ with } \emptyset \neq U \neq V. \end{array}$$

Fonlupt and Naddef [1992] characterized for which graphs G each vertex x of (58.20) is integer and has $x(\delta(v)) \equiv 0 \pmod 2$ for each vertex v of G.

Grötschel [1980a] studied the *monotone traveling salesman polytope* of a graph, which is the convex hull of the incidence vectors of subsets of Hamiltonian circuits.

Cornuéjols, Fonlupt, and Naddef [1985] considered the related problem of finding a shortest tour in a graph such that each vertex is traversed *at least* once, and the related polytope (cf. Naddef and Rinaldi [1991]). Further and related studies (also on shortest k-connected spanning subgraphs, on the 'Steiner network problem', and on the (equivalent) 'survivable network design problem') include Bienstock, Brickell, and Monma [1990], Grötschel and Monma [1990], Monma, Munson, and Pulleyblank [1990], Kelsen and Ramachandran [1991,1995], Barahona and Mahjoub [1992,1995], Chopra [1992,1994], Goemans and Williamson [1992,1995a], Grötschel, Monma, and Stoer [1992], Han, Kelsen, Ramachandran, and Tarjan [1992,1995], Khuller and Vishkin [1992,1994], Nagamochi and Ibaraki [1992a], Cheriyan, Kao, and Thurimella [1993], Gabow, Goemans, and Williamson [1993,1998], Garg, Santosh, and Singla [1993], Naddef and Rinaldi [1993], Queyranne and Wang [1993], Williamson, Goemans, Mihail, and Vazirani [1993,1995], Aggarwal and Garg [1994], Goemans, Goldberg, Plotkin, Shmoys, Tardos, and Williamson [1994], Khuller, Raghavachari, and Young [1994,1995a,1996], Mahjoub [1994,1997], Agrawal, Klein, and Ravi [1995], Khuller and Raghavachari [1995], Ravi and Williamson [1995, 1997], Cheriyan and Thurimella [1996a,2000], Didi Biha and Mahjoub [1996], Fernandes [1997,1998], Carr and Ravi [1998], Cheriyan, Sebő, and Szigeti [1998,2001], Auletta, Dinitz, Nutov, and Parente [1999], Czumaj and Lingas [1998,1999], Jain [1998,2001], Fonlupt and Mahjoub [1999], Fleischer, Jain, and Williamson [2001], Cheriyan, Vempala, and Vetta [2002], and Gabow [2002]. This problem relates to connectivity augmentation — see Chapter 63.

58.9. The asymmetric traveling salesman problem

We next consider the *asymmetric* traveling salesman problem. Let $D = (V, A)$ be a directed graph. The *(asymmetric) traveling salesman polytope* of D is the convex hull of the incidence vectors (in $\mathbb{R}^A$) of Hamiltonian circuits in D. Again, since the asymmetric traveling salesman problem is NP-complete, we know that unless NP=co-NP there is no system of linear inequalities that describes the traveling salesman polytope of a digraph such that their validity can be certified in polynomial time.

Again, we can obtain lower bounds on the minimum length of a Hamiltonian circuit in D by including the traveling salesman polytope in a larger polytope (a *relaxation*) over which $l^{\mathsf{T}}x$ can be minimized in polynomial time. The analogue of relaxation (58.4) for the directed case is:

(58.21)
$$\begin{array}{lll} \text{(i)} & 0 \leq x_a \leq 1 & \text{for } a \in A, \\ \text{(ii)} & x(\delta^{\text{in}}(v)) = 1 & \text{for } v \in V, \\ \text{(iii)} & x(\delta^{\text{out}}(v)) = 1 & \text{for } v \in V, \\ \text{(iv)} & x(\delta^{\text{in}}(U)) \geq 1 & \text{for } U \subseteq V \text{ with } \emptyset \neq U \neq V. \end{array}$$

With the ellipsoid method, the minimum of $l^{\mathsf{T}}x$ over (58.21) can be found in strongly polynomial time. However, no combinatorial polynomial-time algorithm is known. (The relaxation (i), (ii), (iii) is due to Robinson [1949].)

Grötschel and Padberg [1977] showed that each inequality (58.21)(iv) determines a facet of the traveling salesman polytope of the complete directed graph, if $2 \leq |U| \leq |U| - 2$. (This result was announced in Grötschel and Padberg [1975].)

(58.21) is not enough to determine the traveling salesman polytope, even not for digraphs on 4 vertices only. This is shown by Figure 58.1. Another example is obtained from the Petersen graph, by replacing each edge by two oppositely oriented edges and putting value $\frac{1}{3}$ on each arc.

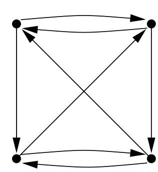

Figure 58.1

Setting $x_a := \frac{1}{2}$ for each arc a, we have a vector x satisfying (58.21) but not belonging to the traveling salesman polytope.

58.10. Directed 1-trees

As in the undirected case, Held and Karp [1970] showed that the minimum of $l^{\mathsf{T}}x$ over (58.21) can be obtained as follows.

Let $D = (V, A)$ be a digraph and fix a vertex 1 of D. Call a subset F of A a *directed* 1-*tree* if F contains exactly one arc, a say, entering 1 and if $F \setminus \{a\}$ is a directed 1-tree such that exactly one arc leaves 1.[7] Each Hamiltonian circuit is a directed 1-tree, and a minimum-length directed 1-tree can be found in strongly polynomial time (by adapting Theorem 52.1).

From Corollary 52.3b one may derive that the convex hull of the incidence vectors of directed 1-trees is determined by:

$$\text{(58.22)} \quad \begin{array}{rll} \text{(i)} & 0 \leq x_a \leq 1 & \text{for } a \in A, \\ \text{(ii)} & x(\delta^{\text{in}}(v)) = 1 & \text{for each } v \in V, \\ \text{(iii)} & x(\delta^{\text{out}}(1)) = 1, & \\ \text{(iv)} & x(\delta^{\text{in}}(U)) \geq 1 & \text{for each nonempty } U \subseteq V \setminus \{1\}. \end{array}$$

Again, a *Lagrangean relaxation* approach can find the minimum of $l^{\mathsf{T}}x$ over (58.21), for $l \in \mathbb{R}^A$. For any $y \in \mathbb{R}^V$ define

$$\text{(58.23)} \quad l_y(a) := l(a) - y(u)$$

for any arc $a = (u, v) \in A$, and define

$$\text{(58.24)} \quad f(y) := \min_F l_y(F) + y(V),$$

where F ranges over directed 1-trees.

Then the minimum of $l^{\mathsf{T}}x$ over (58.21) is equal to the maximum of $f(y)$ over $y \in \mathbb{R}^V$. The proof is similar to that of Theorem 58.2.

58.10a. An integer programming formulation

The integer solutions of (58.21) are precisely the incidence vectors of Hamiltonian circuits, so it gives an integer programming formulation of the asymmetric traveling salesman problem. The system has exponentially many constraints. A.W. Tucker showed in 1960 (cf. Miller, Tucker, and Zemlin [1960]) that the asymmetric TSP can be formulated as the following integer programming problem, of polynomial size only. Set $n := |V|$, fix a vertex v_0 of D, and minimize $l^{\mathsf{T}}x$ where $x \in \mathbb{Z}^A$ and $z \in \mathbb{R}^V$ are such that

$$\text{(58.25)} \quad \begin{array}{rll} \text{(i)} & x_a \geq 0 & \text{for } a \in A, \\ \text{(ii)} & x(\delta^{\text{in}}(v)) = 1 & \text{for } v \in V, \\ \text{(ii)} & x(\delta^{\text{out}}(v)) = 1 & \text{for } v \in V, \\ \text{(iv)} & z_u - z_v + nx_a \leq n - 1 & \text{for } a = (u, v) \in A \text{ with } u, v \neq v_0. \end{array}$$

[7] Held and Karp used the term 1-*arborescence* for a directed 1-tree. To avoid confusion with r-arborescence (a slightly different notion), we have chosen for directed 1-tree.

The conditions (i), (ii), and (iii) and the integrality of x guarantee that x is the incidence vector of a set C of arcs forming directed circuits partitioning V. Then condition (iv) says the following. For any arc $a = (u, v)$ not incident with v_0, one has: if a belongs to C, then $z_u \leq z_v - 1$; if a does not belong to C, then $z_u - z_v \leq n - 1$. This implies that C contains no directed circuit disjoint from v_0. Hence C is a Hamiltonian circuit.

Conversely, for any incidence vector x of a Hamiltonian circuit, one can find $z \in \mathbb{R}^V$ satisfying (58.25).

Unfortunately, the linear programming bound one may derive from (58.25) is generally much worse than that obtained from (58.21).

58.10b. Further notes on the asymmetric traveling salesman problem

Bartels and Bartels [1989] gave a system of inequalities determining the traveling salesman polytope of the complete directed graph on 5 vertices (correcting Heller [1953a] and Kuhn [1955a]).

Padberg and Rao [1974] showed that the diameter of the asymmetric traveling salesman polytope of the complete directed graph on n vertices is equal to 1 if $3 \leq n \leq 5$, and to 2 if $n \geq 6$. Rispoli [1998] showed that the monotonic diameter of the asymmetric traveling salesman polytope of the complete directed graph on n vertices equals $\lfloor n/3 \rfloor$ if $n \geq 3$. (For the definition of monotonic diameter, see Section 58.8b.)

Adjacency of vertices of the asymmetric traveling salesman polytope of a graph $G = (V, E)$ is co-NP-complete, as was shown by Papadimitriou [1978][8]. The number of edges of the asymmetric traveling salesman polytope was estimated by Sarangarajan [1997].

H.W. Kuhn (cf. Heller [1953a], Kuhn [1955a]) claimed that the dimension of the asymmetric traveling salesman polytope of the complete directed graph on n vertices is equal to $n^2 - 3n + 1$ (if $n \geq 3$). A proof of this was supplied by Grötschel and Padberg [1977]. Further work on this polytope is reported in Kuhn [1991].

More valid inequalities for the asymmetric traveling salesman polytope were given by Grötschel and Padberg [1977], Grötschel and Wakabayashi [1981a,1981b], Balas [1989], Fischetti [1991,1992,1995], Balas and Fischetti [1993,1999], and Queyranne and Wang [1995].

A polytope generalizing the directed 1-tree polytope and the asymmetric traveling salesman polytope, the 'fixed-outdegree 1-arborescence polytope', was studied by Balas and Fischetti [1992]. Another polyhedron related to the asymmetric traveling salesman polytope was studied by Chopra and Rinaldi [1996].

Billera and Sarangarajan [1996] showed that each 0,1 polytope is affinely equivalent to the traveling salesman polytope of some directed graph.

Frieze, Karp, and Reed [1992,1995] investigated the tightness of the assignment bound (determined by (58.21)(i)-(iii)). Williamson [1992] compared the Held-Karp lower bound for the asymmetric TSP with the assignment bound.

Carr and Vempala [2000] related the relative error of the asymmetric TSP bound obtained from (58.21) to that of the symmetric TSP bound obtained from (58.4).

[8] Murty [1969] gave a characterization of adjacency that was shown to be false by Rao [1976].

Padberg and Sung [1991] compared different formulations of the asymmetric traveling salesman problem.

An analogue of Christofides' algorithm (Section 58.8a) for the asymmetric case is not known: no factor c and polynomial-time algorithm are known that give a Hamiltonian circuit in a digraph of length at most c times the length of a shortest Hamiltonian circuit, even not if the lengths satisfy the triangle inequality.

58.11. Further notes on the traveling salesman problem

58.11a. Further notes

There is an abundance of papers presenting algorithms, heuristics, and computational results for the traveling salesman problem. We give a short selection of it.

Milestones in solving large-scale symmetric traveling salesman problems were achieved by Dantzig, Fulkerson, and Johnson [1954b] (42 cities), Held and Karp [1962] (48 cities), Karg and Thompson [1964] (57 cities), Held and Karp [1971] (64 cities), Helbig Hansen and Krarup [1974] (80 cities), Camerini, Fratta, and Maffioli [1975] (100 cities), Grötschel [1980b] (120 cities), Crowder and Padberg [1980] and Padberg and Hong [1980] (318 cities), Padberg and Rinaldi [1987] (532 cities), Grötschel and Holland [1991] (666 cities), Padberg and Rinaldi [1990b,1991] (2392 cities), Applegate, Bixby, Chvátal, and Cook [1995] (7397 cities), and Applegate, Bixby, Chvátal, and Cook [1998] (13,509 cities). Although the complexity of a TSP instance is not simply a function of the number of cities, these papers represent substantial steps forward in developing computational techniques for the traveling salesman problem.

Dynamic programming approaches were proposed by Bellman [1962] and Held and Karp [1962]. Several methods were compared by computer experiments by Lin [1965]. The Lagrangean relaxation technique was introduced by Christofides [1970] and Held and Karp [1970,1971]. The Held-Karp method was implemented and extended by Helbig Hansen and Krarup [1974], Smith and Thompson [1977], and Volgenant and Jonker [1982,1983]. Related work includes Bazaraa and Goode [1977].

Miliotis [1976,1978] described a constraint generation approach, mixing subtour elimination constraints with Gomory cuts or with branching. Focusing on the asymmetric TSP are Little, Murty, Sweeney, and Karel [1963] (first reports on a branch-and-bound method), Bellmore and Malone [1971] (on the effect of the subtour elimination constraints), (cf. Garfinkel [1973], Smith, Srinivasan, and Thompson [1977], Lenstra and Rinnooy Kan [1978], Carpaneto and Toth [1980b], Zhang [1997a]), Balas and Christofides [1981] (a Lagrangean approach based on the assignment problem, solving randomly generated asymmetric TSP's with up to 325 cities), Miller and Pekny [1989,1991], Pekny and Miller [1992], and Carpaneto, Dell'Amico, and Toth [1995].

Further bounds for the symmetric and asymmetric TSP were given by Christofides [1972], Carpaneto, Fischetti, and Toth [1989] and Fischetti and Toth [1992].

Important heuristics (algorithms that yield a tour that is expected to be short, but not necessarily shortest) and local search techniques include the *nearest neighbour heuristic*: always go to the closest city not yet visited (Menger [1932a], Gavett

[1965], Bellmore and Nemhauser [1968]), the *Lin-Kernighan heuristic*: start with a Hamiltonian circuit and iteratively replace a limited number of edges by other edges as long as it makes the circuit shorter (Lin and Kernighan [1973]), and Christofides' heuristic discussed in Section 58.8a. From the further work on, and analyses of, heuristics and local search techniques we mention Christofides and Eilon [1972], Rosenkrantz, Stearns, and Lewis [1977], Cornuéjols and Nemhauser [1978], Frieze [1979], d'Atri [1980], Bentley and Saxe [1980], Ong and Moore [1984], Golden and Stewart [1985] (survey), Johnson and Papadimitriou [1985b] (survey), Karp and Steele [1985] (survey), Johnson, Papadimitriou, and Yannakakis [1988], Kern [1989], Bentley [1990,1992], Papadimitriou [1992] (showing that unless P=NP, any local search method taking polynomial time per iteration, can lead to a locally optimum tour that is arbitrarily far from the optimum), Fredman, Johnson, McGeoch, and Ostheimer [1993,1995], Chandra, Karloff, and Tovey [1994,1999], Tassiulas [1997], and Frieze and Sorkin [2001]. A survey and comparison of heuristics and local search techniques for the traveling salesman problem was given by Johnson and McGeoch [1997].

Polynomial-time solvable special cases of the traveling salesman problem were given by Gilmore and Gomory [1964a,1964b], Gilmore [1966], Lawler [1971a], Sysło [1973], Cornuéjols, Naddef, and Pulleyblank [1983], and Hartvigsen and Pulleyblank [1994]. Surveys of such problems were given by Gilmore, Lawler, and Shmoys [1985] and Burkard, Deĭneko, van Dal, van der Veen, and Woeginger [1998].

The standard reference book on the traveling salesman problem, covering a wide variety of aspects, was edited by Lawler, Lenstra, Rinnooy Kan, and Shmoys [1985]. In this book, Grötschel and Padberg [1985] considered the traveling salesman polytope, Padberg and Grötschel [1985] computation with the help of polyhedra, Johnson and Papadimitriou [1985a] the computational complexity of the TSP, and Balas and Toth [1985] branch-and-bound method methods. Computational methods and results are surveyed in the book by Reinelt [1994].

Survey articles on the traveling salesman problem were given by Gomory [1966], Bellmore and Nemhauser [1968], Gupta [1968], Tyagi [1968], Burkard [1979], Christofides [1979], Grötschel [1982] (also on other NP-complete problems), and Johnson and McGeoch [1997] (local search techniques). Introductions are given in the books by Minieka [1978], Sysło, Deo, and Kowalik [1983], Cook, Cunningham, Pulleyblank, and Schrijver [1998], and Korte and Vygen [2000]. An insightful survey of the computational methods for the symmetric TSP was given by Jünger, Reinelt, and Rinaldi [1995]. A framework for guaranteeing quality of TSP solutions was presented by Jünger, Thienel, and Reinelt [1994]. An early survey on branch-and-bound method techniques was given by Lawler and Wood [1966].

Barvinok, Johnson, Woeginger, and Woodroofe [1998] showed that there is a polynomial-time algorithm to find a *longest* Hamiltonian circuit in a complete graph with length determined by a polyhedral norm. Related work was done by Barvinok [1996]. More on the longest Hamiltonian circuit can be found in Fisher, Nemhauser, and Wolsey [1979], Serdyukov [1984], Kostochka and Serdyukov [1985], Kosaraju, Park, and Stein [1994], Hassin and Rubinstein [2000,2001], and Bläser [2002].

58.11b. Historical notes on the traveling salesman problem

Mathematically, the traveling salesman problem is related to, in fact generalizes, the question for a Hamiltonian circuit in a graph. This question goes back to Kirkman

[1856] and Hamilton [1856,1858] and was also studied by Kowalewski [1917b,1917a] — see Biggs, Lloyd, and Wilson [1976]. We restrict our survey to the traveling salesman problem in its general form.

The mathematical roots of the traveling salesman problem are obscure. Dantzig, Fulkerson, and Johnson [1954a] say:

> It appears to have been discussed informally among mathematicians at mathematics meetings for many years.

A 1832 manual

The traveling salesman problem has a natural interpretation, and Müller-Merbach [1983] detected that the problem was formulated in a 1832 manual for the successful traveling salesman, *Der Handlungsreisende — wie er sein soll und was er zu thun hat, um Aufträge zu erhalten und eines glücklichen Erfolgs in seinen Geschäften gewiß zu sein — Von einem alten Commis-Voyageur*[9] ('ein alter Commis-Voyageur' [1832]). (Whereas the politically correct nowadays prefer to speak of the traveling sales*person* problem, the manual presumes that the 'Handlungsreisende' is male, and it warns about the risks of women in or out of business.)

The booklet contains no mathematics, and formulates the problem as follows:

> Die Geschäfte führen die Handlungsreisenden bald hier, bald dort hin, und es lassen sich nicht füglich Reisetouren angeben, die für alle vorkommende Fälle passend sind; aber es kann durch eine zweckmäßige Wahl und Eintheilung der Tour, manchmal so viel Zeit gewonnen werden, daß wir es nicht glauben umgehen zu dürfen, auch hierüber einige Vorschriften zu geben. Ein Jeder möge so viel davon benutzen, als er es seinem Zwecke für dienlich hält; so viel glauben wir aber davon versichern zu dürfen, daß es nicht wohl thunlich sein wird, die Touren durch Deutschland in Absicht der Entfernungen und, worauf der Reisende hauptsächlich zu sehen hat, des Hin- und Herreisens, mit mehr Oekonomie einzurichten. Die Hauptsache besteht immer darin: so viele Orte wie möglich mitzunehmen, ohne den nämlichen Ort zweimal berühren zu müssen.[10]

The manual suggests five tours through Germany (one of them partly through Switzerland). In Figure 58.2 we compare one of the tours with a shortest tour, found with 'modern' methods. (Most other tours given in the manual do not qualify for 'die Hauptsache' as they contain subtours, so that some places are visited twice.)

Menger's Botenproblem 1930

K. Menger seems to be the first mathematician to have written about the traveling salesman problem. The root of his interest is given in his paper Menger [1928c]. In

---

[9] 'The traveling salesman — how he should be and what he has to do, to obtain orders and to be sure of a happy success in his business — by an old traveling salesman'

[10] Business brings the traveling salesman now here, then there, and no travel routes can be properly indicated that are suitable for all cases occurring; but sometimes, by an appropriate choice and arrangement of the tour, so much time can be gained, that we don't think we may avoid giving some rules also on this. Everybody may use that much of it, as he takes it for useful for his goal; so much of it however we think we may assure, that it will not be well feasible to arrange the tours through Germany with more economy in view of the distances and, which the traveler mainly has to consider, of the trip back and forth. The main point always consists of visiting as many places as possible, without having to touch the same place twice.

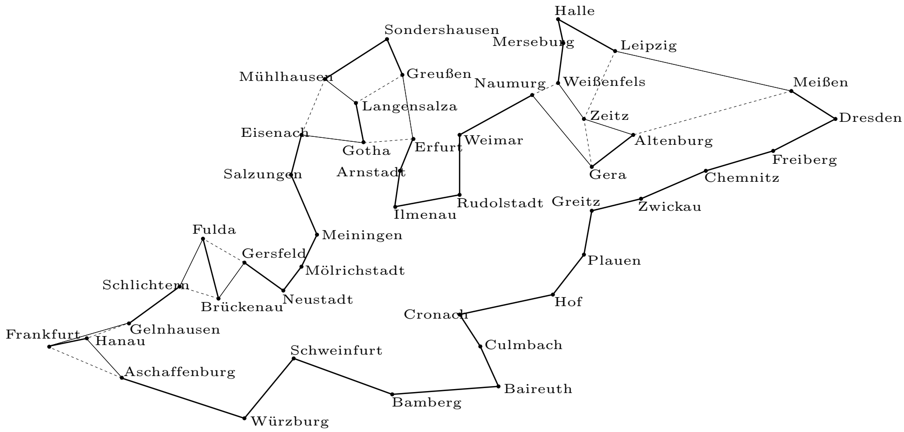

Figure 58.2

A tour along 45 German cities, as described in the 1832 traveling salesman manual, is given by the unbroken (bold and thin) lines (1285 km). A shortest tour is given by the unbroken bold and by the dashed lines (1248 km). We have taken geodesic distances — taking local conditions into account, the 1832 tour might be optimum.

this, he studies the *length* $l(C)$ of a simple curve C in a metric space S, which is, by definition,

$$l(C) := \sup \sum_{i=1}^{n-1} \operatorname{dist}(x_i, x_{i+1}), \tag{58.26}$$

where the supremum ranges over all choices of $x_1, \ldots, x_n$ on C *in the order determined by* C. What Menger showed is that we may relax this to finite subsets X of C and minimize over all possible orderings of X. To this end he defined, for any finite subset X of a metric space, $\lambda(X)$ to be the shortest length of a path through X (in graph terminology: a *Hamiltonian path*), and he showed that

$$l(C) = \sup_X \lambda(X), \tag{58.27}$$

where the supremum ranges over all finite subsets X of C. It amounts to showing that for each $\varepsilon > 0$ there is a finite subset X of C such that $\lambda(X) \geq l(C) - \varepsilon$.

Menger [1929a] sharpened this to:

$$l(C) = \sup_X \kappa(X), \tag{58.28}$$

where again the supremum ranges over all finite subsets X of C, and where $\kappa(X)$ denotes the minimum length of a *spanning tree* on X.

These results were reported also in Menger [1930]. In a number of other papers, Menger [1928b,1929b,1929a] gave related results on these new characterizations of the length function.

The parameter $\lambda(X)$ clearly is close to the practical interpretation of the traveling salesman problem. This relation was made explicit by Menger in the session of 5 February 1930 of his *mathematisches Kolloquium* in Vienna. Menger [1931a, 1932a] reported that he first asked if a further relaxation is possible by replacing $\kappa(X)$ by the minimum length of an (in current terminology) *Steiner tree* connecting X — a spanning tree on a superset of X in S. (So Menger toured along some basic combinatorial optimization problems.) This problem was solved for Euclidean spaces by Mimura [1933].

Next Menger posed the traveling salesman problem, as follows:

> Wir bezeichnen als *Botenproblem* (weil diese Frage in der Praxis von jedem Postboten, übrigens auch von vielen Reisenden zu lösen ist) die Aufgabe, für endlichviele Punkte, deren paarweise Abstände bekannt sind, den kürzesten die Punkte verbindenden Weg zu finden. Dieses Problem ist natürlich stets durch endlichviele Versuche lösbar. Regeln, welche die Anzahl der Versuche unter die Anzahl der Permutationen der gegebenen Punkte herunterdrücken würden, sind nicht bekannt. Die Regel, man solle vom Ausgangspunkt erst zum nächstgelegenen Punkt, dann zu dem diesem nächstgelegenen Punkt gehen usw., liefert im allgemeinen nicht den kürzesten Weg.[11]

So Menger asked for a shortest Hamiltonian path through the given points. He was aware of the complexity issue in the traveling salesman problem, and he realized that the now well-known nearest neighbour heuristic might not give an optimum solution.

Harvard, Princeton 1930-1934

Menger spent the period September 1930-February 1931 as visiting lecturer at Harvard University. In one of his seminar talks at Harvard, Menger presented his results (quoted above) on lengths of arcs and shortest paths through finite sets of points. According to Menger [1931b], a suggestion related to this was given by Hassler Whitney, who at that time did his Ph.D. research in graph theory at Harvard. This paper of Menger however does not mention if the practical interpretation was given in the seminar talk.

The year after, 1931-1932, Whitney was a National Research Council Fellow at Princeton University, where he gave a number of seminar talks. In a seminar talk, he mentioned the problem of finding the shortest route along the 48 States of America.

There are some uncertainties in this story. It is not sure if Whitney spoke about the 48 States problem during his 1931-1932 seminar talks (which talks he did give), or later, in 1934, as is said by Flood [1956] in his article on the traveling salesman problem:

> This problem was posed, in 1934, by Hassler Whitney in a seminar talk at Princeton University.

That memory can be shaky might be indicated by the following two quotes. Dantzig, Fulkerson, and Johnson [1954a] remark:

[11] We denote by *messenger problem* (since in practice this question should be solved by each postman, anyway also by many travelers) the task to find, for finitely many points whose pairwise distances are known, the shortest route connecting the points. Of course, this problem is solvable by finitely many trials. Rules which would push the number of trials below the number of permutations of the given points, are not known. The rule that one first should go from the starting point to the closest point, then to the point closest to this, etc., in general does not yield the shortest route.

> Both Flood and A.W. Tucker (Princeton University) recall that they heard about the problem first in a seminar talk by Hassler Whitney at Princeton in 1934 (although Whitney, recently queried, does not seem to recall the problem).

However, when asked by David Shmoys, Tucker replied in a letter of 17 February 1983 (see Hoffman and Wolfe [1985]):

> I cannot confirm or deny the story that I heard of the TSP from Hassler Whitney. If I did (as Flood says), it would have occurred in 1931-32, the first year of the old Fine Hall (now Jones Hall). That year Whitney was a postdoctoral fellow at Fine Hall working on Graph Theory, especially planarity and other offshoots of the 4-color problem. ... I was finishing my thesis with Lefschetz on n-manifolds and Merrill Flood was a first year graduate student. The Fine Hall Common Room was a very lively place — 24 hours a day.

(Whitney finished his Ph.D. at Harvard University in 1932.)

Another uncertainty is in which form Whitney has posed the problem. That he might have focused on finding a shortest route along the 48 states in the U.S.A., is suggested by the reference by Flood, in an interview on 14 May 1984 with Tucker [1984a], to the problem as the '48 States Problem of Hassler Whitney'. In this respect Flood also remarked:

> I don't know who coined the peppier name 'Traveling Salesman Problem' for Whitney's problem, but that name certainly has caught on, and the problem has turned out to be of very fundamental importance.

TSP, Hamiltonian paths, and school bus routing

Flood [1956] remembered that in 1937, A.W. Tucker pointed out to him the connections of the TSP with Hamiltonian games and Hamiltonian paths in graphs:

> I am indebted to A.W. Tucker for calling these connections to my attention, in 1937, when I was struggling with the problem in connection with a schoolbus routing study in New Jersey.

In the following quote from the interview by Tucker [1984a], Flood referred to school bus routing in a different state (West Virginia), and he mentioned the involvement in the TSP of Koopmans, who spent 1940-1941 at the Local Government Surveys Section of Princeton University ('the Princeton Surveys'):

> Koopmans first became interested in the "48 States Problem" of Hassler Whitney when he was with me in the Princeton Surveys, as I tried to solve the problem in connection with the work by Bob Singleton and me on school bus routing for the State of West Virginia.

1940

In 1940, some papers appeared that study the traveling salesman problem, in a different context. They seem to be the first containing mathematical results on the problem.

In the American continuation of Menger's *mathematisches Kolloquium*, Menger [1940] returned to the question of the shortest path through a given set of points in a metric space, followed by investigations of Milgram [1940] on the shortest Jordan curve that covers a given, not necessarily finite, set of points in a metric space. As the set may be infinite, a shortest curve need not exist.

Fejes [1940] investigated the problem of a shortest curve through n points in the unit square. In consequence of this, Verblunsky [1951] showed that its length is less than $2 + \sqrt{2.8n}$. Later work in this direction includes Few [1955], Beardwood, Halton, and Hammersley [1959], Steele [1981], Moran [1984], Karloff [1989], and Goddyn [1990].

Lower bounds on the expected value of a shortest path through n random points in the plane were studied by Mahalanobis [1940] in order to estimate the cost of a sample survey of the acreage under jute in Bengal. This survey took place in 1938 and one of the major costs in carrying out the survey was the transportation of men and equipment from one survey point to the next. He estimated (without proof) the minimum length of a tour along n random points in the plane, for Euclidean distance:

> It is also easy to see in a general way how the journey time is likely to behave. Let us suppose that n sampling units are scattered at random within any given area ; and let us assume that we may treat each such sample unit as a geometrical point. We may also assume that arrangements will usually be made to move from one sample point to another in such a way as to keep the total distance travelled as small as possible ; that is, we may assume that the path traversed in going from one sample point to another will follow a straight line. In this case it is easy to see that the mathematical expectation of the total length of the path travelled in moving from one sample point to another will be $(\sqrt{n} - 1/\sqrt{n})$. The cost of the journey from sample to sample will therefore be roughly proportional to $(\sqrt{n} - 1/\sqrt{n})$. When n is large, that is, when we consider a sufficiently large area, we may expect that the time required for moving from sample to sample will be roughly proportional to $\sqrt{n}$, where n is the total number of samples in the given area. If we consider the journey time per sq. mile, it will be roughly proportional to $\sqrt{y}$, where y is the density of number of sample units per sq. mile.

This research was continued by Jessen [1942], who estimated empirically a similar result for l_1-distance (Manhattan distance), in a statistical investigation of a sample survey for obtaining farm facts in Iowa:

> If a route connecting y points located at random in a fixed area is minimized, the total distance, D, of that route is[12]
>
> $$D = d\left(\frac{y-1}{\sqrt{y}}\right)$$
>
> where d is a constant.
> This relationship is based upon the assumption that points are connected by direct routes. In Iowa the road system is a quite regular network of mile square mesh. There are very few diagonal roads, therefore, routes between points resemble those taken on a checkerboard. A test wherein several sets of different members of points were located at random on an Iowa county road map, and the minimum distance of travel from a given point on the border of the county through all the points and to an end point (the county border nearest the last point on route), revealed that
>
> $$D = d\sqrt{y}$$
>
> works well. Here y is the number of randomized points (border points not included). This is of great aid in setting up a cost function.

[12] at this point, Jessen referred in a footnote to Mahalanobis [1940].

Marks [1948] gave a proof of Mahalanobis' bound. In fact he showed that $\sqrt{\frac{1}{2}A}(\sqrt{n}-1/\sqrt{n})$ is a lower bound, where A is the area of the region. Ghosh [1949] showed that this bound asymptotically is close to the expected value, by giving a heuristic for finding a tour, yielding an upper bound of $1.27\sqrt{An}$. He also observed the complexity of the problem:

> After locating the n random points in a map of the region, it is very difficult to find out *actually* the shortest path connecting the points, unless the number n is very small, which is seldom the case for a large-scale survey.

TSP, transportation, and assignment

As is the case for several other combinatorial optimization problems, the RAND Corporation in Santa Monica, California, played an important role in the research on the TSP. Hoffman and Wolfe [1985] write that

> John Williams urged Flood in 1948 to popularize the TSP at the RAND Corporation, at least partly motivated by the purpose of creating intellectual challenges for models outside the theory of games. In fact, a prize was offered for a significant theorem bearing on the TSP. There is no doubt that the reputation and authority of RAND, which quickly became the intellectual center of much of operations research theory, amplified Flood's advertizing.

(John D. Williams was head of the Mathematics Division of RAND at that time.)

At RAND, researchers considered the idea of transferring the successful methods for the transportation problem to the traveling salesman problem. Flood [1956] mentioned that this idea was brought to his attention by Koopmans in 1948. In the interview with Tucker [1984a], Flood remembered:

> George Dantzig and Tjallings Koopmans met with me in 1948 in Washington, D.C., at the meeting of the International Statistical Institute, to tell me excitedly of their work on what is now known as the linear programming problem and with Tjallings speculating that there was a significant connection with the Traveling Salesman Problem.

The issue was taken up in a RAND Report by Julia Robinson [1949], who, in an 'unsuccessful attempt' to solve the traveling salesman problem, considered, as a relaxation, the assignment problem, for which she found a cycle reduction method. The relation is that the assignment problem asks for an optimum permutation, and the TSP for an optimum *cyclic* permutation.

Robinson's RAND report might be the earliest mathematical reference using the term 'traveling salesman problem':

> The purpose of this note is to give a method for solving a problem related to the traveling salesman problem. One formulation is to find the shortest route for a salesman starting from Washington, visiting all the state capitals and then returning to Washington. More generally, to find the shortest closed curve containing n given points in the plane.

Flood wrote (in a letter of 17 May 1983 to E.L. Lawler) that Robinson's report stimulated several discussions on the TSP of him with his research assistant at RAND, D.R. Fulkerson, during 1950-1952[13].

It was noted by Beckmann and Koopmans [1952] that the TSP can be formulated as a quadratic assignment problem, for which however no fast methods are known.

[13] Fulkerson started at RAND only in March 1951.

Dantzig, Fulkerson, Johnson 1954

Fundamental progress on the traveling salesman was made in a seminal paper by the RAND researchers Dantzig, Fulkerson, and Johnson [1954a] — according to Hoffman and Wolfe [1985] 'one of the principal events in the history of combinatorial optimization'. The paper introduced several new methods for solving the traveling salesman problem that are now basic in combinatorial optimization. In particular, it shows the importance of *cutting planes* for combinatorial optimization.

While the subtour elimination constraints (58.4)(iii) are enough to cut off the noncyclic permutation matrices from the polytope of doubly stochastic matrices (determined by (58.4)(i) and (ii)), they generally do not yield all facets of the traveling salesman polytope, as was observed by Heller [1953a]: there exist doubly stochastic matrices, of any order $n \geq 5$, that satisfy (58.4) but are not a convex combination of cyclic permutation matrices.

The subtour elimination constraints can nevertheless be useful for the TSP, since it gives a lower bound for the optimum tour length if we minimize over the constraints (58.4). This lower bound can be calculated with the simplex method, taking the (exponentially many) constraints (58.4)(iii) as *cutting planes* that can be added during the process when needed. In this way, Dantzig, Fulkerson, and Johnson were able to find the shortest tour along cities chosen in the 48 U.S. states and Washington, D.C. Incidentally, this is close to the problem mentioned by Julia Robinson in 1949 (and maybe also by Whitney in the 1930s).

The Dantzig-Fulkerson-Johnson paper gives no algorithm, but rather gives a tour and proves its optimality with the help of the subtour elimination constraints. This work forms the basis for most of the later work on large-scale traveling salesman problems.

Early studies of the traveling salesman polytope were reported by Heller [1953a,1953b,1955a,1955b,1956a,1956b], Kuhn [1955a], Norman [1955], and Robacker [1955b], who also made computational studies of the probability that a random instance of the traveling salesman problem needs the subtour elimination constraints (58.4)(iii) (cf. Kuhn [1991]). This made Flood [1956] remark on the intrinsic complexity of the traveling salesman problem:

> Very recent mathematical work on the traveling-salesman problem by I. Heller, H.W. Kuhn, and others indicates that the problem is fundamentally complex. It seems very likely that quite a different approach from any yet used may be required for succesful treatment of the problem. In fact, there may well be no general method for treating the problem and impossibility results would also be valuable.

Flood mentioned a number of other applications of the traveling salesman problem, in particular in machine scheduling, brought to his attention in a seminar talk at Columbia University in 1954 by George Feeney.

Other work on the traveling salesman problem in the 1950s was done by Morton and Land [1955] (a linear programming approach with a 3-exchange heuristic), Barachet [1957] (a graphic solution method), Bock [1958], Croes [1958] (a heuristic), and Rossman and Twery [1958]. In a reaction to Barachet's paper, Dantzig, Fulkerson, and Johnson [1959] showed that their method yields the optimality of Barachet's (heuristically found) solution.

In 1962, the soap company Proctor and Gamble run a contest, requiring to solve a traveling salesman problem along 33 U.S. cities. Little, Murty, Sweeney, and Karel [1963] report:

> The traveling salesman problem recently achieved national prominence when a soap company used it as the basis of a promotional contest. Prizes up to $10,000 were offered for identifying the most correct links in a particular 33-city problem. Quite a few people found the best tour. (The tie-breaking contest for these successful mathematicians was to complete a statement of 25 words or less on "I like...because...".) A number of people, perhaps a little over-educated, wrote the company that the problem was impossible—an interesting misinterpretation of the state of the art.

Chapter 59

Matching forests

Giles [1982a,1982b,1982c] introduced the concept of a *matching forest* in a mixed graph (V, E, A), which is a subset F of $E \cup A$ such that $F \cap A$ is a branching and $F \cap E$ is a matching only covering roots of the branching $F \cap A$. Equivalently, F contains no circuit (in the underlying undirected graph) and each $v \in V$ is head of at most one $e \in F$. (Here, for an undirected edge e, both ends of e are called head of e.)
Matching forests generalize both matchings in undirected graphs and branchings in directed graphs. Giles gave a polynomial-time algorithm to find a maximum-weight matching forest, yielding as a by-product a characterization of the matching forest polytope (the convex hull of the incidence vectors of matching forests).
Giles' results generalize the polynomial-time solvability and the polyhedral characterizations for matchings (Chapters 24–26) and for branchings (Chapter 52).

59.1. Introduction

A *mixed graph* is a triple (V, E, A), where (V, E) is an undirected graph and (V, A) is a directed graph. In this chapter, a graph can have multiple edges, but no loops. The *underlying* undirected graph of a mixed graph is the undirected graph obtained from the mixed graph by forgetting the orientations of the directed edges.

As usual, if an edge e is directed from u to v, then u is called the *tail* and v the *head* of e. In this chapter, if e is undirected and connects u and v, then both u and v will be called *head* of e.

A subset F of $E \cup A$ is called a *matching forest* if F contains no circuits (in the underlying undirected graph) and any vertex v is head of at most one edge in F. We call a vertex v a *root* of F if v is head of no edge in F. We denote the set of roots of F by $R(F)$.

It is convenient to consider the relations of matching forests with matchings in undirected graphs and branchings in directed graphs: M is a matching in an undirected graph (V, E) if and only if M is a matching forest in the mixed graph $(V, E, \emptyset)$. In this case, the roots of M are the vertices not covered by M. Similarly, B is a branching in a directed graph (V, A) if and only if B

is a matching forest in the mixed graph $(V, \emptyset, A)$. In this case, the concept of root of a branching and root of a matching forest coincide.

In turn, we can characterize matching forests in terms of matchings and branchings: for any mixed graph (V, E, A), a subset F of $E \cup A$ is a matching forest if and only if $F \cap A$ is a branching in (V, A) and $F \cap E$ is a matching in (V, E) such that $F \cap E$ only covers roots of $F \cap A$.

It will be useful to observe the following formulas, for any matching forest F in a mixed graph (V, E, A), setting $M := F \cap E$ and $B := F \cap A$:

(59.1) $\qquad R(F) = R(M) \cap R(B)$ and $V = R(M) \cup R(B)$.

In fact, for any matching M in (V, E) and any branching B in (V, A), the set $M \cup B$ is a matching forest if and only if $R(M) \cup R(B) = V$.

59.2. The maximum size of a matching forest

Giles [1982a] described a min-max formula for the maximum size of a matching forest. It can be derived from the Tutte-Berge formula with the following direct formula:

Theorem 59.1. *Let (V, E, A) be a mixed graph and let $\mathcal{K}$ be the collection of those strong components K of the directed graph (V, A) that satisfy $d_A^{\mathrm{in}}(K) = 0$. Consider the undirected graph H with vertex set $\mathcal{K}$, where two distinct $K, L \in \mathcal{K}$ are adjacent if and only if there is an edge in E connecting K and L. Then the maximum size of a matching forest in (V, E, A) is equal to*

(59.2) $\qquad \nu(H) + |V| - |\mathcal{K}|.$

Here $\nu(H)$ denotes the maximum size of a matching in H.

Proof. Let M' be a matching in H of size $\nu(H)$. Then M' yields a matching M of size $\nu(H)$ in (V, E), where each edge in M connects two components in $\mathcal{K}$. Now there exists a branching B in (V, A) such that B has exactly $|\mathcal{K}|$ roots, such that each $K \in \mathcal{K}$ contains exactly one root, and such that each vertex covered by M is a root of B. (To see that such a branching B exists, choose, for any $K \in \mathcal{K}$ not intersecting M, an arbitrary vertex in K. Let X be the set of chosen vertices together with the vertices covered by M. As X intersects each $K \in \mathcal{K}$, each vertex in V is reachable in (V, A) by a directed path from X. Hence there exists a branching B with root set X. This B has the required properties.)

Then $M \cup B$ is a matching forest, of size $\nu(H) + |V| - |\mathcal{K}|$ (as B has size $|V| - |\mathcal{K}|$).

To see that there is no larger matching forest, let F be any matching forest. Let $U := \bigcup \mathcal{K}$. Then F has at most $|V \setminus U|$ edges with at least one head in $V \setminus U$. Since no directed edge enters U, all other edges are contained in

U. So it suffices to show that F has at most $\nu(H)+|U|-|\mathcal{K}|$ edges contained in U.

Let N be the set of (necessarily undirected) edges in F connecting two different components in $\mathcal{K}$. For each $K \in \mathcal{K}$, let α_K be the number of edges in N incident with K. Then

(59.3) $$|N| - \sum_{K\in\mathcal{K}} \max\{0, \alpha_K - 1\} \leq \nu(H),$$

since by deleting, for each $K \in \mathcal{K}$, at most $\max\{0, \alpha_K - 1\}$ edges from N incident with K, we obtain a matching in the graph H defined above.

We have moreover that any $K \in \mathcal{K}$ spans at most $|K| - \max\{1, \alpha_K\}$ edges of F. With (59.3) this implies that the number of edges in F contained in U is at most

(59.4) $$|N| + \sum_{K\in\mathcal{K}} (|K| - \max\{1, \alpha_K\}) \leq \nu(H) + \sum_{K\in\mathcal{K}} (|K| - 1)$$
$$= \nu(H) + |U| - |\mathcal{K}|,$$

as required. ∎

The method described in this proof also directly implies that a maximum-size matching forest can be found in polynomial time (Giles [1982a]).

59.3. Perfect matching forests

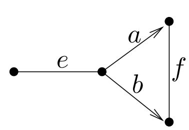

Figure 59.1
$\{e, f\}$ and $\{e, a, b\}$ are perfect matching forests.

A matching forest F is called *perfect* if each vertex is head of exactly one edge in F. (So a perfect matching forest need not be a maximum-size matching forest — cf. Figure 59.1.) The following is easy to see:

(59.5) A mixed graph (V, E, A) contains a perfect matching forest F if and only if the graph (V, E) contains a matching M such that each strong component K of (V, A) with $d^{\mathrm{in}}(K) = 0$ is intersected by at least one edge in M.

Indeed, if a perfect matching forest F exists, then $M := F \cap E$ is such a matching. Conversely, if such a matching M exists, any vertex is reachable by a directed path from at least one vertex covered by M; hence M can be augmented with directed arcs to a perfect matching forest.

This shows (59.5), which implies the following characterization for perfect matching forests of Giles [1982b]:

Theorem 59.2. *Let (V, E, A) be a mixed graph and let $\mathcal{K}$ be the collection of strong components K of (V, A) with $d_A^{\text{in}}(K) = 0$. Then (V, E, A) has a perfect matching forest if and only if for each $U \subseteq V$ and $\mathcal{L} \subseteq \mathcal{K}$ the graph $(V, E) - U$ has at most $|U| + \left|\bigcup \mathcal{L}\right| - |\mathcal{L}|$ odd components that are contained in $\bigcup \mathcal{L}$.*

Proof. Extend $G = (V, E)$ by, for each $K \in \mathcal{K}$, a clique C_K of size $|K| - 1$, such that each vertex in C_K is adjacent to each vertex in K. This makes the undirected graph H. Then (V, E, A) has a perfect matching forest if and only if graph H has a matching covering $\bigcup \mathcal{K}$. So we can apply Corollary 24.6a. ∎

This method also gives a polynomial-time algorithm to find a perfect matching forest.

59.4. An exchange property of matching forests

As a preparation for characterizing the matching forest polytope, we show an exchange property of matching forests. It generalizes the well-known and trivial exchange property of matchings in an undirected graph, based on considering the union of two matchings.

Lemma 59.3α. *Let F_1 and F_2 be matching forests in a mixed graph (V, E, A). Let $s \in R(F_2) \setminus R(F_1)$. Then there exist matching forests F_1' and F_2' such that $F_1' \cap F_2' = F_1 \cap F_2$, $F_1' \cup F_2' = F_1 \cup F_2$, $s \in R(F_1')$, and*

(59.6)
- (i) $|F_1'| < |F_1|$,
- or (ii) $|F_1'| = |F_1|$ and $|R(F_1')| > |R(F_1)|$,
- or (iii) $|F_1'| = |F_1|$, $R(F_1') = (R(F_1) \setminus \{t\}) \cup \{s\}$ for some $t \in R(F_1)$, and $|R(F_1' \cap A) \cap K| = |R(F_1 \cap A) \cap K|$ for each strong component K of the directed graph (V, A).

Proof. We may assume that F_1 and F_2 partition $E \cup A$, as we can delete edges that are not in $F_1 \cup F_2$, and add parallel edges to those in $F_1 \cap F_2$.

Define $M_i := F_i \cap E$ and $B_i := F_i \cap A$ for $i = 1, 2$. Let $\mathcal{K}$ be the collection of strong components K of the directed graph (V, A) with $\delta_A^{\text{in}}(K) = \emptyset$. Then each set in $\mathcal{K}$ intersects both $R(B_1)$ and $R(B_2)$, and $\{v\} \in \mathcal{K}$ for each $v \in R(B_1) \cap R(B_2)$.

So each $K \in \mathcal{K}$ with $|K| \geq 2$ intersects $R(B_1)$ and $R(B_2)$ in disjoint subsets. Hence we can choose for each such K

(59.7) a pair $e_K \subseteq K$ consisting of a vertex in $R(B_1) \setminus R(B_2)$ and a vertex in $R(B_2) \setminus R(B_1)$.

Let N be the set of pairs e_K for $K \in \mathcal{K}$ with $|K| \geq 2$. So N consists of disjoint pairs.

Then the undirected graph H on V with edge set

(59.8) $M_1 \cup M_2 \cup N$

consists of a number of vertex-disjoint paths and circuits, since no vertex in $R(B_1) \setminus R(B_2)$ is covered by M_2, and no vertex in $R(B_2) \setminus R(B_1)$ is covered by M_1.

Moreover, s has degree at most one in H. Indeed, s is not covered by M_2, as $s \in R(F_2) = R(M_2) \cap R(B_2)$. If s is covered by M_1, then $s \in R(B_1)$, and so $s \in R(B_1) \cap R(B_2)$, implying that s is not covered by N.

So s is the starting vertex of a path component P of H (possibly only consisting of s). Let Y be the set of edges in $M_1 \cup M_2$ occurring in P, and set

(59.9) $M_1' := M_1 \triangle Y$ and $M_2' := M_2 \triangle Y$

(where $\triangle$ denotes symmetric difference). Since Y is the union of the edge sets of some path components of the graph $(V, M_1 \cup M_2)$, we know that M_1' and M_2' are matchings again.

Then, obviously, $R(M_1')$ and $R(M_2')$ arise from $R(M_1)$ and $R(M_2)$ by exchanging these sets on VP; that is:

(59.10) $R(M_1') = (R(M_1) \setminus VP) \cup (R(M_2) \cap VP)$ and
$R(M_2') = (R(M_2) \setminus VP) \cup (R(M_1) \cap VP)$.

We show that a similar operation can be performed with respect to B_1 and B_2; that is, we show that there exist disjoint branchings B_1' and B_2' in (V, A) satisfying

(59.11) $R(B_1') = (R(B_1) \setminus VP) \cup (R(B_2) \cap VP)$ and
$R(B_2') = (R(B_2) \setminus VP) \cup (R(B_1) \cap VP)$.

By Lemma 53.2α, it suffices to show that each $K \in \mathcal{K}$ intersects both sets in (59.11). If $|K| = 1$, then K is contained in both $R(B_1)$ and $R(B_2)$, and hence in both sets in (59.11). If $|K| \geq 2$, then e_K intersects both $R(B_1)$ and $R(B_2)$. Since e_K is either contained in VP or disjoint from VP, e_K intersects both sets in (59.11). Hence, as $e_K \subseteq K$, also K intersects both sets in (59.11). Therefore, branchings B_1' and B_2' satisfying (59.11) exist.

(59.10) and (59.11) imply:

(59.12) $F_1' := M_1' \cup B_1'$ and $F_2' := M_2' \cup B_2'$ are matching forests.

To see this, we must show that $R(M_1') \cup R(B_1') = V$ and $R(M_2') \cup R(B_2') = V$. Since $R(M_1) \cup R(B_1) = V$ and $R(M_2) \cup R(B_2) = V$, this follows directly from (59.10) and (59.11). This shows (59.12).

Since $R(F) = R(M) \cap R(B)$ for any matching forest F (with $M := F \cap E$ and $B := F \cap A$), (59.10) and (59.11) imply that also $R(F_1')$ and $R(F_2')$ arise from $R(F_1)$ and $R(F_2)$ by swapping on P; that is:

(59.13) $R(F_1') = (R(F_1) \setminus VP) \cup (R(F_2) \cap VP)$ and
$R(F_2') = (R(F_2) \setminus VP) \cup (R(F_1) \cap VP)$.

This implies:

(59.14) $s \in R(F_1') \setminus R(F_2')$,

since $s \in VP$ and $s \in R(F_2) \setminus R(F_1)$.

We study the effects of the exchanges (59.10) and (59.11), to show that one of the alternatives (59.6) holds. It is based on the following observations on the sizes of M_1' and B_1'. Let t be the last vertex of P (possible $t = s$).

Suppose that none of the alternatives (59.6) hold. If $s = t$, then s is not covered by M_1, and so $M_1' = M_1$ and $R(B_1') = R(B_1) \cup \{s\}$, implying $|F_1'| < |F_1|$, which is alternative (59.6)(i). So $s \neq t$.

By the exchanges made, $|M_1| - |M_1'| = |M_1 \cap EP| - |M_2 \cap EP|$ and $|R(F_1)| - |R(F_1')| = |R(F_1) \cap VP| - |R(F_2) \cap VP|$. This gives, as $|F_1'| \geq |F_1|$, since alternative (59.6)(i) does not hold:

(59.15) $|M_1 \cap EP| - |M_2 \cap EP| + |R(F_1) \cap VP| - |R(F_2) \cap VP|$
$= |M_1| + |R(F_1)| - |M_1'| - |R(F_1')| = |F_1'| - |F_1| \geq 0.$

(The last equality holds as $|F_i'| = |V| - |M_i'| - |R(F_i')|$ for $i = 1, 2$, since $|F_i'| + |M_i'|$ is the number of heads of edges in F_i'.)

We next note:

(59.16) no intermediate vertex v of P belongs to $R(F_1) \cup R(F_2)$.

For suppose that $v \in R(F_1)$. Then (as v is an intermediate vertex of P) v is covered by M_2 and some $e_K \in N$. Hence $v \in R(B_2)$, and therefore $v \notin R(B_1)$ (by (59.7)), contradicting the fact that $v \in R(F_1)$. One similarly shows that $v \notin R(F_2)$, proving (59.16).

As $s \in R(F_2) \setminus R(F_1)$, (59.16) implies that

(59.17) $|R(F_1) \cap VP| \leq |R(F_2) \cap VP|$, with equality if and only if $t \in R(F_1) \setminus R(F_2)$.

With (59.15) this gives that $|M_1 \cap EP| \geq |M_2 \cap EP|$.

Let k be the number of edges in $M_1 \cup M_2$ on P. Note that the edges in $M_1 \cup M_2$ occur along P alternatingly in M_1 and M_2, as any intermediate $e_K \in N$ on P connects an edge in M_1 and an edge in M_2 (as by (59.7), $e_K \in N$ consists of a vertex not in $R(B_2)$ and a vertex not in $R(B_1)$).

Suppose that k is odd. Then $|M_1 \cap EP| = |M_2 \cap EP| + 1$. So the last edge in $M_1 \cup M_2$ along P (seen from s) belongs to M_1. Moreover, one has that $t \notin R(F_1)$. For if $t \in R(F_1)$, then t is not covered by M_1, and hence t belongs to some $e_K = \{v, t\} \in N$ with v covered by M_1. Hence $v \in R(B_1)$, and hence $t \notin R(B_1)$ (by (59.7)), contradicting the fact that $t \in R(F_1)$. So $t \notin R(F_1)$.

Then (59.17) implies that $|R(F_2) \cap VP| > |R(F_1) \cap VP|$. This implies with (59.15) that $|F_1'| = |F_1|$ (as $|M_1 \cap EP| = |M_2 \cap EP| + 1$), and with (59.13) that $|R(F_1')| > |R(F_1)|$. So (59.6)(ii) holds, a contradiction.

So k is even, and hence $|M_1 \cap EP| = |M_2 \cap EP|$, which implies with (59.13), (59.15), and (59.17) that $|R(F_1)| = |R(F_2)|$ and $t \in R(F_1) \setminus R(F_2)$. Therefore, $|F_1'| = |F_1|$ (by (59.16)) and $R(F_1') = (R(F_1) \setminus \{t\}) \cup \{s\}$.

Finally, $|R(B_1') \cap K| = |R(B_1) \cap K|$ for each strong component K of D. This follows directly (with (59.11)) from the fact that for any $v \in K \cap VP$ one has either $K = \{v\}$ (if $|K| = 1$) or $v \in e_K$ (if $|K| \geq 2$). For suppose that $v \in VP$ is incident with no $e_K \in N$. We show that $v \in R(B_1) \cap R(B_2)$, implying $\{v\} \in \mathcal{K}$. If v is an intermediate vertex of P, then v is covered by M_1 and M_2 and hence v belongs to $R(B_1)$ and $R(B_2)$. If $v = s$, then $v \in R(F_2)$ (so $v \in R(B_2)$) and v is covered by M_1, so $v \in R(B_1)$. If $v = t$, then $v \in R(F_1)$ (so $v \in R(B_1)$) and v is covered by M_2, so $v \in R(B_2)$. ∎

59.5. The matching forest polytope

The *matching forest polytope* of a mixed graph (V, E, A) is the convex hull of the incidence vectors of the matching forests. So the matching forest polytope is a polytope in $\mathbb{R}^{E \cup A}$.

Giles [1982b] showed that the matching forest polytope is determined by the following inequalities:

(59.18)
(i) $x_e \geq 0$ for each $e \in E \cup A$,
(ii) $x(\delta^{\text{head}}(v)) \leq 1$ for each $v \in V$,
(iii) $x(\gamma(\mathcal{L})) \leq \lfloor |\bigcup \mathcal{L}| - \frac{1}{2}|\mathcal{L}| \rfloor$ for each subpartition $\mathcal{L}$ of V with $|\mathcal{L}|$ odd and all classes nonempty.

Here we use the following notation and terminology. $\delta^{\text{head}}(v)$ denotes the set of edges with head v. A *subpartition* of V is a collection of disjoint subsets of V. As usual, $\bigcup \mathcal{L}$ denotes the union of the sets in $\mathcal{L}$. For each subpartition $\mathcal{L}$, we define:

(59.19) $\gamma(\mathcal{L}) :=$ the set of undirected edges spanned by $\bigcup \mathcal{L}$ and directed edges spanned by any set in $\mathcal{L}$.

The inequalities (i) and (ii) in (59.18) are trivially valid for the incidence vector of any matching forest F. To see that (iii) is valid, we can assume that $F \subseteq \gamma(\mathcal{L})$ and that $V = \bigcup \mathcal{L}$. Then $|R(F \cap A)| \geq |\mathcal{L}|$, since each set in $\mathcal{L}$ contains at least one root of $F \cap A$ (since no directed edge enters any set in $\mathcal{L}$). Moreover, $|F \cap E| \leq \lfloor \frac{1}{2}|R(F \cap A)| \rfloor$, since $F \cap E$ is a matching on a subset of $R(F \cap A)$. As $|F \cap A| = |V| - |R(F \cap A)|$, this gives:

(59.20)
$$|F| = |F \cap E| + |F \cap A| \leq \lfloor \tfrac{1}{2}|R(F \cap A)| \rfloor + (|V| - |R(F \cap A)|) = \lfloor |V| - \tfrac{1}{2}|R(F \cap A)| \rfloor \leq \lfloor |\bigcup \mathcal{L}| - \tfrac{1}{2}|\mathcal{L}| \rfloor,$$

as required.

Each integer solution x of (59.18) is the incidence vector of a matching forest. Indeed, as x is a $0,1$ vector by (i) and (ii), we know that $x = \chi^F$ for some $F \subseteq E \cup A$. By (ii), each vertex is head of at most one edge in F. Hence, if F would contain a circuit (in the underlying undirected graph), it is a directed circuit C. But then for $\mathcal{L} := \{VC\}$, condition (iii) is violated. So F is a matching forest.

We show that system (59.18) is totally dual integral. This implies that it determines an integer polytope, which therefore is the matching forest polytope.

The proof method is a generalization of the method in Section 25.3a for proving the Cunningham-Marsh formula, stating that the matching constraints are totally dual integral.

The total dual integrality of (59.18) is equivalent to the following. For any weight function $w : E \cup A \to \mathbb{Z}$, let ν_w denote the maximum weight of a matching forest. Call a matching forest F *w-maximal* if $w(F) = \nu_w$. Let Λ be the set of subpartitions $\mathcal{L}$ of V with $|\mathcal{L}|$ odd and with all classes nonempty.

Then the total dual integrality of (59.18) is equivalent to: for each weight function $w : E \cup A \to \mathbb{Z}$, there exist $y : V \to \mathbb{Z}_+$ and $z : \Lambda \to \mathbb{Z}_+$ satisfying

$$\text{(59.21)} \qquad \sum_{v \in V} y_v + \sum_{\mathcal{L} \in \Lambda} z(\mathcal{L}) \left\lfloor |\bigcup \mathcal{L}| - \tfrac{1}{2}|\mathcal{L}| \right\rfloor \leq \nu_w$$

and

$$\text{(59.22)} \qquad \sum_{v \in V} y_v \chi^{\delta^{\text{head}}(v)} + \sum_{\mathcal{L} \in \Lambda} z(\mathcal{L}) \chi^{\gamma(\mathcal{L})} \geq w.$$

Now we can derive (Schrijver [2000b]):

Theorem 59.3. *For each mixed graph* (V, E, A)*, system* (59.18) *is totally dual integral.*

Proof. We must prove that for each mixed graph (V, E, A) and each function $w : E \cup A \to \mathbb{Z}$, there exist y, z satisfying (59.21) and (59.22).

In proving this, we can assume that w is nonnegative. For suppose that w has negative entries, and let w' be obtained from w by setting all negative entries to 0. As $\nu_{w'} = \nu_w$ and $w' \geq w$, any y, z satisfying (59.21) and (59.22) with respect to w', also satisfy (59.21) and (59.22) with respect to w.

Suppose that the theorem is not true. Choose a counterexample (V, E, A) and $w : E \cup A \to \mathbb{Z}_+$ with $|V| + |E \cup A| + \sum_{e \in E \cup A} w(e)$ as small as possible.

Then the underlying undirected graph of (V, E, A) is connected, since otherwise one of the components will form a smaller counterexample. Moreover, $w(e) \geq 1$ for each edge e, since otherwise we can delete e to obtain a smaller counterexample.

Next:

(59.23) for each $v \in V$, there exists a w-maximal matching forest F with $v \in R(F)$.

For suppose that no such matching forest exists. For any edge e, let $w'(e) := w(e) - 1$ if v is head of e and $w'(e) := w(e)$ otherwise. Then $\nu_{w'} = \nu_w - 1$. By the minimality of w, there exist y, z satisfying (59.21) and (59.22) with respect to w'. Replacing y_v by $y_v + 1$ we obtain y, z satisfying (59.21) and (59.22) with respect to w, contradicting our assumption. This proves (59.23).

This implies:

(59.24) each weak component of the directed graph (V, A) is strongly connected.

To see this, it suffices to show that each directed edge $e = (u, v)$ is contained in some directed circuit. By (59.23) there exists a w-maximal matching forest F with $v \in R(F)$. Then the weak component of F containing v is an arborescence rooted at v. As F has maximum weight, $F \cup \{e\}$ is not a matching forest, and hence $F \cap A$ contains a directed $v-u$ path. This makes a directed circuit containing e, and proves (59.24).

Let $\mathcal{K}$ denote the collection of strong components of (V, A). Define $w'(e) := w(e) - 1$ for each edge e. The remainder of this proof consists of showing that $|\mathcal{K}|$ is odd (so $\mathcal{K} \in \Lambda$), and that

(59.25) $\nu_w \geq \nu_{w'} + \lfloor |V| - \frac{1}{2}|\mathcal{K}| \rfloor$.

This is enough, since, by the minimality of w, there exist y, z satisfying (59.21) and (59.22) with respect to w'. Replacing $z(\mathcal{K})$ by $z(\mathcal{K}) + 1$ we obtain y, z satisfying (59.21) and (59.22) with respect to w (note that $\gamma(\mathcal{K}) = E \cup A$), contradicting our assumption.

To show (59.25), choose a w'-maximal matching forest F of maximum size $|F|$. Under this condition, choose F such that it maximizes $|R(F)|$.

We show that for each $s \in V$ the following holds, where r is the root of the arborescence[14] in $F \cap A$ containing s:

(59.26) there exist a $t \in R(F)$ and a w'-maximal matching forest F' satisfying $|F'| = |F|$, $R(F') = (R(F) \setminus \{t\}) \cup \{s\}$, and $|R(F' \cap A) \cap K| = R(F \cap A) \cap K|$ for each strong component K of (V, A); if $r \in R(F)$, then moreover $t = r$ and $R(F' \cap A) = (R(F \cap A) \setminus \{r\}) \cup \{s\}$.

Let $F_1 := F$ and let F_2 be a w-maximal forest with $s \in R(F_2)$ (which exists by (59.23)). We first find F_1' and F_2' as follows.

If $r \notin R(F)$, then $s \notin R(F) = R(F_1)$ (since otherwise s is a root of $F \cap A$, and hence $r = s \in R(F)$). Applying Lemma 59.3α to F_1 and F_2 yields the matching forests F_1' and F_2'.

If $r \in R(F)$, then $s \notin R(F \cap A)$. Apply Theorem 53.2 to $B_1 := F_1 \cap A$ and $B_2 := F_2 \cap A$. It yields branchings B_1' and B_2' in (V, A) satisfying $B_1' \cap B_2' =$

[14] An *arborescence in* a branching B is a weak component of (V, B), or just the arc set of it.

$B_1 \cap B_2$, $B_1' \cup B_2' = B_1 \cup B_2$, and $R(B_1') = R(B_1) \cup \{s\}$ or $R(B_1') = (R(B_1) \setminus \{r\}) \cup \{s\}$. This implies $R(B_2') = R(B_2) \setminus \{s\}$ or $R(B_2') = (R(B_2) \setminus \{s\}) \cup \{r\}$. Now define $F_i' := (F_i \cap E) \cup B_i'$ for $i = 1, 2$. Then the F_i' are matching forests, since $r \in R(F_1 \cap E)$ and $s \in R(F_2 \cap E)$.

In both constructions, $|F_1'| \leq |F_1|$, and if $|F_1'| = |F_1|$, then $|R(F_1')| \geq |R(F_1)|$. Moreover,

$$\chi^{F_1'} + \chi^{F_2'} = \chi^{F_1} + \chi^{F_2}, \tag{59.27}$$

which implies that $w(F_1') + w(F_2') = w(F_1) + w(F_2)$. Hence

$$\begin{aligned} w'(F_1') + w(F_2') &= w(F_1') + w(F_2') - |F_1'| \geq w(F_1) + w(F_2) - |F_1| \\ &= w'(F_1) + w(F_2). \end{aligned} \tag{59.28}$$

Therefore, since F_1 is a w'-maximal matching forest and F_2 is a w-maximal matching forest, we have equality throughout in (59.28). So F_1' is w'-maximal and $|F_1'| = |F_1|$. Hence $|R(F_1')| \geq |R(F_1)|$. Then, by the maximality of $|R(F)|$, we know that $|R(F_1')| = |R(F_1)|$.

Set $F' := F_1'$. If $r \notin R(F)$, we know that (59.6)(iii) holds, which gives (59.26). If $r \in R(F)$, then (59.26) holds for $t := r$, and $R(B_1') = (R(B_1) \setminus \{t\}) \cup \{s\}$ or $R(B_2') = (R(B_2) \setminus \{s\}) \cup \{t\}$ (since $|F_1'| = |F_1|$, $F_1' \cap E = F_1 \cap E$, $|F_2'| = |F_2|$, $F_2' \cap E = F_2 \cap E$). Moreover, s and t belong to the same strong component of (V, A): as $r = t$ is the root of the arborescence in $F_1 \cap A$ containing s, there exists a $t - s$ path in (V, A); since each weak component of (V, A) is a strong component (by (59.24)), there is a directed $s - t$ path in (V, A). This implies (59.26).

Note that (59.26) implies in particular that $R(F) \neq \emptyset$. Suppose $|R(F)| \geq 2$. Choose F under the additional condition that the minimum distance in (V, E, A) between distinct vertices $u, v \in R(F)$ is as small as possible. Here, the distance in (V, E, A) is the length of a shortest $u - v$ path in the underlying undirected graph.

Necessarily, this distance is at least two, since otherwise we can extend F by an edge connecting u and v, thereby maintaining w'-maximality but increasing the size. This contradicts the maximality of $|F|$.

So we can choose an intermediate vertex s on a shortest $u - v$ path. Let F' be the matching forest described in (59.26), with $t \in R(F)$. By symmetry of u and v we can assume that $t \neq u$. So $u, s \in R(F')$, contradicting the choice of F, as the distance of u and s is smaller than that of u and v.

This implies that $|R(F)| = 1$. Let $R(F) = \{r\}$ and let K be the strong component of (V, A) containing r. We choose F (and r) under the additional constraint that $|R(F \cap A) \cap K|$ is as large as possible.

Suppose $|R(F \cap A) \cap K| \geq 2$. Choose F under the additional constraint that r has minimal distance in (V, A) from some root u of $F \cap A$ in $K \setminus \{r\}$. In this case, the distance in (V, A) from u to r is the length of a shortest directed $u - r$ path. (Such a path exists, since K is strongly connected.)

Let T be the arborescence in $F \cap A$ containing r. Let s be the first vertex on a shortest directed $u - r$ path Q in (V, A) that belongs to T. Necessarily

$s \neq r$, since otherwise we can extend F by the last edge of Q, contradicting the maximality of $|F|$.

Let F' be the matching forest described in (59.26). Then $s \in R(F')$ and $R(F' \cap A) = (R(F \cap A) \setminus \{r\}) \cup \{s\}$. Hence u remains a root of $F' \cap A$, while the distance in (V, A) from u to s is shorter than that from u to r. This contradicts our choice of F (replacing K, r by L, s).

So $|R(F \cap A) \cap K| = 1$. Suppose that there exists a component L of (V, A) with $|R(F \cap A) \cap L| \geq 2$. Choose s in L arbitrarily. Let F' be the matching forest described in (59.26). Then $s \in R(F')$ while $|R(F' \cap A) \cap L| \geq 2$, contradicting the choice of F.

So no such component L exists; that is, each $L \in \mathcal{K}$ contains exactly one root of $F \cap A$. So $|F \cap A| = |V| - |\mathcal{K}|$. Moreover, as $|R(F)| = 1$, $|\mathcal{K}|$ is odd and $|F \cap E| = \lfloor \frac{1}{2}|\mathcal{K}| \rfloor$. So $|F| = |F \cap A| + |F \cap E| = \lfloor |V| - \frac{1}{2}|\mathcal{K}| \rfloor$. Hence

(59.29) $$\nu_w \geq w(F) = w'(F) + |F| = \nu_{w'} + |F| = \nu_{w'} + \lfloor |V| - \tfrac{1}{2}|\mathcal{K}| \rfloor,$$

thus proving (59.25). ∎

We remark that the optimum dual solution y, z constructed in this proof has the following additional property: if $\mathcal{K}, \mathcal{L} \in \Lambda$ and $z(\mathcal{K}), z(\mathcal{L}) > 0$, then $\mathcal{K}$ and $\mathcal{L}$ are 'laminar' in the following sense:

(59.30) $$\begin{aligned} &\forall K \in \mathcal{K} \;\; \exists L \in \mathcal{L} : K \subseteq L, \\ &\text{or } \forall L \in \mathcal{L} \;\; \exists K \in \mathcal{K} : L \subseteq K, \\ &\text{or } \forall K \in \mathcal{K} \;\; \forall L \in \mathcal{L} : K \cap L = \emptyset. \end{aligned}$$

Theorem 59.3 implies the characterization of the matching forest polytope of Giles [1982b]:

Corollary 59.3a. *For each mixed graph* (V, E, A)*, the matching forest polytope is determined by* (59.18)*.*

Proof. By Theorems 59.3 and 5.22, the vertices of the polytope determined by (59.18) are integer. Since the integer solutions of (59.18) are the incidence vectors of matching forests, this proves the corollary. ∎

59.6. Further results and notes

59.6a. Matching forests in partitionable mixed graphs

Call a mixed graph $G = (V, E, A)$ *partitionable (into R and S)* if V can be partitioned into classes R and S such that each undirected edge connects R and S, while each directed arc is spanned by R or by S.

Trivially, a mixed graph is partitionable if and only if each circuit has an even number of undirected edges. That is, by contracting all directed arcs we obtain a bipartite graph. (Another characterization is: the incidence matrix is totally unimodular.)

In a different form, we have studied matching forests in partitionable mixed graphs before. Let $G = (V, E, A)$ be a mixed graph partitionable into R and S. Orient the edges in E from R to S, and turn the orientation of any arc in A spanned by R. We obtain a directed graph $D' = (V, A')$. Then it is easy to see that:

(59.31) a set of edges and arcs of G is a matching forest $\Longleftrightarrow$ the corresponding arcs in D' form an $R-S$ bifurcation.

This implies that a number of theorems on matching forests in a partitionable mixed graph can be obtained from those on $R-S$ bifurcations. First we have:

Theorem 59.4. *Let $G = (V, E, A)$ be a partitionable mixed graph. Then the maximum size of a matching forest in G is equal to the minimum size of $|V| - |\mathcal{L}|$, where $\mathcal{L}$ is a collection of strong components K of the directed graph $D = (V, A)$ with $d_D^{\text{in}}(K) = 0$ such that no edge in E connects two components in $\mathcal{L}$.*

Proof. This is equivalent to Theorem 54.9. ∎

We similarly obtain a min-max relation for the maximum weight of a matching forest in a partitionable mixed graph, by the total dual integrality of the following system:

(59.32)
$$\begin{array}{rll} \text{(i)} & x_e \geq 0 & \text{for each } e \in E \cup A, \\ \text{(ii)} & x(\delta^{\text{head}}(v)) \leq 1 & \text{for each } v \in V, \\ \text{(iii)} & x(A[U]) \leq |U| - 1 & \text{for each nonempty } U \text{ with } U \subseteq R \text{ or } U \subseteq S. \end{array}$$

Here $\delta^{\text{head}}(v)$ is the set of edges and arcs having v as head.

Theorem 59.5. *If G is a mixed graph partitionable into R and S, then* (59.32) *is TDI and determines the matching forest polytope.*

Proof. This is equivalent to Corollary 54.10a. ∎

For covering by matching forests in partitionable mixed graphs we have:

Theorem 59.6. *Let $G = (V, E, A)$ be a mixed graph partitionable into R and S. Then $E \cup A$ can be covered by k matching forests if and only if*

(59.33)
$$\begin{array}{rl} \text{(i)} & |\delta^{\text{head}}(v)| \leq k \textit{ for each } v \in V; \\ \text{(ii)} & |A[U]| \leq k(|U| - 1) \textit{ for each nonempty subset } U \textit{ of } R \textit{ or } S. \end{array}$$

Proof. This is equivalent to Corollary 54.11c. ∎

The case $A = \emptyset$ is Kőnig's edge-colouring theorem (Theorem 20.1).

An equivalent, polyhedral way of formulating Theorem 59.6 is:

Corollary 59.6a. *If G is a partitionable mixed graph, then the matching forest polytope has the integer decomposition property.*

Proof. Directly from Theorem 59.6. ∎

59.6b. Further notes

The facets of the matching forest polytope are characterized in Giles [1982c].

Matching forests form a special case of matroid matching. Let $G = (V, E, A)$ be a mixed graph. Consider the space $\mathbb{R}^V \times \mathbb{R}^V$. Associate with any undirected edge $e = uv \in E$, the pair $(\chi^u, 0)$, $(\chi^v, 0)$ of vectors in $\mathbb{R}^V \times \mathbb{R}^V$. Associate with any directed arc $a = (u, v) \in A$, the pair $(\chi^v, 0)$, $(0, \chi^u - \chi^v)$ of vectors in $\mathbb{R}^V \times \mathbb{R}^V$. One easily checks that $M \subseteq E \cup A$ is a matching forest if and only if its associated pairs form a matroid matching. Thus matroid matching theory implies a min-max relation and a polynomial-time algorithm for the maximum size of a matching forest. However, as we saw in Section 59.2, there is an easy direct method for this.

Chapter 60

Submodular functions on directed graphs

At two structures we came across the proof technique of making a collection of subsets cross-free: at submodular functions (like in polymatroid intersection) and at directed graphs (like in the proof of the Lucchesi-Younger theorem).
Edmonds and Giles [1977] combined the two structures into one general framework, consisting of a submodular function defined on the vertex set of a directed graph. Johnson [1975a] and Frank [1979b] designed a variant of Edmonds and Giles' framework, containing the polymatroid intersection theorem and the optimum arborescence theorem as special cases.
We first describe the results of Edmonds and Giles, and after that we present a variant, from which the results of Frank can be derived. At the base is the method of Edmonds and Giles to represent any cross-free family by a directed tree (the *tree-representation*) and to derive a network matrix if the family consists of subsets of the vertex set of a directed graph — see Section 13.4.

60.1. The Edmonds-Giles theorem

Let $D = (V, A)$ be a digraph and let $\mathcal{C}$ be a crossing family of subsets of V (that is, if $T, U \in \mathcal{C}$ with $T \cap U \neq \emptyset$ and $T \cup U \neq V$, then $T \cap U, T \cup U \in \mathcal{C}$). A function $f : \mathcal{C} \to \mathbb{R}$ is called *submodular on crossing pairs*, or *crossing submodular*, if for all $T, U \in \mathcal{C}$ with $T \cap U \neq \emptyset$ and $T \cup U \neq V$ one has

(60.1) $$f(T) + f(U) \geq f(T \cap U) + f(T \cup U).$$

Given such $D, \mathcal{C}, f$, a *submodular flow* is a function $x \in \mathbb{R}^A$ satisfying:

(60.2) $$x(\delta^{\text{in}}(U)) - x(\delta^{\text{out}}(U)) \leq f(U) \text{ for each } U \in \mathcal{C}.$$

The set P of all submodular flows is called the *submodular flow polyhedron*.

Equivalently, P is equal to the set of all vectors x in $\mathbb{R}^A$ with the property that the 'gain' vector of x is in the extended polymatroid EP_f. (The *excess function* of x equals Mx where M is the $V \times A$ incidence vector of D.)

Then Edmonds and Giles [1977] showed:

Theorem 60.1 (Edmonds-Giles theorem). *If f is crossing submodular, then* (60.2) *is box-TDI.*

Proof. Choose $w \in \mathbb{R}^A$, and let y be an optimum solution to the dual of maximizing $w^{\mathsf{T}}x$ over (60.2):

$$(60.3) \qquad \min\{\sum_{U\in\mathcal{C}} y(U)f(U) \mid y \in \mathbb{R}_+^{\mathcal{C}}, \sum_{U\in\mathcal{C}} y(U)(\chi^{\delta^{\text{in}}(U)} - \chi^{\delta^{\text{out}}(U)}) = w\}.$$

Choose y such that

$$(60.4) \qquad \sum_{U\in\mathcal{C}} y(U)|U||V\setminus U|$$

is as small as possible. Let $\mathcal{C}_0 := \{U \in \mathcal{C} \mid y(U) > 0\}$. We first prove that $\mathcal{C}_0$ is cross-free.

Suppose to the contrary that $T, U \in \mathcal{C}_0$ with $T \not\subseteq U \not\subseteq T$, $T \cap U \neq \emptyset$, $T \cup U \neq V$. Let $\alpha := \min\{y(T), y(U)\} > 0$. Then decreasing $y(T)$ and $y(U)$ by α, and increasing $y(T \cap U)$ and $y(T \cup U)$ by α, maintains feasibility of z, u, y, while its value is not increased (hence it remains optimum). However, sum (60.4) decreases (by Theorem 2.1). This contradicts the minimality of (60.4).

As $\mathcal{C}_0$ is cross-free, the submatrix formed by the constraints corresponding to $\mathcal{C}_0$ is totally unimodular (by Corollary 13.21a). Hence, by Theorem 5.35, (60.2) is box-TDI. ∎

Note that the proof also yields that the solution y in (60.3) can be taken such that the collection $\{U \in \mathcal{C} \mid y(U) > 0\}$ is cross free.

Box-TDI implies primal integrality (a polyhedron P is *box-integer* if $P \cap \{x \mid d \leq x \leq c\}$ is integer for all integer vectors d, c):

Corollary 60.1a. *If f is integer, the polyhedron determined by* (60.2) *is box-integer.*

Proof. By Theorem 60.1, $\max\{w^{\mathsf{T}}x \mid x \in P\}$ is achieved by an integer solution x, for each vector w. ∎

Complexity. The algorithmic results on polymatroid intersection of Cunningham and Frank [1985] and Fujishige, Röck, and Zimmermann [1989] imply that the optimization problem associated with the Edmonds-Giles theorem can be solved in strongly polynomial time.

Indeed, let $D = (V, A)$ be a digraph, let $\mathcal{C}$ be a crossing family, let $f : \mathcal{C} \to \mathbb{Q}$ be crossing submodular, and let $c, d, l : A \to \mathbb{Q}$. If we want to find a submodular flow x with $d \leq x \leq c$ minimizing $l^{\mathsf{T}}x$, we can assume that all arcs in A are vertex-disjoint. Moreover, we can assume that for each arc $a = (u, v) \in A$ we have $f(\{v\}) = c(a)$ and $f(\{u\}) = -d(a)$. Hence we can ignore d and c, and assume that we want to find a submodular flow x minimizing $l^{\mathsf{T}}x$.

Now define $\mathcal{C}_2 := \{\{u,v\} \mid (u,v) \in A\}$ and $f_2(\{u,v\}) := 0$, $w(v) := l(u,v)$, and $w(u) := 0$, for each $(u,v) \in A$. Then the problem is equivalent to finding a vector x in $EP_f \cap EP_{f_2}$ with $x(V) = 0$ and minimizing $w^{\mathsf{T}}x$. This can be solved in strongly polynomial time by Theorem 49.9.

(Frank [1982b] gave a strongly polynomial-time algorithm for the special case if f is integer, $c = \mathbf{1}$, and $d = \mathbf{0}$.)

A similar reduction of submodular flows to polymatroid intersection was given by Kovalev and Pisaruk [1984].

60.1a. Applications

Network flows. If we take $\mathcal{C} := \{\{v\} \mid v \in V\}$ and $f = \mathbf{0}$, then (60.2) determines circulations, and Theorem 60.1 passes into a theorem on minimum-cost circulations. It may be specialized easily to several other results on flows in networks, e.g., to the max-flow min-cut theorem (Theorem 10.3; take $d = \mathbf{0}, c \geq \mathbf{0}$, and $w(a) = 0$ for $a \neq (s,r)$ and $w((s,r)) = 1$) and to Hoffman's circulation theorem (Theorem 11.2).

Lucchesi-Younger theorem. Let $D = (V,A)$ be a digraph and define

(60.5) $\quad \mathcal{C} := \{U \subseteq V \mid \emptyset \neq U \neq V \text{ and } d_A^{\text{out}}(U) = 0\}.$

So $\mathcal{C}$ consists of all sets U such that the collection of arcs entering U forms a directed cut. Taking $f := -\mathbf{1}$, $c := \mathbf{0}$, $d := -\boldsymbol{\infty}$, and $w := \mathbf{1}$, Theorem 60.1 passes into the Lucchesi-Younger theorem (Theorem 55.2, cf. Corollary 55.2b): the minimum size of a directed cut cover is equal to the maximum number of disjoint directed cuts. For arbitrary w we obtain a weighted version.

Polymatroid intersection. Let f_1 and f_2 be nonnegative submodular set function on S. Let S' and S'' be two disjoint copies of S, let $V = S' \cup S''$, and define $\mathcal{C}$ by

(60.6) $\quad \mathcal{C} := \{U' \mid U \subseteq S\} \cup \{S' \cup U'' \mid U \subseteq S\}$

where U' and U'' denote the sets of copies of elements of U in S' and S''. Define $f : \mathcal{C} \to \mathbb{R}_+$ by

(60.7)
$$\begin{aligned} f(U') &:= f_1(U) && \text{for } U \subseteq S, \\ f(V \setminus U'') &:= f_2(U) && \text{for } U \subseteq S, \\ f(S') &:= \min\{f_1(S), f_2(S)\}. \end{aligned}$$

Then $\mathcal{C}$ and f satisfy (60.1). If we take $d = \mathbf{0}$ and $c = \boldsymbol{\infty}$, Theorem 60.1 passes into the polymatroid intersection theorem (Corollary 46.1a, cf. Theorem 46.1).

Frank and Tardos [1989] showed that also Theorem 44.7 (a generalization of Lovász [1970a] of Kőnig's matching theorem) fits into the Edmonds-Giles model. For applications of the Edmonds-Giles theorem to graph orientation, see Chapter 61.

60.1b. Generalized polymatroids and the Edmonds-Giles theorem

The Edmonds-Giles theorem (Theorem 60.1) also comprises the total dual integrality of the system defining the intersection of two generalized polymatroids (Section 49.11b). Indeed, let S be a finite set, let, for $i = 1,2$, $\mathcal{C}_i$ and $\mathcal{D}_i$ be collections of subsets of S, and let $f_i : \mathcal{C}_i \to \mathbb{R}$ and $g_i : \mathcal{D}_i \to \mathbb{R}$ form a paramodular pair (f_i, g_i). Then the system

(60.8)
$$\begin{aligned} x(U) &\leq f_1(U) && \text{for } U \in \mathcal{C}_1,\\ x(U) &\geq g_1(U) && \text{for } U \in \mathcal{D}_1,\\ x(U) &\leq f_2(U) && \text{for } U \in \mathcal{C}_2,\\ x(U) &\geq g_2(U) && \text{for } U \in \mathcal{D}_2, \end{aligned}$$

is box-totally dual integral, which is Corollary 49.12b.

To see this as a special case of the Edmonds-Giles theorem, let S_1 and S_2 be disjoint copies of S, and let $V := S_1 \cup S_2$. For each $s \in S$, let a_s be the arc (s_2, s_1), where s_1 and s_2 are the copies of s in S_1 and S_2 respectively. Let $A := \{a_s \mid s \in S\}$.

Let

(60.9) $\mathcal{C} := \{U_1 \mid U \in \mathcal{C}_1\} \cup \{V \setminus U_1 \mid U \in \mathcal{D}_1\} \cup \{V \setminus U_2 \mid U \in \mathcal{C}_2\} \cup \{U_2 \mid U \in \mathcal{D}_2\}$,

where U_i denotes the set of copies of the elements in U in S_i $(i = 1, 2)$. It is easy to see that $\mathcal{C}$ is a crossing family.

Define $f : \mathcal{C} \to \mathbb{R}$ by:

(60.10)
$$\begin{aligned} f(U_1) &:= f_1(U) && \text{for } U \in \mathcal{C}_1,\\ f(V \setminus U_1) &:= -g_1(U) && \text{for } U \in \mathcal{D}_1,\\ f(V \setminus U_2) &:= f_2(U) && \text{for } U \in \mathcal{C}_2,\\ f(U_2) &:= -g_2(U) && \text{for } U \in \mathcal{D}_2. \end{aligned}$$

(In case that $f(S_1)$ or $f(S_2)$ would be defined more than once, we take the smallest of the values.) Then f is submodular on crossing pairs. Now the system (in $x \in \mathbb{R}^A$)

(60.11) $x(\delta^{\text{in}}(U)) - x(\delta^{\text{out}}(U)) \leq f(U)$ for $U \in \mathcal{C}$

is the same as (60.8) (after renaming each variable $x(s)$ to $x(a_s)$). So the box-total dual integrality of (60.8) follows from the Edmonds-Giles theorem.

Frank [1984b] showed that, conversely, the solution set of the 'Edmonds-Giles' system (60.2) is the projection of the intersection of two generalized polymatroids.

60.2. A variant

We now give a theorem similar to Theorem 60.1, which includes as special cases again the Lucchesi-Younger theorem and the polymatroid intersection theorem, and moreover theorems on optimum arborescences, bibranchings, and strong connectors.

For any digraph $D = (V, A)$ and any family $\mathcal{C}$ of subsets of V, define the $\mathcal{C} \times A$ matrix M by

(60.12)
$$M_{U,a} := \begin{cases} 1 & \text{if } a \text{ enters } U,\\ 0 & \text{otherwise,} \end{cases}$$

for $U \in \mathcal{C}$ and $a \in A$.

This matrix is totally unimodular if $\mathcal{C}$ is cross-free and the following condition holds:

(60.13) if $X, Y, Z \in \mathcal{C}$ with $X \subseteq V \setminus Y \subseteq Z$, then no arc of D enters both X and Z.

Theorem 60.2. *If $\mathcal{C}$ is cross-free and* (60.13) *holds, then M is totally unimodular.*

Proof. Let $T = (W, B)$ and $\pi : V \to W$ form a tree-representation for $\mathcal{C}$. For any arc $a = (u, v)$ of D, the set of forward arcs in the undirected $\pi(u) - \pi(v)$ path in T is contiguous, that is, forms a directed path, say from u' to v'. This follows from the fact that there exist no arcs b, c, d in this order on the path with b and d forward and c backward, by (60.13).

Define $a' := (u', v')$, and let $D' = (W, A')$ be the digraph with $A' := \{a' \mid a \in A\}$. Then M is equal to the network matrix generated by T and D' (identifying $b \in B$ with the set X_b in $\mathcal{C}$ determined by b). Hence by Theorem 13.20, M is totally unimodular. ∎

Recall that a function g on a crossing family $\mathcal{C}$ is called *supermodular on crossing pairs*, or *crossing supermodular*, if for all $T, U \in \mathcal{C}$:

(60.14) $\quad$ if $T \cap U \neq \emptyset$ and $T \cup U \neq V$, then $g(T) + g(U) \leq g(T \cap U) + g(T \cup U)$.

Consider the polyhedron P determined by:

(60.15)
$$\begin{array}{ll} x_a \geq 0 & \text{for } a \in A, \\ x(\delta^{\text{in}}(U)) \geq g(U) & \text{for } U \in \mathcal{C}. \end{array}$$

Theorem 60.3. *If g is crossing supermodular and* (60.13) *holds, then system* (60.15) *is box-TDI.*

Proof. Let $w \in \mathbb{R}^A$ and let y achieve the maximum in the dual of minimizing $w^{\mathsf{T}} x$ over (60.15):

(60.16)
$$\max\{\sum_{U \in \mathcal{C}} y(U) g(U) \mid y \in \mathbb{R}_+^{\mathcal{C}}, \sum_{U \in \mathcal{C}} y(U) \chi^{\delta^{\text{in}}(U)} \geq w\},$$

in such a way that

(60.17)
$$\sum_{U \in \mathcal{C}} y(U) |U| |V \setminus U|$$

is as small as possible. Define

(60.18)
$$\mathcal{C}_0 := \{U \in \mathcal{C} \mid y(U) > 0\}.$$

We first show that $\mathcal{C}_0$ is cross-free. Suppose to the contrary that there are T, U in $\mathcal{C}$ with $T \not\subseteq U \not\subseteq T$, $T \cap U \neq \emptyset$, and $T \cup U \neq V$. Let $\alpha := \min\{y(T), y(U)\}$. Now decrease $y(T)$ and $y(U)$ by α, and increase $y(T \cap U)$ and $y(T \cup U)$ by α. Then y remains feasible and optimum, while sum (60.17) decreases (Theorem 2.1), a contradiction.

Since $\mathcal{C}_0$ determines a totally unimodular submatrix by Theorem 60.2, by Corollary 5.20b system (60.15) is box-TDI. ∎

Note that the proof yields that (60.16) has a solution y with $\{U \in \mathcal{C} \mid y(U) > 0\}$ cross-free. Condition (60.13) cannot be deleted, as is shown by Figure 60.1.

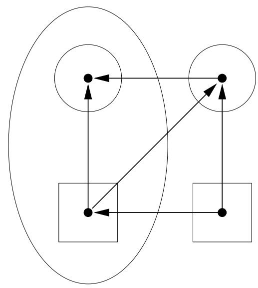

Figure 60.1
A collection and a digraph showing that condition (60.13) **cannot be deleted in Theorem 60.3.** In this Venn-diagram, the collection is represented by the *interiors* of the ellipses and by the *exteriors* of the rectangles.

Again, there is the following standard corollary for primal integrality:

Corollary 60.3a. *If g is integer, the polyhedron determined by* (60.15) *is box-integer.*

Proof. As before. ∎

Notes. Johnson [1975a] proved Theorem 60.3 for the special case that $\mathcal{C}$ is the collection of all nonempty subsets of $V \setminus \{r\}$ (where r is a fixed element of V), and Frank [1979b] extended this result to the case where $\mathcal{C}$ is any intersecting family of subsets of $V \setminus \{r\}$. Note that in this case condition (60.13) is trivially satisfied.

60.2a. Applications

We list some applications of Theorem 60.3, which may be compared with the applications of the Edmonds-Giles theorem (Section 60.1a).

Kőnig-Rado edge cover theorem. Let $G = (V, E)$ be a bipartite graph, with colour classes V_1 and V_2. Let $D = (V, A)$ be the digraph arising from G by orienting all edges from V_2 to V_1. Define $\mathcal{C} := \{\{v\} \mid v \in V_1\} \cup \{V \setminus \{v\} \mid v \in V_2\}$ and let $d := \mathbf{0}$, $c := \infty$, $g := \mathbf{1}$, $w := \mathbf{1}$. Then Theorem 60.3 gives the Kőnig-Rado edge cover theorem (Theorem 19.4): the minimum size of an edge cover in a bipartite graph is equal to the maximum size of a stable set. Taking w arbitrary gives a weighted version.

Optimum arborescence theorem. Let $D = (V, A)$ be a digraph, let $r \in V$, and let $\mathcal{C}$ be the collection of all nonempty subsets of $V \setminus \{r\}$. Let $g := \mathbf{1}$, $d := \mathbf{0}$, $c := \infty$, and let $w : A \to \mathbb{Z}_+$. Theorem 60.3 now gives the optimum arborescence theorem (Theorem 52.3): the minimum weight of an r-arborescence is equal to the maximum number of r-cuts such that no arc a is in more than $w(a)$ of these r-cuts.

Optimum bibranching theorem. Let $D = (V, A)$ be a digraph and let V be split into sets R and S. Define $\mathcal{C} := \{U \subseteq V \mid \emptyset \neq U \subseteq S$ or $S \subseteq U \subset V\}$ and $d := \mathbf{0}$, $c := \infty$, $g := \mathbf{1}$, and let $w : A \to \mathbb{Z}_+$. Then Theorem 60.3 gives Corollary 54.8b: the minimum weight of a bibranching is equal to the maximum number of subsets in $\mathcal{C}$ such that no arc a enters more than $w(a)$ of these subsets.

Lucchesi-Younger theorem. Let $D = (V, A)$ be a digraph and let $\mathcal{C}$ be the collection of all nonempty proper subsets U of V with $\delta^{\text{out}}_A(U) = \emptyset$. Let $g := \mathbf{1}$, $d := \mathbf{0}$, $c := \infty$, and $w := \mathbf{1}$. Then Theorem 60.3 gives the Lucchesi-Younger theorem (Theorem 55.2): the minimum size of a directed cut cover is equal to the maximum number of disjoint directed cuts. Taking w arbitrary, gives a weighted version.

Strong connectors. Suppose that $g = \mathbf{1}$, $d = \mathbf{0}$, and $c = \infty$, and that for all $V_1, V_2 \in \mathcal{C}$ we have: if $V_1 \cap V_2 \neq \emptyset$, then $V_1 \cap V_2 \in \mathcal{C}$, and if $V_1 \cup V_2 \neq V$, then $V_1 \cup V_2 \in \mathcal{C}$. Then Theorem 60.3 is equivalent to Theorem 57.3.

Indeed, let $D = (V, A)$ and $D_0 = (V, A_0)$ be digraphs such that for each arc $a = (u, v)$ of D there are vertices u' and v' such that D_0 contains directed paths from u to u', from v' to v, and from v' to u'. Let $w : A \to \mathbb{Z}_+$. Then the minimum weight of a strong connector in D for D_0 is equal to the maximum number of D_0-cuts in D such that no arc a of D is in more than $w(a)$ of these D_0-cuts.

This can be derived from Theorem 60.3 by taking $\mathcal{C} := \{U \subseteq V \mid \emptyset \neq U \neq V, \delta^{\text{in}}_{A_0}(U) = \emptyset\}$. Conversely, if $\mathcal{C}$ satisfies the condition given above, we can take $A_0 := \{(u, v) \mid u, v \in V, (u, v)$ enters no $U \in \mathcal{C}\}$.

Polymatroid intersection. Let g_1 and g_2 be integer supermodular nondecreasing set functions on S with $g_1(\emptyset) = g_2(\emptyset) = 0$. Then

(60.19)
$$\min\{x(S) \mid x \in \mathbb{Z}^S_+, x(U) \geq g_i(U) \text{ for } U \subseteq S, i = 1, 2\} = \max_{U \subseteq S}(g_1(U) + g_2(S \setminus U)).$$

This follows by taking disjoint copies S' and S'' of S, and setting $V := S' \cup S''$, $\mathcal{C} := \{T \subseteq V \mid T \subseteq S'$ or $S' \subseteq T\}$, $A := \{(s'', s') \mid s \in S\}$, $g(U') := g_1(U)$ and $g(V \setminus U'') := g_2(U)$ for $U \subseteq S$ (without loss of generality, $g_1(S) = g_2(S)$), $d := \mathbf{0}$, $c := \infty$, $w := \mathbf{1}$.

By taking d, c, w arbitrary, several other (contra)polymatroid intersection theorems follow.

60.3. Further results and notes

60.3a. Lattice polyhedra

In a series of papers, Hoffman [1976a,1978] and Hoffman and Schwartz [1978] developed a theory of 'lattice polyhedra', which extends results of Johnson [1975a]. This theory has much in common with the theories described above.

Let $(L, \leq)$ be a partially ordered set and let $\wedge : L \times L \to L$ be a function such that

(60.20) for all $a, b \in L$: $a \wedge b \leq a$ and $a \wedge b \leq b$.

Let S be a finite set and let $\phi : L \to \mathcal{P}(S)$ be such that

(60.21) if $a < b < c$, then $\phi(a) \cap \phi(c) \subseteq \phi(b)$

for a, b, c in L. Let $\vee : L \times L \to L$ and let $f : L \to \mathbb{R}_+$ satisfy:

(60.22) $f(a \wedge b) + f(a \vee b) \leq f(a) + f(b)$

for all a, b in L. So f is, in a sense, *submodular*.

Define

(60.23) $S' := \{u \in S \mid \forall a, b \in L : \chi^{\phi(a\wedge b)}(u) + \chi^{\phi(a\vee b)}(u) \leq \chi^{\phi(a)}(u) + \chi^{\phi(b)}(u)\}$ and
$S'' := \{u \in S \mid \forall a, b \in L : \chi^{\phi(a\wedge b)}(u) + \chi^{\phi(a\vee b)}(u) \geq \chi^{\phi(a)}(u) + \chi^{\phi(b)}(u)\}$.

The polyhedron determined by:

(60.24)
$$\begin{array}{ll} x_u \geq 0 & (u \in S \setminus S'), \\ x_u \leq 0 & (u \in S \setminus S''), \\ x(\phi(a)) \leq f(a) & (a \in L). \end{array}$$

is called a *lattice polyhedron*. Hoffman and Schwartz [1978] showed that system (60.24) is box-totally dual integral.

Theorem 60.4. *System* (60.24) *is box-TDI.*

Proof. Choose $w \in \mathbb{R}^S_+$. Consider the dual of maximizing $w^\mathsf{T} x$ over (60.24):

(60.25) $\min\{y^\mathsf{T} f \mid y \in \mathbb{R}^L_+, \sum_{a\in L} y_a \chi^{\phi(a)} \leq w(u)$ if $u \in S'$ and $\sum_{a\in L} y_a \chi^{\phi(a)} \geq w(u)$ if $u \in S''\}$.

Order the elements of L as $a_1, \ldots, a_n$ such that if $a_i \leq a_j$, then $i \leq j$. Let y attain (60.25), such that $y(L)$ is minimal, and, under this condition, such that

(60.26) $(y(a_1), \ldots, y(a_n))$

is lexicographically maximal.

Then the collection $C := \{a \in L \mid y_a > 0\}$ is a chain in L. For suppose to the contrary that $a, b \in C$ with $a \not\leq b \not\leq a$. Let $\alpha := \min\{y_a, y_b\}$. Reset y by decreasing y_a and y_b by α, and increasing $y(a \wedge b)$ and $y(a \vee b)$ by α. One easily checks, using (60.22) and (60.23), that the new y again attains the minimum (60.25), and moreover that $(y(a_1), \ldots, y(a_n))$ lexicographically increases, contradicting our assumption.

By (60.21) for each u in S, the set of a in C with $u \in \phi(a)$ forms an interval in C. So the linear inequalities corresponding to C make up a totally unimodular matrix (as it is a network matrix generated by a directed path and a directed graph (Theorem 13.20)). Therefore, by Theorem 5.35, system (60.24) is box-TDI. ∎

We give some applications of Theorem 60.4 (more applications are in Hoffman [1976a], Hoffman and Schwartz [1978], and Gröflin [1984,1987]).

Shortest paths (Johnson [1975a]). Let $D = (V, A)$ be a digraph and let $s, t \in V$. Let $L := \{U \subseteq V \mid s \in U, t \notin U\}$ and let $\leq := \subseteq$, $\wedge := \cap$, $\vee := \cup$. Let $S := A$ and let for each $U \in L$, $\phi(U) := \delta^{\text{out}}(U)$. These data satisfy (60.20) and (60.21), where $S' := S$. If $f = -\mathbf{1}$, Theorem 60.4 gives: the minimum length of an $s-t$ path is equal to the maximum number of $s-t$ cuts such that no arc a is in more than $c(a)$ of these $s-t$ cuts — the max-potential min-work theorem (Theorem 7.1).

Matroid intersection (Hoffman [1976a]). Let $(S, \mathcal{I})$ and $(S, \mathcal{I}_2)$ be matroids, with rank functions r_1 and r_2 and assume $r_1(S) = r_2(S)$. Let S' and S'' be two disjoint copies of S and let $V := S' \cup S''$. Let $L := \{U \subseteq V \mid U \subseteq S' \text{ or } S' \subseteq U\}$. Let $\leq := \subseteq$, $\wedge := \cap$, $\vee := \cup$. Define for $T \subseteq S$:

(60.27) $$\begin{aligned} f(T') &:= r_1(T), & \phi(T') &:= T, \\ f(V \setminus T'') &:= r_2(T), & \phi(V \setminus T'') &:= T. \end{aligned}$$

As these data satisfy (60.20), (60.21), and (60.22), Theorem 60.4 yields the matroid intersection theorem. Polymatroid intersection can be included similarly.

Chains and antichains in partially ordered sets (Hoffman and Schwartz [1978]). Let $(V, \preceq)$ be a partially ordered set and let L be the collection of lower ideals of V (a subset Y of V is a *lower ideal* if $y \preceq x \in V$ implies $y \in V$). Define $\leq := \subseteq$, $\wedge := \cap$, $\vee := \cup$.

First, let $S := V$. For $Y \in L$, let $\phi(Y)$ be the collection of maximal elements of Y. These data satisfy (60.20) and (60.21), and $S' = S'' = S$.

Theorem 60.4 with $f(Y) := k$ for each $Y \in L$ then gives the theorem of Greene [1976] (Corollary 14.10b) that the maximum size of the union of k chains is equal to the minimum value of $|V \setminus Y| + k \cdot c_1(Y)$, where Y ranges over all subsets of V and where $c_1(Y)$ denotes the maximum size of a chain contained in Y.

Indeed, Theorem 60.4 gives the total dual integrality of

(60.28) $$\begin{aligned} &0 \leq x_v \leq 1 && \text{for } v \in V, \\ &x(A) \leq k && \text{for each antichain } A. \end{aligned}$$

Hence the maximum size of the union of k chains is, by Dilworth's decomposition theorem, equal to (where $\mathcal{A}$ denotes the collection of antichains in V)

(60.29) $$\begin{aligned} &\max\{\mathbf{1}^{\mathsf{T}} x \mid x \in \{0,1\}^V, x(A) \leq k \text{ for } A \in \mathcal{A}\} \\ &= \min\{k \sum_{A \in \mathcal{A}} y_A + z(V) \mid y \in \mathbb{Z}_+^{\mathcal{A}}, z \in \mathbb{Z}_+^V, \sum_{A \in \mathcal{A}} y_A \chi^A + z \geq \mathbf{1}\} \\ &= \min_{Y \subseteq V} (|V \setminus Y| + k \cdot (\text{minimum number of antichains covering } Y)) \\ &= \min_{Y \subseteq V} (|V \setminus Y| + k \cdot c_1(Y)). \end{aligned}$$

Also the dual result (exchanging ‘chain’ and ‘antichain’) due to Greene and Kleitman [1976] (Corollary 14.8b) can be derived. Let $L, \leq, \wedge, \vee$ be as above and let $S := V \cup \{w\}$, where w is some new element. For $Y \in L$, let $\phi(Y)$ be the collection of maximal elements of Y together with w and let $f(Y) := -|\phi(Y)|$. These data again satisfy (60.20) and (60.21), and $S' = S'' = S$.

Then Theorem 60.4 gives the box-total dual integrality of the system

(60.30) $\quad x(A) + \lambda \leq -|A|$ for each antichain A,

and hence of the system

(60.31) $\quad x(A) + \lambda \geq |A|$ for each antichain A.

Then the maximum union of k antichains is equal to

(60.32)
$$\begin{aligned} &\max\{\sum_{A\in\mathcal{A}} y_A|A| \mid y \in \mathbb{Z}_+^{\mathcal{A}}, \sum_{A\in\mathcal{A}} y_A\chi^A \leq \mathbf{1}, \sum_{A\in\mathcal{A}} y_A = k\} \\ &= \min\{x(V) + k\cdot\lambda \mid x \in \mathbb{Z}_+^V, \lambda \in \mathbb{Z}, x(A) + \lambda \geq |A| \text{ for each } A \in \mathcal{A}\} \\ &\geq \min_{Y\subseteq V}(|V \setminus Y| + k\cdot(\text{maximum size of an antichain contained in } Y)). \end{aligned}$$

The equality follows from the box-total dual integrality of (60.31). The inequality follows by taking $Y := \{v \in V \mid x_v = 0\}$. Then λ is at least the maximum size of an antichain contained in Y, since for any antichain $A \subseteq Y$: $\lambda = x(A) + \lambda \geq |A|$.

Common base vectors in two polymatroids (Gröflin and Hoffman [1981]). Let f_1 and f_2 be submodular set functions on S. The polymatroid intersection theorem gives:

(60.33)
$$\begin{aligned} f(T) &:= \max\{x(T) \mid x(U) \leq f_i(U) \text{ for } U \subseteq S \text{ and } i = 1, 2\} \\ &= \min_{U\subseteq T}(f_1(U) + f_2(T \setminus U)), \end{aligned}$$

for $T \subseteq S$. Gröflin and Hoffman [1981] showed that Theorem 46.4 follows from Theorem 60.4 above as follows. (The proof of Theorem 46.4 was modelled after the proof of Theorem 60.4.)

Let L be the set of all pairs (T, U) of subsets of S with $T \cap U = \emptyset$, partially ordered by $\leq$ as follows:

(60.34) $\quad (T, U) \leq (T', U')$ and only if $T \subseteq T'$ and $U \supseteq U'$.

Then $(L, \leq)$ is a lattice with lattice operations $\wedge$ and $\vee$ (say). Define $\phi(T, U) := |S \setminus (T \cup U)|$ and $f(T, U) := f_1(T) + f_2(U) - f(S)$. As these data satisfy (60.20), (60.21), and (60.22), Theorem 60.4 applies. We have $S' = S'' = S$. Hence the system

(60.35) $\quad x(S \setminus (T \cup U)) \geq f_1(T) + f_2(U) - f(S)$ for $(T, U) \in L$

is box-TDI. With the definition of f, this implies the box-total dual integrality of

(60.36) $\quad x(T) \leq f(S \setminus T) - f(S)$ for $T \subseteq S$,

and (equivalently) of

(60.37) $\quad x(T) \geq f(S) - f(S \setminus T)$ for $T \subseteq S$.

That is, we have Theorem 46.4.

Convex sets in partially ordered sets (Gröflin [1984]). Let $(S, \leq)$ be a partially ordered set. A subset C of S is called *convex* if $a, b \in C$ and $a \leq x \leq b$ imply $x \in C$. Then the system

(60.38) $\quad x(C) \leq 1$ for each convex subset C of S,

is box-TDI. Note that this system describes the polar of the convex hull of the incidence vectors of convex sets.

To see the box-total dual integrality of (60.38), define

(60.39) $\quad L := \{(A, B) \mid A \text{ lower ideal and } B \text{ upper ideal in } S \text{ with } A \cup B = S\}.$

(An *upper ideal* is a subset B such that if $b \in B$ and $x \geq b$, then $x \in B$. Similarly, a *lower ideal* is a subset B such that if $b \in B$ and $x \leq b$, then $x \in B$.) Make L to a lattice by defining a partial order $\preceq$ on L by:

(60.40) $\quad (A, B) \preceq (A', B') \iff A \subseteq A', B \supseteq B'.$

Define $f : L \to \mathbb{R}$ and $\phi : L \to \mathcal{P}(S)$ by: $f(A, B) := 1$ and $\phi(A, B) := A \cap B$, for $(A, B) \in L$. Applied to this structure, Theorem 60.4 gives the box-total dual integrality of (60.38).

('Greedy' algorithms for some lattice polyhedra problems were investigated by Kornblum [1978].)

An extension of lattice polyhedra, to handle rooted-connectivity augmentation of a digraph, was given by Frank [1999b].

60.3b. Polymatroidal network flows

Hassin [1978,1982] and Lawler and Martel [1982a,1982b] gave the following 'polymatroidal network flow' model equivalent to that of Edmonds and Giles. Let $D = (V, A)$ be a digraph. For each $v \in V$, let $\mathcal{C}_v^{\text{out}}$ and $\mathcal{C}_v^{\text{in}}$ be intersecting families of subsets of $\delta^{\text{out}}(v)$ and $\delta^{\text{in}}(v)$, respectively, and let $f_v^{\text{out}} : \mathcal{C}_v^{\text{out}} \to \mathbb{R}$ and $f_v^{\text{in}} : \mathcal{C}_v^{\text{in}} \to \mathbb{R}$ be submodular on intersecting pairs. Then the system

(60.41)
$$\begin{array}{ll} x(\delta^{\text{out}}(v)) = x(\delta^{\text{in}}(v)) & \text{for } v \in V, \\ x(B) \leq f_v^{\text{in}}(B) & \text{for each } v \in V \text{ and } B \in \mathcal{C}_v^{\text{in}}, \\ x(B) \leq f_v^{\text{out}}(B) & \text{for each } v \in V \text{ and } B \in \mathcal{C}_v^{\text{out}}, \end{array}$$

is box-TDI. Frank [1982b] showed that this can be derived from the Edmonds-Giles theorem (Theorem 60.1) as follows. Make a digraph $D' = (V', A')$, where A' consists of disjoint arcs $a' := (u_a, v_a)$ for each $a \in A$. Let $\mathcal{C}$ consist of all subsets U of V' such that there exists a $v \in V$ satisfying:

(60.42)
$$\begin{array}{l} U = \{v_a \mid a \in \delta^{\text{in}}(v)\} \cup \{u_a \mid a \in \delta^{\text{out}}(v)\}, \\ \text{or } \exists B \in \mathcal{C}_v^{\text{in}} : U = \{v_a \mid a \in B\}, \\ \text{or } \exists B \in \mathcal{C}_v^{\text{out}} : U = V' \setminus \{u_a \mid a \in B\}. \end{array}$$

Define $f(U) := 0$, $f(U) := f_v^{\text{in}}(B)$, and $f(U) := f_v^{\text{in}}(B)$, respectively. Then the box-total dual integrality of (60.41) is equivalent to that of

(60.43) $\quad x(\delta_{A'}^{\text{in}}(U)) - x(\delta_{A'}^{\text{out}}(U)) \leq f(U)$ for $U \in \mathcal{C}$, which follows from Theorem 60.1.

Lawler [1982] showed that, conversely, the Edmonds-Giles model is a special case of the polymatroidal network flow model. To see this, let $D = (V, A)$ be a digraph, let $\mathcal{C}$ be a crossing family of subsets of V, and let $f : \mathcal{C} \to \mathbb{R}$ be crossing submodular. Let $\hat{\mathcal{C}}$ be the collection of all sets $U = U_1 \cap \cdots \cap U_t$ with $U_1, \ldots, U_t \in \mathcal{C} \setminus \{V\}$ such that $U_i \cup U_j = V$ for all i, j with $1 \le i < j \le t$. Define $\hat{f} : \hat{\mathcal{C}} \to \mathbb{R}$ by

(60.44) $$\hat{f}(U) := \min(f(U_1) + \cdots + f(U_t)),$$

where the minimum ranges over sets $U_1, \ldots, U_t$ as above. Then $\hat{\mathcal{C}}$ is an intersecting family and $\hat{f}$ is intersecting submodular (Theorem 49.6).

Now extend D by a new vertex r, and arcs (v, r) for $v \in V$, thus making the digraph $D' = (V \cup \{r\}, A')$. Let $\mathcal{C}_r^{\text{in}}$ consist of all subsets B of $\delta_{A'}^{\text{in}}(r)$ for which there is a $U \in \hat{\mathcal{C}}$ satisfying

(60.45) $$B = \{(v, r) \mid v \in U\}.$$

Define $f_r^{\text{in}}(B) := \hat{f}(U)$. Then

(60.46) $$\begin{aligned} x(\delta_{A'}^{\text{out}}(v)) &= x(\delta_{A'}^{\text{in}}(v)) && \text{for } v \in V,\\ x(\delta_{A'}^{\text{in}}(r)) &= 0, &&\\ x(B) &\le f_r^{\text{in}}(B) && \text{for } B \in \mathcal{C}_r^{\text{in}}, \end{aligned}$$

is a special case of (60.41). Moreover, the box-total dual integrality of (60.46) implies the box-total dual integrality of

(60.47) $$x(\delta_A^{\text{in}}(U)) - x(\delta^{\text{out}}(U)) \le f(U) \text{ for } U \in \mathcal{C},$$

since in (60.46) we can restrict B to those B for which there exists a $U \in \mathcal{C}$ with $B = \{(v, r) \mid v \in U\}$ (since $x(\delta_{A'}^{\text{in}}(r)) = 0$). Then

(60.48) $$x(B) = \sum_{v \in U} \big(x(\delta_A^{\text{in}}(v)) - x(\delta_A^{\text{out}}(v)) \big) = x(\delta_A^{\text{in}}(U)) - x(\delta_A^{\text{out}}(U)).$$

So it implies the Edmonds-Giles theorem (Theorem 60.1).

60.3c. A general model

In Schrijver [1984a] the following general framework was given. Let S be a finite set, let $n \in \mathbb{Z}_+$, let $\mathcal{C}$ be a collection of subsets of S, let $b, c \in (\mathbb{R} \cup \{\pm\infty\})^n$, and let $f : \mathcal{C} \to \mathbb{R}$ and $h : \mathcal{C} \to \{0, \pm 1\}^n$ satisfy:

(60.49)
(i) if $\{T_1, T_2, T_3\}$ is a cross-free subcollection of $\mathcal{C}$, then for each $j = 1, \ldots, n$, there exist $u, v \in S$ such that for $i = 1, 2, 3$: $h(T_i)_j = +1$ if and only if (u, v) enters T_i, and $h(T_i)_j = -1$ if and only if (u, v) leaves T_i;
(ii) if T and U are crossing sets in $\mathcal{C}$, then there exist $T', U' \in \mathcal{C}$ such that $T' \subset T$ and
$$f(T) + f(U) - f(T') - f(U') \ge (h(T) + h(U) - h(T') - h(U'))x$$
for each x with $b \le x \le c$.

Then the system (in $x \in \mathbb{R}^n$)

(60.50) $$\begin{aligned} & b \leq x \leq c, \\ & h(T)x \leq f(T) \quad \text{for } T \in \mathcal{C}, \end{aligned}$$

is box-TDI. This contains the Edmonds-Giles theorem (Theorem 60.1) and Theorems 60.3 and 60.4 as special cases.

A proof of the box-total dual integrality of (60.50) can be sketched as follows. If we maximize a linear functional $w^{\mathsf{T}}x$ over (60.50), condition (60.49)(ii) implies that there exists an optimum dual solution whose active constraints correspond to a cross-free subfamily of $\mathcal{C}$. Next, condition (60.49)(i) implies that these constraints form a network matrix, hence a totally unimodular matrix, proving the box-total dual integrality of (60.50) with Theorem 5.35.

60.3d. Packing cuts and Győri's theorem

Let $D = (V, A)$ be a digraph and let $g : \mathcal{P}(V) \to \mathbb{Z}_+$ satisfy the supermodular inequality

(60.51) $$g(U) + g(W) \leq g(U \cap W) + g(U \cup W)$$

for all $U, W \subseteq V$ such that $\delta^{\text{in}}(U) \cap \delta^{\text{in}}(W) \neq \emptyset$ and $g(U) > 0$, $g(W) > 0$.

The following was shown by Frank and Jordán [1995b] (in the terminology of bisupermodular functions — see Corollary 60.5a):

Theorem 60.5. *Let $D = (V, A)$ be a digraph satisfying:*

(60.52) *V can be partitioned into two sets S and T such that A consists of all arcs from S to T.*

Let g be as above, with $g(U) = 0$ if $\delta^{\text{in}}(U) = \emptyset$. Then the minimum of $x(A)$ taken over all $x : A \to \mathbb{Z}_+$ satisfying

(60.53) *$x(\delta^{\text{in}}(U)) \geq g(U)$ for each $U \subseteq V$,*

is equal to the maximum value of $\sum_{U \in \mathcal{B}} g(U)$, where $\mathcal{B}$ is a collection of subsets U such that the $\delta^{\text{in}}(U)$ for $U \in \mathcal{B}$ are disjoint.

Proof. Let $\tau(g)$ and $\nu(g)$ denote the minimum and maximum value, respectively.

Then $\nu(g) \leq \tau(g)$, since, if $x : A \to \mathbb{Z}_+$ satisfies (60.53) and $\mathcal{B}$ is as described, then

(60.54) $$x(A) \geq \sum_{U \in \mathcal{B}} x(\delta^{\text{in}}(U)) \geq \sum_{U \in \mathcal{B}} g(U).$$

The reverse inequality $\tau(g) \leq \nu(g)$ is shown by induction on $\nu(g)$. If $\nu(g) = 0$, then $g(U) = 0$ for all $U \subseteq V$, and hence $\tau(g) = 0$. Now let $\nu(g) \geq 1$.

For each $a \in A$, define a function g^a by

(60.55) $$g^a(U) := \begin{cases} g(U) - 1 & \text{if } a \in \delta^{\text{in}}(U) \text{ and } g(U) \geq 1, \\ g(U) & \text{otherwise,} \end{cases}$$

for $U \subseteq V$. In other words:

(60.56) $$g^a(U) = \max\{g(U) - d^{\text{in}}_{\{a\}}(U), 0\}.$$

Then

(60.57) g^a again satisfies (60.51).

Indeed, if $\delta^{\text{in}}(U) \cap \delta^{\text{in}}(W) \neq \emptyset$, and $g^a(U) > 0$ and $g^a(W) > 0$, then $g(U) > 0$ and $g(W) > 0$, and $g^a(U) = g(U) - d^{\text{in}}_{\{a\}}(U)$ and $g^a(W) = g(W) - d^{\text{in}}_{\{a\}}(W)$. Hence

(60.58)
$$\begin{aligned} g^a(U) + g^a(W) &= g(U) + g(W) - d^{\text{in}}_{\{a\}}(U) - d^{\text{in}}_{\{a\}}(W) \\ &\leq g(U \cap W) + g(U \cup W) - d^{\text{in}}_{\{a\}}(U \cap W) - d^{\text{in}}_{\{a\}}(U \cup W) \\ &\leq g^a(U \cap W) + g^a(U \cup W). \end{aligned}$$

So g^a satisfies (60.51).

The following is the key of the proof:

(60.59) there exists an arc a with $\nu(g^a) \leq \nu(g) - 1$.

Suppose to the contrary that $\nu(g^a) = \nu(g)$ for all $a \in A$. As $\nu(g) \geq 1$, there exists a $W \subseteq V$ with $g(W) \geq 1$. For each $a \in \delta^{\text{in}}(W)$, as $\nu(g^a) = \nu(g)$, there exists a collection $\mathcal{B}^a$ such that any arc of D enters at most one $U \in \mathcal{B}^a$, such that $g^a(\mathcal{B}^a) = \nu_g$, and such that $g(U) > 0$ for each $U \in \mathcal{B}^a$. As $g(\mathcal{B}^a) \leq g^a(\mathcal{B}^a)$, a enters no $U \in \mathcal{B}^a$.

Now for each $U \subseteq V$, let $w(U)$ be the number of times U occurs among the $\mathcal{B}^a$ (over all $a \in \delta^{\text{in}}(W)$). Reset $w(W) := w(W) + 1$. Then w has the following properties:

(60.60)
(i) $\sum_{U \subseteq V} w(U)\chi^{\delta^{\text{out}}(U)} \leq |\delta^{\text{in}}(W)| \cdot \mathbf{1}$ and
(ii) $\sum_{U \subseteq V} w(U)g(U) > |\delta^{\text{in}}(W)|\nu(g)$.

Moreover, $g(U) \geq 1$ whenever $w(U) > 0$.

Now as long as there exist $U, U' \subseteq V$ with $w(U) > 0$ and $w(U') > 0$ and not satisfying:

(60.61) $\delta^{\text{in}}(U) \cap \delta^{\text{in}}(U') = \emptyset$ or $U \subseteq U'$ or $U' \subseteq U$,

decrease $w(U)$ and $w(U')$ by 1, and increase $w(U \cap U')$ and $w(U \cup U')$ by 1. This operation maintains (60.60) and decreases

(60.62)
$$\sum_{U \in \mathcal{P}(V)} w(U)|U||V \setminus U|$$

(by Theorem 2.1). So after a finite number of these operations, w satisfies (60.60) and all U, U' with $w(U) > 0$ and $w(U') > 0$ satisfy (60.61).

Let $\mathcal{F}$ be the collection of $U \subseteq V$ with $w(U) > 0$. We apply the length-width inequality for partially ordered sets (Theorem 14.5) to $(\mathcal{F}, \subseteq)$. By (60.60)(i), the maximum of $w(\mathcal{C})$ taken over chains in $\mathcal{F}$ is at most $|\delta^{\text{in}}(W)|$, since by (60.52), there is an arc $a \in A$ entering all $U \in \mathcal{C}$ (as $\delta^{\text{in}}(U) \neq \emptyset$, since $g(U) \geq 1$, for each $U \in \mathcal{F}$). Moreover, the maximum of $g(\mathcal{B})$ taken over antichains $\mathcal{B}$ in $\mathcal{F}$ is at most $\nu(g)$, since the elements in $\mathcal{F}$ satisfy (60.61), and therefore $\mathcal{B}$ gives a collection of disjoint cuts. But then (60.60)(ii) contradicts the length-width inequality. This proves (60.59).

We now can apply induction, since trivially $\tau(g) \leq \tau(g^a) + 1$, as increasing x_a by 1 for any x satisfying (60.53) with respect to g^a, gives an x satisfying (60.53) with respect to g. So $\tau(g) \leq \tau(g^a) + 1 = \nu(g^a) + 1 \leq \nu(g)$. ∎

This theorem can be equivalently formulated as follows. Let S and T be finite sets. Consider functions $h : \mathcal{P}(S) \times \mathcal{P}(T) \to \mathbb{R}$ satisfying

(60.63) $h(X_1 \cap X_2, Y_1 \cup Y_2) + h(X_1 \cup X_2, Y_1 \cap Y_2) \geq h(X_1, Y_1) + h(X_2, Y_2)$ for all $X_1, X_2 \subseteq S$ and $Y_1, Y_2 \subseteq T$ with $X_1 \cap X_2 \neq \emptyset$, $Y_1 \cap Y_2 \neq \emptyset$, $h(X_1, Y_1) > 0$, and $h(X_2, Y_2) > 0$.

Call a collection $\mathcal{F} \subseteq \mathcal{P}(S) \times \mathcal{P}(T)$ *independent* if $X_1 \cap X_2 = \emptyset$ or $Y_1 \cap Y_2 = \emptyset$ for all distinct (X_1, Y_1), (X_2, Y_2) in $\mathcal{F}$. So $\mathcal{F}$ is independent if the sets $X \times Y$ for $(X, Y) \in \mathcal{F}$ are disjoint.

As usual,

(60.64) $$h(\mathcal{F}) := \sum_{(X,Y)\in\mathcal{F}} h(X, Y).$$

Moreover, if $z : S \times T \to \mathbb{R}$, denote

(60.65) $$z(X \times Y) := \sum_{(x,y)\in X\times Y} z(x, y)$$

for $X \subseteq S$ and $Y \subseteq T$.

Corollary 60.5a. *Let $h : \mathcal{P}(S)\times\mathcal{P}(T) \to \mathbb{Z}_+$ satisfy* (60.63)*, such that $h(X, Y) = 0$ if $X = \emptyset$ or $Y = \emptyset$. Then the minimum value of $z(S \times T)$ where $z : S \times T \to \mathbb{Z}_+$ satisfies*

(60.66) $z(X \times Y) \geq h(X, Y)$ *for all* $X \subseteq S$, $Y \subseteq T$,

is equal to the maximum value of $h(\mathcal{F})$ where $\mathcal{F}$ is independent.

Proof. We can assume that S and T are disjoint. Let $V := S \cup T$, and define a set function g on V by:

(60.67) $g(U) := h(S \setminus U, T \cap U)$

for $U \subseteq V$. Let $D = (V, A)$ be the digraph with A consisting of all arcs from S to T. Then D and g satisfy the condition of Theorem 60.5, and the min-max equality proved in Theorem 60.5 is equivalent to the min-max equality described in the present corollary. ∎

Frank and Jordán showed that this theorem implies the following 'minimax theorem for intervals' of Győri [1984]. Let $\mathcal{I}$ and $\mathcal{J}$ be collections of sets. Then $\mathcal{J}$ is said to *generate* $\mathcal{I}$ if each set in $\mathcal{I}$ is a union of sets in $\mathcal{J}$. Győri's theorem characterizes the minimum size of a collection of intervals generating a given finite collection $\mathcal{I}$ of intervals. For this, we can take an 'interval' to be a finite, contiguous set of integers.

To describe the min-max equality, consider the undirected graph $G_{\mathcal{I}} = (V_{\mathcal{I}}, E_{\mathcal{I}})$ with

(60.68) $V_{\mathcal{I}} := \{(s, I) \mid s \in I \in \mathcal{I}\}$,

where two distinct pairs (s, I) and (s', I') are adjacent if and only if $s \in I'$ and $s' \in I$. Call a subset C of $V_{\mathcal{I}}$ *stable* if any two elements of C are nonadjacent (in other words, C is a stable set in $G_{\mathcal{I}}$).

Corollary 60.5b (Győri's theorem)**.** *Let $\mathcal{I}$ be a finite collection of intervals. Then the minimum size of a collection of intervals generating $\mathcal{I}$ is equal to the maximum size of a stable subset of $V_{\mathcal{I}}$.*

Proof. To see that the minimum is not less than the maximum, observe that if $\mathcal{J}$ generates $\mathcal{I}$ and C is a stable subset of $V_{\mathcal{I}}$, then for any $J \in \mathcal{J}$, there is at most one $(s, I) \in C$ with $s \in J \subseteq I$, while for any $(s, I) \in C$ there is at least one such $J \in \mathcal{J}$. So $|\mathcal{J}| \geq |C|$.

Equality is shown with Corollary 60.5a. Let S be the union of the intervals in $\mathcal{I}$. Define a function $h : \mathcal{P}(S) \times \mathcal{P}(S) \to \{0, 1\}$ by

(60.69) $h(X, Y) = 1$ if and only if X and Y are nonempty intervals such that $\max X = \min Y$ and $X \cup Y \in \mathcal{I}$, and such that there is no $I \in \mathcal{I}$ with $X \cap Y \subseteq I \subset X \cup Y$,

for $X, Y \subseteq S$. (Here $\max Z$ and $\min Z$ denote the maximum and minimum element of Z, respectively.)

Then h satisfies (60.63). To see this, note first that each (X, Y) with $h(X, Y) = 1$ is characterized by a point $s \in S$ and an inclusionwise minimal interval $I \in \mathcal{I}$ containing s (inclusionwise minimal among all intervals in $\mathcal{I}$ containing s). The relation is that $\{s\} = X \cap Y$ and $I = X \cup Y$.

To see that h satisfies (60.63), let $h(X_1, Y_1) = 1$ and $h(X_2, Y_2) = 1$ and $X_1 \cap X_2 \neq \emptyset$ and $Y_1 \cap Y_2 \neq \emptyset$. We show $h(X_1 \cap X_2, Y_1 \cup Y_2) = 1$ (then $h(X_1 \cup X_2, Y_1 \cap Y_2) = 1$ follows by symmetry).

In fact, this is straightforward case-checking. Let $X_i = [a_i, b_i]$, $Y_i = [b_i, c_i]$, and $I_i := X_i \cup Y_i$ for $i = 1, 2$. As $X_1 \cap I_2 \neq \emptyset \neq Y_1 \cap I_2$, we know that $b_1 \in [a_2, c_2]$, and similarly $b_2 \in [a_1, c_1]$. By symmetry, we can assume that $a_1 \leq a_2$. Hence, by the minimality of $X_1 \cup Y_1$ as an interval containing b_1, $c_1 \leq c_2$. Now, if $b_2 \leq b_1$, we have $X_1 \cap X_2 = [a_2, b_2] = X_2$ and $Y_1 \cup Y_2 = [b_2, c_2] = Y_2$, and therefore $h(X_1 \cap X_2, Y_1 \cup Y_2) = h(X_2, Y_2) = 1$. If $b_1 < b_2$, then $X_1 \cap X_2 = [a_2, b_1]$ and $Y_1 \cup Y_2 = [b_1, c_2]$. Suppose that there is an $I \in \mathcal{I}$ with $b_1 \in I \subset [a_2, c_2]$. By the minimality of $[a_2, c_2]$ as an interval containing b_2, we know $b_2 \notin I$. Hence $I \subset [a_1, c_1]$, contradicting the minimality of $[a_1, c_1]$ as an interval containing b_1. Therefore, no such I exists, and hence we have $h(X_1 \cap X_2, Y_1 \cup Y_2) = 1$.

So Corollary 60.5a applies (taking $T := S$). Let z and $\mathcal{F}$ attain the minimum and maximum respectively. Let $\mathcal{J}$ be the collection of intervals $[s, t]$ with $z(s, t) \geq 1$ and $s \leq t$. Let C be the collection of pairs (s, I) with $s \in S$ and $I \in \mathcal{I}$ such that there is an $(X, Y) \in \mathcal{F}$ with $h(X, Y) = 1$, $X \cap Y = \{s\}$, and $X \cup Y = I$. Then $\mathcal{J}$ generates $\mathcal{I}$, since $z(X \times Y) \geq h(X, Y)$ for all X, Y. Moreover, C is stable as $\mathcal{F}$ is independent. Finally, $|\mathcal{J}| \leq z(S \times S) = h(\mathcal{F}) = |C|$. ∎

(Frank [1999a] gave an alternative, algorithmic proof.)

Győri's theorem in fact states that the colouring number of the complementary graph of $G_{\mathcal{I}}$ is equal to its clique number. It has the following consequence, proved by Chaiken, Kleitman, Saks, and Shearer [1981] and conjectured by V. Chvátal. Let P be a rectilinear polygon in $\mathbb{R}^2$ (where each side horizontal or vertical), such that the intersection of P with each horizontal or vertical line is convex. Then the minimum number of rectangles contained in P needed to cover P, is equal to the maximum number of points in P no two of which are contained in any rectangle contained in P.

Franzblau and Kleitman [1984] gave an $O(|\mathcal{I}|^2)$-time algorithm to find the optima in Győri's theorem, with a proof of equality as by-product.

Győri's theorem was extended by Lubiw [1991a] to a weighted version. She noted that a fully weighted version of the theorem does not hold; that is, taking integer weights $w(s, I)$ on any pair (s, I), the maximum weight of a stable set need not be equal to the minimum size of a family $\mathcal{J}$ of intervals such that for any (s, I) there are at least $w(s, I)$ intervals J in $\mathcal{J}$ satisfying $s \in J \subseteq I$. (In other words, $G_{\mathcal{I}}$ need not be perfect.)

However, as Lubiw showed, these two optima are equal if $w(s, I)$ only depends on s; that is, if $w(s, I) = w(s)$ for some $w : S \to \mathbb{Z}_+$. Also this can be derived from Frank and Jordán's theorem: instead of defining $h(X, Y) := 1$ in (60.69), define $h(X, Y) := w(s)$ where $\{s\} = X \cap Y$.

As Frank and Jordán observed, their method extends Győri's theorem to the case where we take 'interval' to mean: interval on the circle (instead of just the real line).

Other applications of Theorem 60.5 are to vertex-connectivity augmentation — see Theorem 63.11.

60.3e. Further notes

For another model equivalent to that of Edmonds and Giles, based on distributive lattices, see Gröflin and Hoffman [1982] — cf. Schrijver [1984b]. Grishuhin [1981] gave a lattice model requiring total unimodularity as a condition.

Further algorithms for minimum-cost submodular flow were given by Fujishige [1978a,1987], Zimmermann [1982b,1992], Barahona and Cunningham [1984], Cui and Fujishige [1988], Chung and Tcha [1991], Gabow [1993a], McCormick and Ervolina [1993], Iwata, McCormick, and Shigeno [1998,1999,2000,2002], Wallacher and Zimmermann [1999], Fleischer and Iwata [2000], and Fleischer, Iwata, and McCormick [2002]. A survey on algorithms for submodular flows was presented by Fujishige and Iwata [2000].

Zimmermann [1982a,1982b,1985] considered group-valued extensions of some of the models. Federgruen and Groenevelt [1988] extended some models to more general objective functions. Zimmermann [1986] considered duality for balanced submodular flows. Qi [1988a] and Murota [1999] gave generalizations of submodular flows. Convex-cost submodular flows were considered by Iwata [1996,1997].

An algorithm for a model comprising the Edmonds-Giles and the lattice polyhedron model (Section 60.3a) was given by Karzanov [1983]. For 0,1 problems it is polynomial-time.

The effectivity of uncrossing techniques is studied by Hurkens, Lovász, Schrijver, and Tardos [1988] and Karzanov [1996].

The facets of submodular flow polyhedra were studied by Giles [1975].

For a comparison of models, see Schrijver [1984b], and for a survey, including results on the dimension of faces of submodular flow polyhedra, see Frank and Tardos [1988]. A survey of submodular functions and flows is given by Murota [2002].

Chapter 61

Graph orientation

Orienting an undirected graph so as to obtain a k-arc-connected directed graph is the object of study in this chapter. Recall that a directed graph D is called an *orientation* of an undirected graph G if G is the underlying undirected graph of D.

Central result is a deep theorem of Nash-Williams showing that each undirected graph has an orientation that keeps at least half of the connectivity (rounded down) between any two vertices.

It implies that a $2k$-edge-connected undirected graph has a k-arc-connected orientation. This can be proved alternatively and easier with the help of submodular functions (cf. Section 61.4).

61.1. Orientations with bounds on in- and outdegrees

We first consider orientations obeying bounds on the indegrees and/or outdegrees. The results follow quite directly from bipartite matching or (equivalently) flow theory.

Hakimi [1965] considered lower bounds on the indegrees:

Theorem 61.1. *Let $G = (V, E)$ be an undirected graph and let $l : V \to \mathbb{Z}_+$. Then G has an orientation $D = (V, A)$ with $\deg^{\text{in}}_A(v) \geq l(v)$ for each $v \in V$ if and only if each $U \subseteq V$ is incident with at least $l(U)$ edges.*

Proof. Let $\mathcal{A}$ be the family of subsets of E obtained by taking set $\delta(v)$ with multiplicity $l(v)$, for each $v \in V$. Then the existence of an orientation as required is equivalent to the existence of a transversal of $\mathcal{A}$. By Hall's marriage theorem (Theorem 22.1), this is equivalent to the condition in the theorem. ∎

A direct consequence is:

Corollary 61.1a. *Let $G = (V, E)$ be an undirected graph and let $l : V \to \mathbb{Z}_+$. Then G has an orientation $D = (V, A)$ with $\deg^{\text{in}}_A(v) = l(v)$ for each $v \in V$ if and only if $l(V) = |E|$ and each $U \subseteq V$ is incident with at least $l(U)$ edges.*

Proof. Directly from Theorem 61.1. ∎

Another consequence concerns upper bounds:

Corollary 61.1b. *Let $G = (V, E)$ be an undirected graph and let $u : V \to \mathbb{Z}_+$. Then G has an orientation $D = (V, A)$ with $\deg^{\text{in}}_A(v) \leq u(v)$ for each $v \in V$ if and only if each $U \subseteq V$ spans at most $u(U)$ edges.*

Proof. For each $v \in V$, define $l(v) := \deg(v) - u(v)$. (We may assume that, for each $v \in V$, $u(v) \leq \deg(v)$, since otherwise resetting $u(v) := \deg(v)$ does not change the conditions in the theorem.)

Now G has an orientation with $\deg^{\text{in}}(v) \leq u(v)$ for each v if and only if G has an orientation with $\deg^{\text{in}}(v) \geq l(v)$ for each v (just by reversing the orientation of all edges). By Theorem 61.1, the latter is equivalent to: each $U \subseteq V$ is incident with at least $l(U)$ edges; that is: $E[U]| + |\delta_E(U)| \geq l(U)$. Since

(61.1) $$l(U) = \sum_{v \in U} (\deg(v) - u(v)) = 2|E[U]| + |\delta_E(U)| - u(U),$$

it is equivalent to: $|E[U]| \leq u(U)$, as required. ∎

Frank and Gyárfás [1978] gave a characterization for the case of lower bounds on both indegrees and outdegrees:

Theorem 61.2. *Let $G = (V, E)$ be an undirected graph and let $l, u : V \to \mathbb{Z}_+$ with $l \leq u$. Then G has an orientation $D = (V, A)$ with $l(v) \leq \deg^{\text{in}}_A(v) \leq u(v)$ for each $v \in V$ if and only if each $U \subseteq V$ is incident with at least $l(U)$ edges and spans at most $u(U)$ edges.*

Proof. The condition trivially being necessary, we prove sufficiency. Let $D = (V, A)$ be an arbitrary orientation of G. It suffices to show that there exists a function $x : A \to \{0, 1\}$ such that for each $v \in V$:

(61.2) $$l(v) \leq \deg^{\text{in}}_A(v) - x(\delta^{\text{in}}_A(v)) + x(\delta^{\text{out}}_A(v)) \leq u(v),$$

since reversing the orientation of the arcs a with $x(a) = 1$ then gives an orientation as required. Condition (61.2) is equivalent to:

(61.3) $$\deg^{\text{in}}_A(v) - u(v) \leq x(\delta^{\text{in}}_A(v)) - x(\delta^{\text{out}}_A(v)) \leq \deg^{\text{in}}_A(v) - l(v).$$

By Corollary 11.2i, such an x exists if and only if

(61.4) $$|\delta^{\text{in}}_A(U)| \geq \max\{\sum_{v \in U} (\deg^{\text{in}}_A(v) - u(v)), \sum_{v \in V \setminus U} (l(v) - \deg^{\text{in}}_A(v))\}$$

for each $U \subseteq V$. Since $|\delta^{\text{in}}_A(U)| + \sum_{v \in V \setminus U} \deg^{\text{in}}_A(v)$ is equal to the number of edges incident with $V \setminus U$ and since $\sum_{v \in U} \deg^{\text{in}}_A(v) - |\delta^{\text{in}}_A(U)|$ is equal to the number of edges spanned by U, this is equivalent to the condition given in the theorem. ∎

Ford and Fulkerson [1962] observed that the undirected edges of a mixed graph (V, E, A) can be oriented so as to obtain an Eulerian directed graph if and only if

(61.5) (i) $\deg_E(v) + \deg_A^{\text{in}}(v) + \deg_A^{\text{out}}(v)$ is even for each $v \in V$,

(ii) $d_A^{\text{out}}(U) - d_A^{\text{in}}(U) \leq d_E(U)$ for each $U \subseteq V$.

This can be proved similarly.

61.2. 2-edge-connectivity and strongly connected orientations

Each $2k$-edge-connected undirected graph has a k-arc-connected orientation, which will be seen in Section 61.3. In the present section we consider the special case $k = 2$, which goes back to a theorem of Robbins [1939]. Tarjan [1972] showed that depth-first search is the tool behind. We follow his approach.

Theorem 61.3. *Given an undirected graph $G = (V, E)$ we can find an orientation D of G, in linear time, such that for each $u, v \in V$, if G has two edge-disjoint $u - v$ paths, then D has a directed $u - v$ path.*

Proof. Choose $s \in V$ arbitrarily, and consider a depth-first search tree T starting at s. Orient each edge in T away from s. For each remaining edge $e = uv$, there is a directed path in T that connects u and v. Let the path run from u to v. Then orient e from v to u. This gives the orientation D of G.

Then any edge not in T belongs to a directed circuit in D. Moreover, any edge f in T that is not a cut edge, belongs to a directed circuit in D (since there is an edge $e \notin T$ connecting the two components of $T - f$). This implies that D is as required. ∎

This implies the theorem of Robbins [1939] on strongly connected orientations:

Corollary 61.3a (Robbins' theorem)**.** *An undirected graph G has a strongly connected orientation if and only if G is 2-edge-connected.*

Proof. Necessity is easy, and sufficiency follows from Theorem 61.3. ∎

(The proof by Robbins [1939] uses the fact that each 2-edge-connected graph has an 'ear-decomposition' — cf. Section 15.5a.)

The above proof also shows that a strongly connected orientation can be found in linear time:

Corollary 61.3b. *Given a 2-edge-connected graph G, a strongly connected orientation of G can be found in linear time.*

Proof. Directly from Theorem 61.3. ∎

Robbins' theorem (Corollary 61.3a) extends to the following result of Frank [1976a] and Boesch and Tindell [1980] for mixed graphs.

Theorem 61.4. *Let $G = (V, E)$ be a graph in which part of the edges is oriented. Then the remainder of the edges can be oriented so as to obtain a strongly connected digraph if and only if G is 2-edge-connected and there is no nonempty proper subset U of V such that all edges in $\delta(U)$ are oriented from U to $V \setminus U$.*

Proof. Necessity being easy, we show sufficiency. Let G be a counterexample with a minimum number of undirected edges. Then there is at least one undirected edge, say $e = uv$. By the minimality assumption, orienting e from s to t violates the condition. That is, there exists a $U \subseteq V$ with $u \in U$, $v \in V \setminus U$, such that each edge $\neq e$ in $\delta(U)$ is oriented from U to $V \setminus U$. Similarly, there exists a $T \subseteq V$ with $v \in T$, $u \in V \setminus T$, such that each edge $\neq e$ $\delta(T)$ is oriented from T to $V \setminus T$.

Then each edge in $\delta(U \cap T)$ is oriented from $U \cap T$ to $V \setminus (U \cap T)$, and hence $U \cap T = \emptyset$. Similarly, $U \cup T = V$. Hence $\delta(U) = \{e\}$, a contradiction. ∎

The graph $K_{2,3}$ shows that a 2-edge-connected graph need not have an orientation in which each two vertices belong to a directed circuit; that is an orientation such that for each two vertices s, t there exists an arc-disjoint pair of an $s - t$ and a $t - s$ path.

Chung, Garey, and Tarjan [1985] gave a linear-time algorithm to find an orientation as described in Theorem 61.4.

61.2a. Strongly connected orientations with bounds on degrees

Robbins' theorem (Corollary 61.3a) states that an undirected graph G has a strongly connected orientation if and only if G is 2-edge-connected. Frank and Gyárfás [1978] extended this to the case where upper and lower bounds are prescribed on the indegrees of the orientation.

Let $\kappa(G)$ denote the number of its components of any graph G.

Theorem 61.5. *Let $G = (V, E)$ be a 2-edge-connected undirected graph and let $l, u \in \mathbb{Z}_+^V$ with $l \leq u$. Then G has a strongly connected orientation $D = (V, A)$ satisfying $l(v) \leq \deg_A^{\text{in}}(v) \leq u(v)$ for each $v \in V$ if and only if for each $U \subseteq V$:*

(61.6) (i) $|E[U]| + \kappa(G - U) \leq u(U)$,
(ii) $|E[U]| + |\delta(U)| - \kappa(G - U) \geq l(U)$.

Proof. It is easy to see that condition (61.6) is necessary. To see sufficiency, let (61.6) hold. Let $D = (V, A)$ be a strongly connected orientation of G with

(61.7) $$\sum_{v \in V} \max\{0, \deg_A^{\text{in}}(v) - u(v), l(v) - \deg_A^{\text{in}}(v)\}$$

as small as possible. (A strongly connected orientation exists by Corollary 61.3a.)

If sum (61.7) is 0, we are done, so assume that it is positive. Then there exists a vertex v_0 with $\deg_A^{\text{in}}(v_0) > u(v_0)$ or $l(v_0) > \deg_A^{\text{in}}(v_0)$. Suppose that $\deg_A^{\text{in}}(v_0) > u(v_0)$. Let U be the set of vertices v for which D has two arc-disjoint $v - v_0$ paths. Then $\deg_A^{\text{in}}(v) \geq u(v)$ for each $v \in U$, since otherwise we can reverse the orientation on the arcs of one of the two arc-disjoint $v - v_0$ paths, thereby keeping the orientation strongly connected while decreasing sum (61.7).

We claim that U violates (61.6)(i). To this end, we show that

(61.8) each component K of $G - U$ is left by exactly one arc of D.

This can be seen as follows. For each $v \in K$, there exists a $U_v \subseteq V$ with $d_A^{\text{out}}(U_v) = 1$ and $v \in U_v$, $v_0 \notin U_v$ (as there exist no two arc-disjoint $v_0 - v$ paths). We choose each U_v inclusionwise maximal.

It suffices to show that

(61.9) $U_v = K$ for each $v \in K$.

To see this, note first that, for each $v \in K$, we have $U_v \subseteq K$. Indeed, $U_v \cap U = \emptyset$, since if say $v_1 \in U \cap U_v$, then there exist no two arc-disjoint $v_1 - v_0$ paths in D, contradicting the definition of U. If U_v would intersect another component K' of $G - U$, then $d_A^{\text{out}}(U_v) = d_A^{\text{out}}(U_v \cap K) + d_A^{\text{out}}(U_v \cap K') \geq 2$ — a contradiction.

Moreover, if $v \neq v'$ and $U_v \cap U_{v'} \neq \emptyset$, then $U_v = U_{v'}$. This follows from:

(61.10) $$1 \leq d_A^{\text{out}}(U_v \cup U_{v'}) \leq d_A^{\text{out}}(U_v) + d_A^{\text{out}}(U_{v'}) - d_A^{\text{out}}(U_v \cap U_{v'}) \leq 1 + 1 - 1 = 1.$$

So, if $U_v \neq U_{v'}$, we would increase U_v or $U_{v'}$ by replacing it by $U_v \cup U_{v'}$ — a contradiction.

So the U_v partition K. Now if $U_v \neq K$, there exist v and v' such that $U_v \neq U_{v'}$ and such that G has an edge connecting U_v and $U_{v'}$. We can assume that it is oriented from $U_{v'}$ to U_v. So it is the unique edge leaving $U_{v'}$. Hence $d_A^{\text{out}}(U_v \cup U_{v'}) \leq d_A^{\text{out}}(U_v) = 1$. So replacing U_v by $U_v \cup U_{v'}$ would increase U_v — a contradiction. This shows (61.9), and hence (61.8).

So $d_A^{\text{out}}(K) = 1$ for each component K of $G - U$. Therefore

(61.11) $$|E[U]| + \kappa(G - U) = \sum_{v \in U} \deg_A^{\text{in}}(v) > u(U).$$

Thus U violates (61.6)(i).

One similarly shows that $\deg_A^{\text{in}}(v_0) < l(v_0)$ implies violation of (61.6)(ii). ∎

This implies an alternative characterization:

Corollary 61.5a. *Let $G = (V, E)$ be a 2-edge-connected undirected graph and let $l, u \in \mathbb{Z}_+^V$ with $l \leq u$. Then G has a strongly connected orientation $D = (V, A)$ satisfying $l(v) \leq \deg_A^{\text{in}}(v) \leq u(v)$ for each $v \in V$ if and only if G has strongly connected orientations $D' = (V, A')$ and $D'' = (V, A'')$ with $l(v) \leq \deg_{A'}^{\text{in}}(v)$ and $\deg_{A''}^{\text{in}}(v) \leq u(v)$ for each $v \in V$.*

Proof. Directly from Theorem 61.5, as (61.6)(i) is void if $u = \infty$ and as (61.6)(ii) is void if $l = \mathbf{0}$ (since $\kappa(G - U) \leq d_G(U)$). ∎

For further results, see Theorem 61.7.

61.3. Nash-Williams' orientation theorem

The result of Robbins [1939] was extended deeply by Nash-Williams [1960]. Before stating and proving it, we give a useful lemma of Nash-Williams [1960]. Let $\phi : V \times V \to \mathbb{R}$ be a symmetric function (that is, $\phi(u, v) = \phi(v, u)$ for all $u, v \in V$). Define a set function R on V by:

(61.12) $$R(U) := \max_{u \in U, v \in V \setminus U} \phi(u, v) \text{ if } \emptyset \subset U \subset V, \text{ and}$$
$$R(\emptyset) := R(V) := 0.$$

Lemma 61.6α. *For all $T, U \subseteq V$:*

(61.13) $$R(T) + R(U) \leq R(T \cap U) + R(T \cup U)$$
$$\text{or } R(T) + R(U) \leq R(T \setminus U) + R(U \setminus T).$$

Proof. Suppose not. Then $\emptyset \neq T \neq V$ and $\emptyset \neq U \neq V$. Choose $s \in T$, $t \in V \setminus T$, $u \in U$, $v \in V \setminus U$ such that $R(T) = \phi(s, t)$ and $R(U) = \phi(u, v)$. By symmetry, we can assume that $R(T) \leq R(U)$ and $u \in T$. So $u \in T \cap U$, and hence $T \cap U$ splits[15] $\{u, v\}$. This implies that $T \cup U$ splits neither $\{s, t\}$, nor $\{u, v\}$, as otherwise the first inequality in (61.13) holds (as $\phi(s, t) \leq \phi(u, v)$).

Hence $t, v \in T \cup U$, and so $t \in U \setminus T$ and $v \in T \setminus U$. Then $T \setminus U$ splits $\{u, v\}$, and $U \setminus T$ splits $\{s, t\}$, implying the second inequality in (61.13). ∎

For any undirected graph $G = (V, E)$ and $s, t \in V$, let $\lambda_G(s, t)$ denote the maximum number of edge-disjoint $s - t$ paths in G. Similarly, for any directed graph $D = (V, A)$ and $s, t \in V$, let $\lambda_D(s, t)$ denote the maximum number of arc-disjoint $s - t$ paths in D.

Theorem 61.6 (Nash-Williams' orientation theorem)**.** *Any undirected graph $G = (V, E)$ has an orientation $D = (V, A)$ with*

(61.14) $$\lambda_D(s, t) \geq \lfloor \tfrac{1}{2} \lambda_G(s, t) \rfloor$$

for all $s, t \in V$.

Proof. Call a partition of a set T into pairs, a *pairing* of T. For any number k, define

(61.15) $$k^* := 2 \lfloor \tfrac{1}{2} k \rfloor.$$

For any subset U of V, define

[15] Set X *splits* set Y if both $Y \cap X$ and $Y \setminus X$ are nonempty.

(61.16) $$r(U) := \max_{u\in U, v\notin U} \lambda_G(u,v),$$

setting $r(U) := 0$ if $U = \emptyset$ or $U = V$. Let T be the set of vertices of odd degree of G.

I. It suffices to show that T has a pairing P such that

(61.17) $d_G(U) - d_P(U) \geq r(U)^*$ for each $U \subseteq V$.

To see that this is sufficient, let $G' = (V, E \cup P)$. That is, G' is the graph obtained from G by adding all pairs in P as new edges (possibly in parallel). Then all degrees in G' are even, and hence G' has an Eulerian orientation $D' = (V, A')$. So

(61.18) $$\deg^{\text{out}}_{D'}(v) = \deg^{\text{in}}_{D'}(v) = \tfrac{1}{2}\deg_{G'}(v)$$

for each $v \in V$. This implies that, for each $U \subseteq V$,

(61.19) $$d^{\text{out}}_{D'}(U) = \tfrac{1}{2} d_{G'}(U).$$

Let A be the restriction of A' to the original edges of G and let $D = (V, A)$. We claim that D is an orientation of G as required. Indeed, by (61.17), for each $U \subseteq V$,

(61.20) $$\begin{aligned} d^{\text{out}}_{D}(U) &\geq d^{\text{out}}_{D'}(U) - d_P(U) = \tfrac{1}{2} d_{G'}(U) - d_P(U) \\ &= \tfrac{1}{2}(d_G(U) - d_P(U)) \geq \lfloor \tfrac{1}{2} r(U) \rfloor. \end{aligned}$$

Hence, for any $u, v \in V$, if $U \subseteq V$ with $u \in U$, $v \notin U$, and $\lambda_D(u,v) = d^{\text{out}}_D(U)$, then

(61.21) $$\lambda_D(u,v) = d^{\text{out}}_D(U) \geq \lfloor \tfrac{1}{2} r(U) \rfloor \geq \lfloor \tfrac{1}{2} \lambda_G(u,v) \rfloor.$$

II. We now prove the theorem. Define for any $Y \subseteq V$ and $U \subseteq V$,

(61.22) $$r_Y(U) := \max_{u\in Y\cap U, v\in Y\setminus U} \lambda_G(u,v),$$

setting $r_Y(U) := 0$ if $Y \cap U = \emptyset$ or $Y \subseteq U$.

By Lemma 61.6α, for any $U, W \subseteq V$,

(61.23) $$\begin{aligned} &r_Y(U)^* + r_Y(W)^* \leq r_Y(U \cap W)^* + r_Y(U \cup W)^* \\ &\text{or } r_Y(U)^* + r_Y(W)^* \leq r_Y(U \setminus W)^* + r_Y(W \setminus U)^*. \end{aligned}$$

This follows from Lemma 61.6α by taking $\phi(u,v) := \lambda_G(u,v)^*$ if $u, v \in Y$ and $\phi(u,v) := 0$ otherwise.

Suppose that there exist graphs G for which T has no pairing P satisfying (61.17). Choose G with $|V| + |E|$ minimal.

Choose $Y \subseteq V$ such that T has no pairing P satisfying

(61.24) $d_G(U) - d_P(U) \geq r_Y(U)^*$ for each $U \subseteq V$,

with $|Y|$ as small as possible. Then

(61.25) For any subset X of V splitting Y and satisfying $d_G(X)^* = r_Y(X)^*$, one has $|X| = 1$ or $|X| = |V| - 1$.

For suppose $1 < |X| < |V| - 1$. Consider the graph $G_1 = (V_1, E_1)$ obtained from G by contracting $V \setminus X$ to one vertex, v_1 say. Let T_1 be the set of vertices of odd degree of G_1. By the minimality of $|V|+|E|$, T_1 has a pairing P_1 such that for each subset U of X:

(61.26) $$d_{G_1}(U) - d_{P_1}(U) \geq r(U)^*.$$

(Note that $r(U) \leq \max_{u \in U, v \in V \setminus U} \lambda_{G_1}(u, v)$.)

Similarly, consider the graph $G_2 = (V_2, E_2)$ obtained from G by contracting X to one vertex, v_2 say. Let T_2 be the set of vertices of odd degree of G_2. Again by the minimality of $|V| + |E|$, T_2 has a pairing P_2 such that for each subset U of $V \setminus X$ and for each $u \in U$, $v \in V_2 \setminus U$:

(61.27) $$d_{G_2}(U) - d_{P_2}(U) \geq r(U)^*.$$

Now define a pairing P of T as follows. (Observe that $v_1 \in T_1$ if and only if $v_2 \in T_2$.) If $v_1 \notin T_1$ and $v_2 \notin T_2$, let $P := P_1 \cup P_2$. If $v_1 \in T_1$ and $v_2 \in T_2$, let $u_1 \in X$ and $u_2 \in V \setminus X$ be such that $u_1v_1 \in P_1$ and $u_2v_2 \in P_2$. Then define

(61.28) $$P := (P_1 \setminus \{u_1v_1\}) \cup (P_2 \setminus \{u_2v_2\}) \cup \{u_1u_2\}.$$

We claim that P satisfies (61.24). To show this, we may assume by (61.23) that $r_Y(U \cap X)^* + r_Y(U \cup X)^* \geq r_Y(U \setminus X)^* + r_Y(X \setminus U)^*$. (Otherwise, replace U by $V \setminus U$.)

Set $U_1 := U \cap X$ and $U_2 := V \setminus (U \cup X)$. Then

(61.29) $$\begin{aligned} d_G(U) + d_G(X) &\geq d_G(U_1) + d_G(U_2) = d_{G_1}(U_1) + d_{G_2}(U_2) \\ &\geq r(U_1)^* + d_{P_1}(U_1) + r(U_2)^* + d_{P_2}(U_2) \geq r_Y(U)^* + r_Y(X)^* + d_P(U) \\ &\geq r_Y(U)^* + d_G(X) + d_P(U) - 1, \end{aligned}$$

using (61.26) and (61.27). As $d_G(U) + d_P(U)$ is even, (61.24) follows. This contradicts our assumption, showing (61.25).

We next show that

(61.30) each edge of G intersects Y.

For assume that G has an edge $e = st$ disjoint from Y. By (61.25), there is no U splitting Y with $d_G(U)^* = r_Y(U)^*$ and $s \in U$, $t \notin U$. So deleting edge e, changes no $r_Y(U)^*$. Let G' be the graph obtained from G by deleting e. Let T' be the set of vertices of G' of odd degree. (So $T' = T \triangle \{s, t\}$.) Then, by the minimality of $|V| + |E|$, we know that T' has a pairing P' such that, for each $U \subseteq V$,

(61.31) $$d_{G'}(U) - d_{P'}(U) \geq r(U)^* \geq r_Y(U)^*.$$

It is not difficult to transform pairing P' of T' to a pairing P of T with the property that $|P \setminus P'| \leq 1$.[16] Then (61.24) holds. Indeed, $d_G(U) \geq d_{G'}(U)$

[16] If $s, t \in T'$ and $st \in P'$, define $P := P' \setminus \{st\}$. If $s, t \in T'$ and $st \notin P'$, let s' and t' be such that $ss' \in P'$ and $tt' \in P'$, and define $P := (P' \setminus \{ss', tt'\}) \cup \{s't'\}$. If $s \in T'$ and $t \notin T'$, let s' be such that $ss' \in P'$, and define $P := (P' \setminus \{ss'\}) \cup \{ts'\}$. If $s \notin T'$ and $t \in T'$, let t' be such that $tt' \in P'$, and define $P := (P' \setminus \{tt'\}) \cup \{st'\}$. If $s \notin T'$ and $t \notin T'$, define $P := P' \cup \{st\}$.

and $d_P(U) \leq d_{P'}(U)+1$ (as $|P \setminus P'| \leq 1$). Hence (61.24) follows from (61.31), with parity. This contradiction proves (61.30).

Next:

(61.32) $\quad |Y| \geq 2.$

For suppose that $|Y| \leq 1$. In G there exist $\frac{1}{2}|T|$ edge-disjoint paths such that each vertex in T occurs exactly once as an end vertex of one of these paths. (This can be seen by taking an arbitrary pairing Q of T, and considering an Eulerian tour C in the graph $G = (V, E \cup Q)$. Then removing Q from C decomposes C into paths as required.) Let P be the set of pairs of end vertices of these paths. Then $d_G(U) \geq d_P(U)$ for each $U \subseteq V$, and (61.24) follows, contradicting our assumption. So we know (61.32).

Choose a set X splitting Y with $d_G(X)$ minimal. Then $d_G(X) = r_Y(X)$. By (61.25), we may assume that $X = \{x\}$ for some $x \in Y$. So $r_Y(U) = d_G(x)$ for any U splitting Y, since for any $y \in Y \setminus U$ we have

(61.33) $\quad d_G(x) \leq d_G(U) \leq r_Y(U) \leq \lambda_G(x, y) \leq d_G(x).$

.

Define $Y' := Y \setminus \{x\}$. Then, by the minimality of $|Y|$, T has a pairing P such that for each $U \subseteq V$,

(61.34) $\quad d_G(U) - d_P(U) \geq r_{Y'}(U)^*.$

We show that (61.24) holds, which forms a contradiction. To this end, choose $U \subseteq V$.

First assume that U splits Y'. Then $r_{Y'}(U) \geq r_Y(U)$, since $\lambda_G(x, y) = d_G(X) \leq r_{Y'}(U)$ for each $y \in Y'$ (by the minimality of $d_G(X)$, since any splitting of Y' also splits Y). This implies (61.34).

So we can assume that U splits Y but does not split Y'; that is, $U \cap Y = \{x\}$. Consider any $u \in U \setminus \{x\}$. Let α_u denote the number of edges connecting u and x and let β_u denote the number of edges connecting u and $Y \setminus \{x\}$. By (61.30), $\alpha_u + \beta_u = \deg_G(u)$. Since $X = \{x\}$ splits Y with $d_G(X)$ minimum, we have $d_G(\{x, u\}) \geq \deg_G(x)$. Hence $\beta_u \geq \alpha_u$, with strict inequality if $u \in T$ (since then $\alpha_u + \beta_u$ is odd).

Therefore, setting $U' := U \setminus \{x\}$ and $\lambda :=$ number of edges connecting x and $V \setminus U$,

(61.35)
$$\begin{aligned} d_G(U) &= \lambda + \sum_{u \in U'} \beta_u \geq \lambda + \sum_{u \in U'} \alpha_u + |U' \cap T| = \deg_G(x) + |U' \cap T| \\ &= r_Y(U) + |U' \cap T| \geq r_Y(U) + |U \cap T| - 1 \geq r_Y(U) + d_P(U) - 1. \end{aligned}$$

Hence, with parity, we have (61.24). ∎

(This is the original proof of Nash-Williams [1960]. Mader [1978a] and Frank [1993a] gave alternative proofs.)

An orientation satisfying the condition described in Theorem 61.6 is called *well-balanced*. Nash-Williams [1969] (giving an introduction to the proof above) remarks that with methods similar to those used in the proof of Theorem 61.6, one can prove that for any graph G and any subgraph H of G, there is a well-balanced orientation of G such that the restriction to H is well-balanced again.

61.4. k-arc-connected orientations of $2k$-edge-connected graphs

Nash-Williams' orientation theorem directly implies:

Corollary 61.6a. *An undirected graph G has a k-arc-connected orientation if and only if G is $2k$-edge-connected.*

Proof. Directly from Theorem 61.6. ∎

A direct proof of this corollary, based on total dual integrality, was given by Frank [1980b] and Frank and Tardos [1984b], and is as follows.

Orient the edges of G arbitrarily, yielding the directed graph $D = (V, A)$. Consider the system

(61.36) (i) $0 \leq x_a \leq 1$ for each $a \in A$,
(ii) $x(\delta^{\text{in}}(U)) - x(\delta^{\text{out}}(U)) \leq d^{\text{in}}(U) - k$ for each nonempty $U \subset V$.

By the Edmonds-Giles theorem (Theorem 60.1), this system is TDI, and hence determines an integer polytope P. If G is $2k$-edge-connected, then P is nonempty, since the vector $x := \frac{1}{2} \cdot \mathbf{1}$ belongs to P.

As P is nonempty and integer, (61.36) has an integer solution x. Then G has a k-arc-connected orientation D': reversing the orientation of the arcs a of D with $x_a = 1$ gives a k-arc-connected orientation D', since

(61.37) $$d^{\text{in}}_{D'}(U) = d^{\text{in}}_{D}(U) - x(\delta^{\text{in}}_{D}(U)) + x(\delta^{\text{out}}_{D}(U)) \geq k$$

for any nonempty proper subset U of V.

Notes. The total dual integrality of (61.36) implies also the following result of Frank, Tardos, and Sebő [1984] (denoting the number of (weak) components of a (di)graph G by $\kappa(G)$). Let $G = (V, E)$ be a 2-edge-connected undirected graph and let $U \subseteq V$. Then the minimum number of arcs entering U over all strongly connected orientations of G is equal to the maximum of

(61.38) $$\sum_{T \in \mathcal{P}} \kappa(G - T),$$

taken over partitions $\mathcal{P}$ of U into nonempty classes such that no edge connects different classes of $\mathcal{P}$.

This implies another result of Frank, Tardos, and Sebő [1984]: Let $D = (V, A)$ be a digraph and let $C = \delta^{\text{in}}(U)$ be a directed cut. Then the minimum of $|B \cap C|$ where B is a directed cut cover is equal to the maximum of

$$(61.39) \qquad \sum_{T \in \mathcal{P}} \kappa(D - T),$$

taken over partitions $\mathcal{P}$ of U into nonempty classes such that no arc of D connects distinct classes of $\mathcal{P}$.

As A. Frank (personal communication 2002) observed, the proof above yields a stronger result of Nash-Williams [1969]: let $G = (V, E)$ be a $2k$-edge-connected graph and let $F \subseteq E$ have an Eulerian orientation; then the remaining edges have an orientation so as to obtain a k-arc-connected digraph. This follows by taking for A any orientation extending the orientation of F, and by setting $x_a := 0$ for each arcs in F, and $x_a := \frac{1}{2}$ for all other arcs a. Then x satisfies (61.36), and the result follows as above.

61.4a. Complexity

By the results in Section 60.1 on the complexity of the Edmonds-Giles problem, one can find a k-arc-connected orientation of a $2k$-edge-connected undirected graph in polynomial time; more generally, one can find a minimum-length k-arc-connected orientation in strongly polynomial time, if we are given a length for each orientation of each edge.

A direct method of finding a minimum-length k-arc-connected orientation can be based on weighted matroid intersection, similarly to the method described in Section 55.5 to find a minimum-length directed k-cover in a directed graph (such that the k-arc-connected orientations form the common bases of two matroids).

61.4b. k-arc-connected orientations with bounds on degrees

Frank [1980b] extended Corollary 61.6a to the case where lower and upper bounds on the indegrees of the vertices are prescribed:

Theorem 61.7. *Let $G = (V, E)$ be a $2k$-connected undirected graph and let $l, u \in \mathbb{Z}_+^V$ with $l \leq u$. Then G has a k-arc-connected orientation D with $l(v) \leq \deg_D^{\text{in}}(v) \leq u(v)$ for each $v \in V$ if and only if*

$$(61.40) \qquad |E[W]| + |\delta(\mathcal{P})| \geq k|\mathcal{P}| + \max\{\sum_{v \in W} l(v), \sum_{v \in W} (\deg_G(v) - u(v))\}$$

for each subpartition $\mathcal{P}$ of V with nonempty classes, where $W := V \setminus \bigcup \mathcal{P}$.

Proof. It is not difficult to see that the condition is necessary. To show sufficiency, by Corollary 61.6a, G has a k-arc-connected orientation D. Choose D such that

$$(61.41) \qquad \sum_{v \in V} \max\{0, \deg_D^{\text{in}}(v) - u(v), l(v) - \deg_D^{\text{in}}(v)\}$$

is as small as possible. If sum (61.41) is 0 we are done, so assume that it is positive. By symmetry, we can assume that there is a vertex r with $\deg_D^{\text{in}}(r) < l(r)$.

Let $\mathcal{P}$ be the collection of inclusionwise maximal nonempty subsets U of $V \setminus \{r\}$ with $d^{\text{in}}(U) = k$, and let $W := V \setminus \bigcup \mathcal{P}$.

Then the sets in $\mathcal{P}$ are disjoint. For let $U, W \in \mathcal{P}$ with $U \cap W \neq \emptyset$. Then

$$(61.42) \qquad 2k \leq d_D^{\text{in}}(U \cap W) + d_D^{\text{in}}(U \cup W) \leq d_D^{\text{in}}(U) + d_D^{\text{in}}(W) = 2k,$$

implying $d_D^{\text{in}}(U \cup W) = k$, and so $U = W = U \cup W$.

Suppose that there exists a vertex $s \in W$ with $\deg_D^{\text{in}}(s) > l(s)$. Then reversing the orientations of the arcs of any $r - s$ path in D gives again a k-arc-connected orientation (since there is no $U \subseteq V$ with $d_D^{\text{in}}(U) = k$ and $s \in U$, $r \notin U$), but decreases sum (61.41). This contradicts our minimality assumption.

So $\deg_D^{\text{in}}(v) \leq l(v)$ for each $v \in W$, with strict inequality for at least one $v \in W$ (namely for r). Now each edge of G that is spanned by no set in $\mathcal{P}$, either enters some $U \in \mathcal{P}$, or has its head in W. So the number of such edges is

(61.43) $$k|\mathcal{P}| + \sum_{v \in W} \deg_D^{\text{in}}(v), \text{ which is less than } k|\mathcal{P}| + \sum_{v \in W} l(v).$$

This contradicts the condition. ∎

This has an alternative characterization as consequence:

Corollary 61.7a. *Let $G = (V, E)$ be an undirected graph, let $k \in \mathbb{Z}_+$, and let $l, u \in \mathbb{Z}_+^E$ with $l \leq u$. Then G has a k-arc-connected orientation D with $l(v) \leq \deg_D^{\text{in}}(v) \leq u(v)$ for each $v \in V$ if and only if G has k-arc-connected orientations D' and D'' with $l(v) \leq \deg_{D'}^{\text{in}}(v)$ and $\deg_{D''}^{\text{in}}(v) \leq u(v)$ for each $v \in V$.*

Proof. This follows from the fact that the condition in Theorem 61.7 can be decomposed into a condition on l and one on u. ∎

61.4c. Orientations of graphs with lower bounds on indegrees of sets

Let $G = (V, E)$ be an undirected graph and let $l : \mathcal{P}(V) \to \mathbb{Z}_+$ be such that

(61.44) $$l(T) + l(U) - d(T, U) \leq l(T \cap U) + l(T \cup U), \text{ for all } T, U \subseteq V \text{ with } T \cap U \neq \emptyset \text{ and } T \cup U \neq V,$$

where $d(T, U)$ denotes the number of edges connecting $T \setminus U$ and $U \setminus T$.

Frank [1980b] showed with submodularity theory:

Theorem 61.8. *Let $G = (V, E)$ be a graph and let $l : \mathcal{P}(V) \to \mathbb{Z}_+$ satisfy* (61.44). *Then G has an orientation $D = (V, A)$ with*

(61.45) $$d_A^{\text{in}}(U) \geq l(U)$$

for each $U \subseteq V$ if and only if

(61.46) $$|\delta(\mathcal{P})| \geq \max\{\sum_{U \in \mathcal{P}} l(U), \sum_{U \in \mathcal{P}} l(V \setminus U)\}$$

for each partition $\mathcal{P}$ of V into nonempty proper subsets, where $\delta(\mathcal{P})$ denotes the set of edges of G connecting different classes of $\mathcal{P}$.

Proof. The necessity of the condition is obvious. To prove sufficiency, let $D = (V, A)$ be an arbitrary orientation of G. Define for each nonempty proper subset U of V

(61.47) $$f(U) := d_A^{\text{in}}(U) - l(U).$$

One easily checks, using (61.44), that f is crossing submodular. Moreover, if $x : A \to \{0,1\}$ is such that

(61.48) $$x(\delta^{\text{in}}_A(U)) - x(\delta^{\text{out}}_A(U)) \le f(U)$$

for each nonempty proper subset U of V, then the digraph $D' = (V, A')$ obtained from $D = (V, A)$ by reversing the direction of the arcs a with $x_a = 1$, has indegrees as required by (61.45), since

(61.49) $$d^{\text{in}}_{A'}(U) = d^{\text{in}}_A(U) - x(\delta^{\text{in}}_A(U)) + x(\delta^{\text{out}}_A(U)) \ge d^{\text{in}}_A(U) - f(U) = l(U).$$

Hence it suffices to show that (61.48) has an integer solution x with $\mathbf{0} \le x \le \mathbf{1}$.

Consider x as a transshipment. The 'excess function' $\text{excess}_x \in \mathbb{R}^V$ of x is given by:

(61.50) $$\text{excess}_v := x(\delta^{\text{in}}_A(v)) - x(\delta^{\text{out}}_A(v))$$

for $v \in V$. Then (61.48) is equivalent to

(61.51) $$y(U) \le f(U).$$

Now y is the excess function of some $x \in \{0,1\}^A$ if and only if x is an integer y-transshipment with $\mathbf{0} \le x \le \mathbf{1}$. So, by Corollary 11.2f, y is the excess function of some $x \in \{0,1\}^A$ if and only if y is integer, $y(V) = 0$, and

(61.52) $$y(U) \le d^{\text{in}}_A(U)$$

for each $U \subseteq V$. Since $l(U) \ge 0$, (61.52) is implied by (61.51).

So it suffices to show that (61.51) has an integer solution y with $y(V) = 0$. By Theorem 49.10, y exists if and only if

(61.53) $$\sum_{U \in \mathcal{P}} f(U) \ge 0$$

for each partition or copartition $\mathcal{P}$ of V, where each set in $\mathcal{P}$ is a nonempty proper subset of V. (A *copartition* of V is a collection of sets whose complements form a partition of V.) This is equivalent to the condition given in the present theorem. ∎

61.4d. Further notes

Frank [1980b] observed that Edmonds' disjoint arborescences theorem implies:

Corollary 61.8a. *Let $G = (V, E)$ be an undirected graph and $r \in V$. Then G has an orientation such that each nonempty subset U of $V \setminus \{r\}$ is entered by at least k arcs if and only if G contains k edge-disjoint spanning trees.*

Proof. Necessity follows from the fact that if the orientation $D = (V, A)$ as required exists, then by Edmonds' disjoint arborescences theorem (Corollary 53.1b), D has k disjoint r-arborescences. Hence G has k edge-disjoint spanning trees.

Sufficiency follows from the fact that we can orient each spanning tree in G so as to become an r-arborescence. Orienting the remaining edges arbitrarily, we obtain an orientation as required. ∎

Frank [1993c] gave a direct proof of the existence of this orientation from the conditions given in the Tutte-Nash-Williams disjoint trees theorem (Corollary

51.1a), yielding (with Edmonds' disjoint arborescences theorem) a proof of the Tutte-Nash-Williams disjoint trees theorem.

Frank [1982a] showed that each k-arc-connected orientation of an undirected graph can be obtained from any other by reversing iteratively directed paths and circuits, without destroying k-arc-connectivity. This can be derived from a result of L. Lovász that two k-arc-connected orientations are adjacent on the polytope determined by (61.36) if and only if they differ on a directed circuit or on a collection of vertex-disjoint directed paths. Frank [1982b] showed that a minimum-cost k-arc-connected orientation can be found in strongly polynomial time, by reduction to the Edmonds-Giles model. Accelerations were given by Gabow [1993a,1993b,1994, 1995c].

Frank, Jordán, and Szigeti [1999,2001] and Frank and Király [1999,2002] studied graph orientations that satisfy parity and connectivity conditions. Orientations preserving prescribed shortest paths are considered by Hassin and Megiddo [1989].

Chvátal and Thomassen [1978] showed that each 2-edge-connected graph of radius r has a strongly connected orientation of radius at most $r^2 + r$. This was extended to mixed graphs by Chung, Garey, and Tarjan [1985].

For surveys on applying submodularity to orientation problems, see Frank [1993a,1996b].

Chapter 62

Network synthesis

The network synthesis problem asks for a graph having prescribed connectivity properties, with a minimum number of edges. If the edges have costs, a minimum total cost is required.
The problem can be seen as the special case of the connectivity augmentation problem where the input graph is edgeless. Connectivity augmentation in general will be discussed in Chapter 63.

62.1. Minimal k-(edge-)connected graphs

We first consider the easy problem of finding a graph of given connectivity, with a minimal number of edges. First, vertex-connectivity:

Theorem 62.1. *Let k and n be positive integers with $n \geq 2$. The minimum number of edges of a k-vertex-connected graph with n vertices is $n-1$ if $k = 1$, $\lceil \frac{1}{2}kn \rceil$ if $1 < k < n$, and $\frac{1}{2}n(n-1)$ otherwise.*

Proof. Since any k-vertex-connected graph contains a spanning tree, has minimum degree at least k if $k < n$, and is a complete graph if $k \geq n$, the values given are lower bounds. Moreover, if $k = 1$ or $k \geq n$, the bound is tight. So we can assume $1 < k < n$, and it suffices to show that there exists a k-vertex-connected graph $G = (V, E)$ with $|V| = n$ and $|E| = \lceil \frac{1}{2}kn \rceil$.

Let $V := \{1, \ldots, n\}$ and let C be the circuit on V with edge set $\{\{i, i+1\} \mid i \in V\}$, taking addition mod n. Let G be the graph on V with edges all pairs of vertices at distance at most $\frac{1}{2}k$ in C.

First assume that k is even. Then G has $\frac{1}{2}kn$ edges. We show that G is k-vertex-connected. Suppose to the contrary that G has a vertex-cut U of size less than k. There are at least two components K of $C[U]$ such that the two neighbours of K in C belong to different components of $G - U$ (as $G - U$ is disconnected). In particular, the two neighbours have distance more than $\frac{1}{2}k$ in C, and so these components each have size at least $\frac{1}{2}k$. This contradicts the fact that $|U| < k$.

Next, if k is odd, we add to G $\lceil \frac{1}{2}n \rceil$ edges $\{i, j\}$, where i and j have distance $\lfloor \frac{1}{2}n \rfloor$ in C, and such that these edges cover all vertices in V. So G has $\lceil \frac{1}{2}kn \rceil$ edges. We show that G is k-vertex-connected.

Suppose that G has a vertex-cut U of size less than k. By the above, $C[U]$ consists of two components of size $l := \frac{1}{2}(k-1)$ each. We can assume that $U = [1, l] \cup [s+1, s+l]$ for some s with $l < s$ and $s+l < n$. Now n is adjacent to no vertex in $[l+1, s]$, while n is adjacent to at least one of $\lfloor \frac{1}{2}n \rfloor$ and $\lceil \frac{1}{2}n \rceil$. So $\lfloor \frac{1}{2}n \rfloor < l+1$ or $\lceil \frac{1}{2}n \rceil > s$, implying $n > 2s$ (as $k < n$). By symmetry of the two components we similarly have $n > 2(n-s)$, that is $n < 2s$, a contradiction. ∎

For edge-connectivity the answer is almost the same:

Theorem 62.2. *Let k and n be positive integers with $n \geq 2$. The minimum number of edges of a k-edge-connected graph with n vertices is $n-1$ if $k = 1$, and $\lceil \frac{1}{2}kn \rceil$ otherwise. If $k \leq n-1$ the minimum is attained by a simple graph.*

Proof. Again, the values are lower bounds, as a k-edge-connected graph contains a spanning tree and has each degree at least k. Clearly the lower bound can be attained if $k = 1$, so assume $k \geq 2$. Let C be a graph on $V := \{1, \ldots, n\}$ with edges all pairs $\{i, i+1\}$ for $i \in V$ (with addition mod n). Let G be the graph obtained from C by replacing each edge by $\lfloor \frac{1}{2}k \rfloor$ parallel edges.

If k is even, then G is k-edge-connected as required. If k is odd, add $\lceil \frac{1}{2}n \rceil$ edges $\{i, j\}$ to G, where i and j have distance $\lfloor \frac{1}{2}n \rfloor$ in C, and such that these edges cover all vertices in V. So G has $\lceil \frac{1}{2}kn \rceil$ edges. We show that G is k-edge-connected. Suppose that $d_G(U) < k$ for some nonempty proper subset U of V. By symmetry, we can assume that $|U| \geq \frac{1}{2}n$. Now $C[U]$ is connected (as otherwise $d_G[U] \geq 4\lfloor \frac{1}{2}k \rfloor \geq k$, since $k > 1$). So we can assume that $U = [1, s]$, with $s \geq \lceil \frac{1}{2}n \rceil$. However, $n \in V \setminus U$ is adjacent to at least one of $\lfloor \frac{1}{2}n \rfloor$ and $\lceil \frac{1}{2}n \rceil$. As both of these vertices belong to U, we have $d_G(U) \geq 2\lfloor \frac{1}{2}k \rfloor + 1 = k$, a contradiction.

Finally, if $k \leq n-1$, the minimum is attained by a simple graph. Indeed, by Theorem 62.1, there is a k-vertex-connected graph $G = (V, E)$ with n vertices and $\lceil \frac{1}{2}kn \rceil$ edges. Necessarily, G is simple. We show that G is k-edge-connected. Suppose that there is a nonempty $U \subset V$ with $d_G(U) < k$. Then $|U||V \setminus U| \geq n-1 \geq k$, and hence there exist $s \in U$ and $t \in V \setminus U$ that are not adjacent. Hence G has k internally vertex-disjoint $s-t$ paths, and therefore k edge-disjoint $s-t$ paths. This contradicts the fact that $d_G(U) < k$. ∎

The directed case is even simpler. For vertex-connectivity one has:

Theorem 62.3. *Let k and n be positive integers with $n \geq 2$. Then the minimum number of arcs of a k-vertex-connected directed graph with n vertices is kn if $k \leq n-1$, and $n(n-1)$ otherwise.*

Proof. Since each vertex should have at least $\min\{k, n-1\}$ outneighbours, the values are lower bounds. Trivially it is attained if $k \geq n$.

If $k \leq n-1$, let D be the directed graph on $V := \{1, \ldots, n\}$ with arcs all pairs $(i, i+l)$ with $i \in V$ and $1 \leq l \leq k$, taking addition mod n. Then D has kn arcs. To see that D is k-vertex-connected, let U be a vertex-cut. Choose $i, j \in V \setminus U$ with j not reachable from i in $D - U$. We may assume that $1 \leq i < j \leq n$ and that $j - i$ is as small as possible. Then $j - i > k$ and $i+1, \ldots, j-1$ belong to U. So $|U| \geq k$. ∎

Finally, for arc-connectivity (Fulkerson and Shapley [1971]):

Theorem 62.4. *Let k and n be positive integers with $n \geq 2$. Then the minimum number of arcs of a k-arc-connected directed graph with n vertices is kn. If $k \leq n-1$, the minimum is attained by a simple directed graph.*

Proof. Since each vertex should be left by at least k arcs, kn is a lower bound. It is attained by the directed graph obtained from a directed circuit on n vertices, by replacing any arc by k parallel arcs.

If $k \leq n-1$, the minimum is attained by a simple directed graph. Indeed, by Theorem 62.3, there is a k-vertex-connected directed graph $D = (V, A)$ with n vertices and kn arcs. Necessarily, D is simple. We show that D is k-arc-connected. Suppose that there is a nonempty $U \subset V$ with $d_D^{\text{out}}(U) < k$. Then $|U||V \setminus U| \geq n-1 \geq k$, and hence there exist $s \in U$ and $t \in V \setminus U$ with $(s,t) \notin A$. Hence D has k internally vertex-disjoint $s-t$ paths, and therefore k arc-disjoint $s-t$ paths. This contradicts the fact that $d_D^{\text{out}}(U) < k$. ∎

Notes. Edmonds [1964] showed that for each simple graph with all degrees at least k, there exists a k-edge-connected simple graph with the same degree-sequence.

62.2. The network synthesis problem

Let V be a finite set and let $r : V \times V \to \mathbb{R}_+$. A *realization* of r is a pair of a directed graph $D = (V, A)$ and a capacity function $c : A \to \mathbb{R}_+$ such that for all $s, t \in V$, each $s-t$ cut in G has capacity at least $r(s,t)$. The pair D, c is called an *exact realization* if for all $s, t \in V$ with $s \neq t$, the minimum capacity of an $s-t$ cut in D as equal to $r(s,t)$.

Obviously, any function r has a realization. We say that r is *exactly realizable* if it has an exact realization. The *network synthesis problem* is the problem to find an exact or cheapest realization for a given r (or to decide that none exist).

The following theorem due to Gomory and Hu [1961] characterizes the exactly realizable *symmetric*[17] functions. It also shows that if $r : V \times V \to \mathbb{R}$ is exactly realizable and symmetric, then r has an *undirected* exact realization

[17] A function $r : V \times V \to \mathbb{R}$ is called *symmetric* if $r(u,v) = r(v,u)$ for all $u, v \in V$.

(more precisely, an exact realization D, c where for each arc $a = (u, v)$ of D, also (v, u) is an arc, with $c(u, v) = c(v, u)$).

Theorem 62.5. *A symmetric function $r : V \times V \to \mathbb{R}_+$ is exactly realizable if and only if*

(62.1) $$r(u, w) \geq \min\{r(u, v), r(v, w)\}$$

for all distinct $u, v, w \in V$. If r is exactly realizable, there is a tree that gives an exact realization of r.

Proof. Necessity being easy, we show sufficiency. Let $T = (V, E)$ be a tree on V maximizing

(62.2) $$\sum_{uv \in E} r(u, v).$$

Taking $c(uv) := r(u, v)$ for each edge $uv \in E$ gives an exact realization of r. To see this, note that for all s, t, the minimum capacity of an $s - t$ cut is equal to $\min_{uv \in EP} r(u, v)$, where P is the $s - t$ path in T. By (62.1) we know that $r(s, t)$ is not smaller than this minimum. To show equality, suppose to the contrary that $r(u, v) < r(s, t)$ for some $uv \in P$. Then replacing T by $(T - uv) \cup st$ gives a tree with larger sum (62.2). ∎

Notes. Obviously, condition (62.1) remains necessary for exact realizability of non-symmetric functions. Resh [1965] claimed that (62.1) also remains sufficient, but a counterexample is given by the function $r : V \times V \to \mathbb{R}_+$ with $V = \{1, 2, 3, 4\}$, and $r(1, 2) = r(1, 3) = r(1, 4) = r(2, 4) = r(3, 4) = 1$, and $r(s, t) = 0$ for all other s, t (cf. Mayeda [1962]).

62.3. Minimum-capacity network design

Theorem 62.5 yields a tree as an exact realization of a given function $r : V \times V \to \mathbb{R}_+$. A tree is a most economical realization in the sense of having a minimum number of edges with nonzero capacity. It generally gives no exact realization for which the sum of the capacities is minimum. Such an exact realization has been characterized by Chien [1960] (extending Mayeda [1960]), while Gomory and Hu [1961] showed that if r is integer, there is a half-integer optimum exact realization.

As a preparation, we first show the following lemma of Gomory and Hu [1961] ($\lambda_G(s, t)$ denotes the maximum number of edge-disjoint $s - t$ paths in G):

Lemma 62.6α. *Let $r : V \times V \to \mathbb{R}_+$ be symmetric and let T be a spanning tree on V maximizing $r(T)$. Then any graph $G = (V, E)$ satisfies*

(62.3) $$\lambda_G(s, t) \geq r(s, t)$$

for all $s, t \in V$ if and only if (62.3) *is satisfied for each edge st of T.*

Proof. Necessity being trivial, we show sufficiency. Let $s, t \in V$ and let P be the $s-t$ path in T. By the maximality of $r(T)$, we know that $r(s,t) \leq r(e)$ for each edge e on P. Hence

$$\text{(62.4)} \qquad \lambda_G(s,t) \geq \min_{e=uv \in EP} \lambda_G(u,v) \geq \min_{e \in EP} r(e) \geq r(s,t),$$

as required. ∎

We also use the following lemma:

Lemma 62.6β. *If $r : V \times V \to \mathbb{R}_+$ is symmetric and exactly realizable, then there exists a spanning tree T on V that maximizes $r(T)$ over all spanning trees, and that moreover is a Hamiltonian path.*

Proof. Let T maximize $r(T)$. Choose T and k such that T contains a path $v_1, \ldots, v_k$, with k as large as possible. Choose T, k moreover such that the vector $(\deg_T(v_1), \ldots, \deg_T(v_k))$ is lexicographically minimal. If T is not a path, there is a j with $1 < j < k$ and $\deg_T(v_j) \geq 3$. Let $v_j u$ be an edge of T incident with v_j, with $u \neq v_{j-1}, v_{j+1}$. If $r(v_{j+1}, u) \geq r(v_j, u)$, we can replace edge $v_j u$ of T by $v_{j+1} u$, contradicting the lexicographic minimality. So $r(v_j, u) > r(v_{j+1}, u)$, and so $r(v_j, v_{j+1}) \leq r(v_{j+1}, u)$, since $r(v_{j+1}, u) \geq \min\{r(v_j, v_{j+1}), r(v_j, u)\}$ by (62.1). Hence replacing edge $v_j v_{j+1}$ of T by $v_{j+1} u$ would give a tree with a longer path, contradicting our assumption. ∎

Now we can formulate and prove the theorem. For any $r : V \times V \to \mathbb{R}$ and $u \in V$ define

$$\text{(62.5)} \qquad R(u) := \max_{v \neq u} r(u,v).$$

Theorem 62.6. *Let $r : V \times V \to \mathbb{R}_+$ be symmetric and exactly realizable. Then the minimum value of $\sum_{e \in E} c(e)$ where $G = (V, E)$ and c form an (undirected) exact realization of r, is equal to*

$$\text{(62.6)} \qquad \tfrac{1}{2} \sum_{u \in V} R(u).$$

Moreover, if r is integer, the minimum is attained by a half-integer exact realization c.

Proof. We may assume that r is integer. (62.6) indeed is a lower bound, since for each exact realization $G = (V, E), c$ of r one has

$$\text{(62.7)} \qquad \sum_{e \in E} c(e) = \tfrac{1}{2} \sum_{u \in V} \sum_{e \in \delta(u)} c(e) \geq \tfrac{1}{2} \sum_{u \in V} R(u).$$

To see that the lower bound is attained by a half-integer exact realization, let T be a spanning tree on V maximizing $r(T)$. By Lemma 62.6β, we can assume that T is a path $v_1, \ldots, v_n$.

Let $k := \max_{u,v} r(u, v)$. For $i = 0, \ldots, k$, let E_i be the set of edges e of T with $r(e) \leq i$, and for each nonsingleton component P of $T - E_i$, make a circuit consisting of edges parallel to P and one edge connecting the end vertices of P. Let $G = (V, E)$ arise by taking the edge-disjoint union of these circuits. Let $c(e) := \frac{1}{2}$ for each $e \in E$. Then

$$(62.8) \qquad \lambda_G(v_j, v_i) = 2r(v_j, v_i)$$

for all i, j with $1 \leq j < i \leq n$.

Indeed, in proving $\geq$, we can assume that $j = i - 1$ (by Lemma 62.6α). As v_{i-1}, v_i are contained in $r(v_{i-1}, v_i)$ edge-disjoint circuits, we have $\lambda_G(v_{i-1}, v_i) \geq 2r(v_{i-1}, v_i)$.

Conversely, the inequality $\leq$ in (62.8) follows from

$$(62.9) \qquad \lambda_G(v_j, v_i) \leq \min_{j<h\leq i} 2r(v_{h-1}, v_h) \leq 2r(v_j, v_i).$$

The first inequality here follows from the fact that for each h with $j < h \leq i$, the number of edges connecting $\{v_1, \ldots, v_{h-1}\}$ and $\{v_h, \ldots, v_n\}$ is equal to $2r(v_{h-1}, v_h)$. The second inequality follows from (62.1). ∎

Notes. Note that also any nonexact realization has size at least (62.6), and therefore, the theorem also characterizes the minimum size of any realization.

Wing and Chien [1961] observed that a minimum-capacity realization can be found by linear programming, and Gomory and Hu [1962,1964] showed that also the weighted case can be solved by linear programming. Indeed, the polyhedron P of all realizations of a given function $r : V \times V \to \mathbb{Q}_+$ can be described as follows. Let E is the collection of all unordered pairs of elements of V. Then P is determined by:

$$(62.10) \qquad \begin{array}{ll} x_e \geq 0 & \text{for all } e \in E, \\ x(\delta(U)) \geq R(U) & \text{for all nonempty } U \subset V, \end{array}$$

where $R(U) := \max_{u\in U, v\in V\setminus U} r(u, v)$.

This formulation was given by Gomory and Hu [1962] and applied to finding a minimum-cost realization with linear programming, by a row-generating implementation of the simplex method (thus avoiding listing the exponential number of constraints). Bland, Goldfarb, and Todd [1981] observed that description (62.10) implies polynomial-time solvability with the ellipsoid method, since the constraints (62.10) can be tested in polynomial time.

A direct, polynomial-size linear programming formulation was given by Gomory and Hu [1964], by extending the number of variables. Indeed, P consists of those $x \in \mathbb{R}^E_+$ such that for all distinct $s, t \in V$, there exists an $s - t$ flow $f_{s,t} : E \to \mathbb{R}^E_+$ with $f \leq x$ and of value $r(s, t)$.

The latter description implies that a minimum-weight realization can be determined in polynomial time, by solving an explicit linear programming problem — in fact, in strongly polynomial time, with the method of Tardos [1986].

Note that the *exact* realizations do not form a convex set; for instance, if $V = \{u, v, w\}$ and $r(s,t) = 1$ for all $s, t \in V$, then $x(uv) = x(vw) = x(uw) = \frac{2}{3}$ is a convex combination of exact realizations, but is not itself an exact realization.

62.4. Integer realizations and r-edge-connected graphs

In Section 62.3, the fractional version of the minimum-capacity network design problem was discussed. We now consider the case where all capacities are required to be integer. It relates to: given $r : V \times V \to \mathbb{Z}_+$, find an r-edge-connected undirected graph $G = (V, E)$ with a minimum number of edges. Here a graph $G = (V, E)$ is called *r-edge-connected* if $\lambda_G(s,t) \geq r(s,t)$ for all $s, t \in V$ with $s \neq t$.

Eswaran and Tarjan [1976] observed that the weighted version of the integer realization problem is NP-complete, as finding a Hamiltonian circuit in an undirected graph can be reduced to it. (So even if $r = \mathbf{2}$ and all weights belong to $\{0, 1\}$, it is NP-complete.)

Chou and Frank [1970] gave a polynomial-time algorithm for finding a minimum-size integer realization, implying the following characterization of the minimum number $\gamma(r)$ of edges of an r-edge-connected graph[18].

To this end we can assume that r is symmetric and exactly realizable, that is, satisfies (62.1) (since resetting $r(s,t)$ to the maximum of $\min_{e=uv \in EP} r(u,v)$ over all $s - t$ paths P, does not change the problem).

Again, define for each $u \in V$,

$$R(u) := \max_{v \neq u} r(u,v). \tag{62.11}$$

Theorem 62.7. *Let $r : V \times V \to \mathbb{Z}_+$ be symmetric and satisfy* (62.1).
(i) *If $R(u) = 1$ for some $u \in V$, then $\gamma(r) = \gamma(r') + 1$, where r' is the restriction of r to $(V \setminus \{u\}) \times (V \setminus \{u\})$.*
(ii) *If $R(u) \neq 1$ for all $u \in V$, then*

$$\gamma(r) = \lceil \tfrac{1}{2} \sum_{u \in V} R(u) \rceil. \tag{62.12}$$

Proof. We first show (i). The inequality $\gamma(r) \leq \gamma(r') + 1$, is easy, since an r-edge-connected graph can be obtained from an r'-edge-connected graph by adding one edge connecting u with some $v \neq u$ with $r(u,v) = 1$.

To see the reverse inequality, let $G = (V, E)$ be an r-edge-connected graph with $|E| = \gamma(r)$. As $R(u) = 1$, we have $\deg_G(u) \geq 1$. Let ut be an edge incident with u. Let H be the graph obtained from G by contracting ut. Then H is r'-edge-connected and has $|E| - 1$ edges, showing $\gamma(r') \leq |E| - 1 = \gamma(r) - 1$.

[18] The construction of Chou and Frank [1970] is lacunary, and does not apply, e.g., to the case where $r(u,v) = 3$ for all u, v and $|V|$ is odd.

We next show (ii). Trivially, for any r-edge-connected graph $G = (V, E)$:

(62.13) $$|E| = \tfrac{1}{2}\sum_{u\in V} \deg_G(u) \geq \tfrac{1}{2}\sum_{u\in V} R(u).$$

This proves $\geq$ in (62.12). To prove $\leq$, order the vertices as $v_1, \ldots, v_n$ such that $R(v_1) \geq R(v_2) \geq \cdots \geq R(v_n)$. Note that $R(v_1) = R(v_2)$.

Let $k := \lfloor \frac{1}{2}R(v_1)\rfloor$. Let W be the set of vertices v with $R(v)$ odd. Let M be a set of $\lceil \frac{1}{2}|W|\rceil$ edges covering W such that if $v_1, v_2 \in W$, then $v_1v_2 \in M$.

For $i = 1, \ldots, k$, let C_i be a circuit on $\{v \in V \mid R(v) \geq 2i\}$. So C_1 is a Hamiltonian circuit. We choose C_1 in such a way that the components of $C_1 - v_1 - v_2$ span no edge in M. Let H be the (edge-disjoint) union of M and C_1. Then for any $U \subseteq V$:

(62.14) if $d_H(U) = 2$ and $U \cap \{v_1, v_2\} = \emptyset$, then $U \cap W = \emptyset$.

Indeed, if $d_H(U) = 2$, then U induces a path on C_1. As $U \cap \{v_1, v_2\} = \emptyset$, U is contained in a component of $C_1 - v_1 - v_2$. Hence each edge in M incident with U belongs to $d_H(U)$. As $d_H(U) = 2$, it follows that no edge in M is incident with U. So $U \cap W = \emptyset$, proving (62.14).

Let G be the (edge-disjoint) union of $M, C_1, \ldots, C_k$. Note that the number of edges of G is equal to

(62.15) $$\begin{aligned}|M| + \sum_{i=1}^{k} |EC_i| &= |M| + \sum_{u\in V} \lfloor \tfrac{1}{2}R(u)\rfloor = \lceil \tfrac{1}{2}|W|\rceil + \sum_{u\in V} \lfloor \tfrac{1}{2}R(u)\rfloor \\ &= \lceil \tfrac{1}{2}\sum_{u\in V} R(u)\rceil.\end{aligned}$$

We finally show that G is r-connected, for which it suffices to show that for $i = 2, \ldots, n$:

(62.16) $$\lambda_G(v_{i-1}, v_i) \geq R(v_i).$$

To see that this is sufficient, note that for $h < j$ one has

(62.17) $$\begin{aligned}\lambda_G(v_h, v_j) &\geq \min_{h<i\leq j} \lambda_G(v_{i-1}, v_i) \geq \min_{h<i\leq j} R(v_i) \\ &= R(v_j) \geq r(v_h, v_j).\end{aligned}$$

To prove (62.16), choose the smallest $i \geq 2$ for which it is not true. Then G has a cut $\delta(U)$ with $v_i \in U$, $v_{i-1} \notin U$, and $d_G(U) < R(v_i)$. By the minimality of i, $\delta(U)$ separates no pair among $v_1, \ldots, v_{i-1}$, and hence $v_1, \ldots, v_{i-1} \notin U$. Now, setting $l := \lfloor \frac{1}{2}R(v_i)\rfloor$:

(62.18) $$2l + 1 \geq R(v_i) > d_G(U) \geq d_H(U) + \sum_{j=2}^{l} d_{C_j}(U) \geq 2l$$

(as C_j covers v_{i-1} and v_i for $j = 1, \ldots, l$). Hence $d_H(U) = 2$ and $R(v_i)$ is odd. So $U \cap W \neq \emptyset$. Hence, by (62.14), $i = 2$. Then $v_1v_2 \in M$, and so $d_H(U) \geq 3$, a contradiction. ∎

Notes. In fact, by choosing M in this proof in such a way that $\deg_M(u) = 1$ if $u \in W \setminus \{v_1\}$, and $\deg_M(u) = 0$ if $u \in (V \setminus W) \setminus \{v_1\}$, we obtain a graph G with $\deg_G(u) = R(u)$ for each $u \neq v_1$. Hence $\lambda_G(u, v) = \min\{R(u), R(v)\}$ for all distinct $u, v \in V$.

The construction can be extended to obtain a strongly polynomial-time algorithm that, for given integer function r, finds a minimum-capacity integer realization c (Sridhar and Chandrasekaran [1990,1992]).

(Chou and Frank [1970] claim to give an algorithm to find a minimum-size *exact* realization, but their construction fails when taking $r(1, 2) := r(3, 4) := r(4, 5) := 5$, $r(2, 3) := r(5, 6) := 3$, and $r(i, j) := \min_{i<h\leq j} r(h-1, h)$ for $i < j$. The construction gives 15 edges, while there is an exact realization with 14 edges only.)

Frank and Chou [1970] announced a polynomial-time algorithm for the problem: given a symmetric $r : V \times V \to \mathbb{Z}_+$, find a *simple* r-edge-connected graph $G = (V, E)$ (if any) with $|E|$ minimal.

Wang and Kleitman [1973] characterized the degree-sequences of k-vertex-connected simple undirected graphs.

Chapter 63

Connectivity augmentation

This last chapter of Part V is devoted to the connectivity augmentation problem: given a graph, find the minimum number of edges to be added to make it k-connected. There is an undirected and a directed variant, and a vertex-connectivity and an edge/arc-connectivity variant. Thus we will come across:

- making a directed graph k-arc-connected (Section 63.1),
- making an undirected graph k-edge-connected (Section 63.3),
- making a directed graph k-vertex-connected (Section 63.5),
- making an undirected graph k-vertex-connected (Section 63.6).

For the first three problems, min-max relations and polynomial-time algorithms have been found. The core is formed by fundamental theorems of Frank and Jordán. As for the fourth problem, only for fixed k the polynomial-time solvability has been proved. The complexity for general k is open.

Two special cases of connectivity augmentation have been considered before: making a digraph 1-arc-connected — that is, strongly connected (Chapter 57), and making an edge- or arcless (di)graph k-vertex- or edge/arc-connected — the network synthesis problem (Chapter 62).

63.1. Making a directed graph k-arc-connected

Let (V, A) and (V, B) be directed graphs. The set B is called a *k-arc-connector for D* if the directed graph $(V, A \cup B)$ is k-arc-connected (where in $A \cup B$ arcs are taken parallel if they occur both in A and in B). So 1-arc-connectors are precisely the strong connectors, which we discussed in Chapter 57.

Frank [1990a,1992a] characterized the minimum size of a k-arc-connector for a directed graph, with the help of the following result of Mader [1982] (we follow the proof of Frank [1992a]).

Lemma 63.1α. *Let $D = (V, A)$ be a directed graph, let $k \in \mathbb{Z}_+$, and let $x, y : V \to \mathbb{Z}_+$. Then D has a k-arc-connector B with $\deg^{\text{in}}_B(v) = x_v$ and $\deg^{\text{out}}_B(v) = y_v$ for each $v \in V$ if and only if $x(V) = y(V)$ and*

$$(63.1) \qquad x(U) \geq k - d^{\text{in}}_A(U) \text{ and } y(U) \geq k - d^{\text{out}}_A(U)$$

for each nonempty proper subset U of V.

Proof. Necessity is easy, since for each nonempty $U \subset V$,

(63.2) $$k \leq d^{\text{in}}_{A\cup B}(U) = d^{\text{in}}_{B}(U) + d^{\text{in}}_{A}(U) \leq x(U) + d^{\text{in}}_{A}(U),$$

and similarly for y.

To see sufficiency, choose a counterexample with $x(V)$ minimal. Trivially, $x(V) \geq 1$. Let $\mathcal{X}$ be the collection of inclusionwise maximal proper subsets U of V satisfying $x(U)+d^{\text{in}}(U) = k$, and let $\mathcal{Y}$ be the collection of inclusionwise maximal proper subsets U of V satisfying $y(U) + d^{\text{out}}(U) = k$. (We set d^{in} and d^{out} for d^{in}_{A} and d^{out}_{A}.)

Let $R := \{v \in V \mid x_v \geq 1\}$ and $S := \{v \in V \mid y_v \geq 1\}$. Then

(63.3) for all $r \in R$ and $s \in S$, there exists a $U \in \mathcal{X} \cup \mathcal{Y}$ with $r, s \in U$.

Otherwise, we could augment D by a new arc (s, r) and decrease both x_r and y_s by 1. Then (63.1) is maintained, and we obtain a smaller counterexample, contradicting our assumption. This shows (63.3).

Now note that for each $U \in \mathcal{X}$:

(63.4) $$y(V \setminus U) \geq k - d^{\text{out}}(V \setminus U) = k - d^{\text{in}}(U) = x(U).$$

This implies, for each $U \in \mathcal{X}$:

(63.5) if $S \subseteq U$, then $U \cap R = \emptyset$; if $R \subseteq U$, then $U \cap S = \emptyset$.

Indeed, if $S \subseteq U$, then $y(V \setminus U) = 0$, implying (with (63.4)) that $x(U) = 0$, that is, $U \cap R = \emptyset$. Similarly, if $R \subseteq U$, then $x(U) = x(V)$, implying (with (63.4)) that $y(V \setminus U) = y(V)$, that is, $U \cap S = \emptyset$. This proves (63.5).

Now choose $r \in R$, $s \in S$, and let $U \in \mathcal{X} \cup \mathcal{Y}$ with $r, s \in U$. By symmetry, we may assume that $U \in \mathcal{X}$. By (63.5), $S \not\subseteq U$. Choose $t \in S \setminus U$. Let $T \in \mathcal{X} \cup \mathcal{Y}$ contain r and t.

First assume that $T \in \mathcal{X}$. Then $T \cup U = V$, by the maximality of T and U and the submodularity of the set function $x(W) + d^{\text{in}}(W)$. This implies (using (63.4)):

(63.6) $$\begin{aligned} y(V) &\geq y(V \setminus U) + y(V \setminus T) \geq x(U) + x(T) = x(T \cup U) + x(T \cap U) \\ &> x(V) = y(V) \end{aligned}$$

(since $V \setminus U$ and $V \setminus T$ are disjoint, and since $r \in T \cap U$), a contradiction.

So $T \in \mathcal{Y}$. But then

(63.7) $$\begin{aligned} 2k &= x(T) + d^{\text{in}}(T) + y(U) + d^{\text{out}}(U) \\ &\geq x(T \setminus U) + d^{\text{in}}(T \setminus U) + y(U \setminus T) + d^{\text{out}}(U \setminus T) + x(T \cap U) \\ &\quad + y(T \cap U) \geq 2k, \end{aligned}$$

implying equality throughout. Hence $x(T \cap U) = 0$, contradicting the fact that $r \in T \cap U$. ∎

From this, the min-max relation for minimum-size k-arc-connectors of Frank [1990a,1992a] (generalizing Corollary 57.2a) easily follows:

Theorem 63.1. *Let $D = (V, A)$ be a directed graph and let $k, \gamma \in \mathbb{Z}_+$. Then D has a k-arc-connector of size at most γ if and only if*

$$(63.8) \qquad \gamma \geq \sum_{X \in \mathcal{P}} (k - d^{\mathrm{in}}(X)) \text{ and } \gamma \geq \sum_{X \in \mathcal{P}} (k - d^{\mathrm{out}}(X))$$

for each collection $\mathcal{P}$ of disjoint nonempty proper subsets of V.

Proof. Necessity follows since for each nonempty subset X of V, at least $k - d^{\mathrm{in}}(X)$ arcs entering X must be in any k-arc-connector, and at least $k - d^{\mathrm{out}}(X)$ arcs leaving X must be in any k-arc-connector. As any new arc can enter at most one set in $\mathcal{P}$, we have (63.8).

To see sufficiency, choose $x : V \to \mathbb{Z}_+$ satisfying $x(U) \geq k - d^{\mathrm{in}}(U)$ for each nonempty $U \subset V$, with $x(V)$ as small as possible.

We show $x(V) \leq \gamma$. Let $\mathcal{P}$ be the collection of inclusionwise maximal proper subsets U of V satisfying $x(U) = k - d^{\mathrm{in}}(U)$. Any two distinct sets $T, U \in \mathcal{P}$ satisfy $T \cup U \neq V$, since otherwise $V \setminus T$ and $V \setminus U$ are disjoint, and we obtain the contradiction

$$(63.9) \qquad \begin{aligned} \gamma &\geq k - d^{\mathrm{out}}(V \setminus T) + k - d^{\mathrm{out}}(V \setminus U) = 2k - d^{\mathrm{in}}(T) - d^{\mathrm{in}}(U) \\ &= x(T) + x(U) \geq x(T \cup U) = x(V) > \gamma. \end{aligned}$$

Moreover, any two distinct $T, U \in \mathcal{P}$ are disjoint, since otherwise we obtain the contradiction

$$(63.10) \qquad \begin{aligned} x(T)+x(U) &= 2k - d^{\mathrm{in}}(T) - d^{\mathrm{in}}(U) \leq 2k - d^{\mathrm{in}}(T \cap U) - d^{\mathrm{in}}(T \cup U) \\ &< x(T \cap U) + x(T \cup U) = x(T) + x(U), \end{aligned}$$

by the maximality of T.

Now each $v \in V$ with $x_v \geq 1$ is contained in some $U \in \mathcal{P}$, as otherwise we could decrease x_v. This gives

$$(63.11) \qquad x(V) = \sum_{U \in \mathcal{P}} x(U) = \sum_{U \in \mathcal{P}} (k - d^{\mathrm{in}}(U)) \leq \gamma.$$

Hence $x(V) \leq \gamma$. Similarly, there exists a $y : V \to \mathbb{Z}_+$ satisfying $y(U) \geq k - d^{\mathrm{out}}(U)$ for each nonempty proper subset U of V and $y(V) \leq \gamma$. We can assume that $x(V) = y(V) = \gamma$. So we can apply Lemma 63.1α, which gives the theorem. ∎

The proof yields a polynomial-time algorithm, as the proof reduces to a polynomial-time number of tests if a given $x : V \to \mathbb{Z}_+$ satisfies

$$(63.12) \qquad x(U) \geq k - d^{\mathrm{in}}(U) \text{ for each nonempty } U \subset V.$$

(Similarly for y.) This can be done by maximum flow calculations: add a new vertex s and for each $v \in V$, add x_v (parallel) arcs from s to v and k parallel arcs from v to s. Then (63.12) is satisfied if and only if in the extended graph there exist k arc-disjoint $u - v$ paths, for all $u, v \in V$.

Thus (Frank [1990a,1992a]):

Theorem 63.2. *Given a directed graph $D = (V, A)$ and $k \in \mathbb{Z}_+$, a minimum-size k-arc-connector can be found in time bounded by a polynomial in the size of D and in k.*

Proof. See above. ∎

63.1a. k-arc-connectors with bounds on degrees

Frank [1990a,1992a] derived similarly characterizations of the existence of k-arc-connectors of given size and satisfying given lower and upper bounds on the in- and outdegrees:

Theorem 63.3. *Let $D = (V, A)$ be an undirected graph, let $k, \gamma \in \mathbb{Z}_+$, and let $l^{\text{in}}, l^{\text{out}}, u^{\text{in}}, u^{\text{out}} \in \mathbb{Z}_+^V$ with $l^{\text{in}} \leq u^{\text{in}}$ and $l^{\text{out}} \leq u^{\text{out}}$. Then D has a k-arc-connector B of size at most γ satisfying $l^{\text{in}}(v) \leq \deg_B^{\text{in}}(v) \leq u^{\text{in}}(v)$ and $l^{\text{out}}(v) \leq \deg_B^{\text{out}}(v) \leq u^{\text{out}}(v)$ for each $v \in V$ if and only if $\gamma \leq u^{\text{in}}(V)$, $\gamma \leq u^{\text{out}}(V)$,*

(63.13) $$k - d^{\text{in}}(U) \leq u^{\text{in}}(U) \text{ and } k - d^{\text{out}}(U) \leq u^{\text{out}}(U)$$

for each nonempty proper subset U of V, and

(63.14) $$\gamma \geq l^{\text{in}}(V \setminus \bigcup \mathcal{P}) + \sum_{X \in \mathcal{P}} (k - d^{\text{in}}(X)) \text{ and}$$
$$\gamma \geq l^{\text{out}}(V \setminus \bigcup \mathcal{P}) + \sum_{X \in \mathcal{P}} (k - d^{\text{out}}(X))$$

for each collection $\mathcal{P}$ of disjoint nonempty proper subsets of V.

Proof. Necessity is easy. To see sufficiency, choose $x : V \to \mathbb{Z}_+$ satisfying $l^{\text{in}} \leq x \leq u^{\text{in}}$, $x(V) \geq \gamma$, and $x(U) \geq k - d^{\text{in}}(U)$ for each nonempty $U \subset V$, with $x(V)$ as small as possible.

We show $x(V) \leq \gamma$. Let $\mathcal{P}$ be the collection of inclusionwise maximal proper subsets U of V satisfying $x(U) = k - d^{\text{in}}(U)$. Any two distinct sets $T, U \in \mathcal{P}$ satisfy $T \cup U \neq V$, since otherwise $V \setminus T$ and $V \setminus U$ are disjoint, and we obtain the contradiction

(63.15) $$\gamma \geq k - d^{\text{out}}(V \setminus T) + k - d^{\text{out}}(V \setminus U) = 2k - d^{\text{in}}(T) - d^{\text{in}}(U)$$
$$= x(T) + x(U) \geq x(T \cup U) \geq x(V) > \gamma.$$

Moreover, any two distinct $T, U \in \mathcal{P}$ are disjoint, since otherwise we obtain the contradiction

(63.16) $$x(T) + x(U) = 2k - d^{\text{in}}(T) - d^{\text{in}}(U) \leq 2k - d^{\text{in}}(T \cap U) - d^{\text{in}}(T \cup U)$$
$$< x(T \cap U) + x(T \cup U) = x(T) + x(U),$$

by the maximality of T.

Now each $v \in V$ with $x_v > l^{\text{in}}(v)$ is contained in some $U \in \mathcal{P}$, as otherwise we could decrease x_v. This gives

(63.17) $$x(V) = l^{\text{in}}(V \setminus \bigcup \mathcal{P}) + \sum_{U \in \mathcal{P}} x(U) = l^{\text{in}}(V \setminus \bigcup \mathcal{P}) + \sum_{U \in \mathcal{P}} (k - d^{\text{in}}(U)) \leq \gamma.$$

Hence $x(V) = \gamma$. Similarly, there exists a $y : V \to \mathbb{Z}_+$ satisfying $l^{\text{out}} \leq y \leq u^{\text{out}}$, $y(V) = \gamma$, and $y(U) \geq k - d^{\text{out}}(U)$ for each nonempty $U \subset V$. So we can apply Lemma 63.1α, which gives the theorem. ∎

Again, this proof yields a polynomial-time algorithm to find a minimum-size k-arc-connector satisfying prescribed bounds on the in- and outdegrees.

Notes. The following problem is NP-complete: given a directed graph $D = (V, A)$, a function $r : V \times V \to \mathbb{Z}_+$, and a cost function $k : V \times V \to \mathbb{Q}_+$, find a minimum-cost set of new arcs whose addition to D makes the graph r-arc-connected. Frank [1990a,1992a] showed that if there are functions $k', k'' : V \to \mathbb{Q}_+$ with $k(u, v) = k'(u) + k''(v)$ for all $u, v \in V$, then this problem is solvable in polynomial time.

Gusfield [1987a] gave a linear-time algorithm to find a minimum number of directed arcs to be added to a mixed graph such that it becomes strongly connected (that is, for all vertices u, v there is a $u - v$ path traversing directed edges in the right direction only).

Frank and Jordán [1995b] gave an alternative proof of Theorem 63.1 based on bisubmodular functions, and showed a number of related results.

Frank [1993c] gave some further methods for the problems discussed in these sections.

Kajitani and Ueno [1986] showed that the minimum size of a k-arc-connector for a directed tree $D = (V, A)$ is equal to the maximum of $\sum_{v \in V} \max\{0, k - \deg^{\text{in}}(v)\}$ and $\sum_{v \in V} \max\{0, k - \deg^{\text{out}}(v)\}$.

Frank [1990a,1992a] gave a polynomial-time algorithm for: given directed graph $D = (V, A)$, $r \in V$, and $k \in \mathbb{Z}_+$, find a minimum number of arcs to be added to D such that for each $s \in V$ there exist k arc-disjoint $r - s$ paths in the augmented graph. The complexity was improved by Gabow [1991b].

63.2. Making an undirected graph 2-edge-connected

Let (V, E) and (V, F) be undirected graphs. The set F is called a *k-edge-connector* for G if the graph $(V, E \cup F)$ is k-edge-connected (where in $E \cup F$ edges are taken parallel if they occur both in E and in F).

The minimum size of a 1-edge-connector of a graph G trivially is one less than the number of components of G. Eswaran and Tarjan [1976] and Plesník [1976] characterized the minimum size of a 2-edge-connector, by first showing:

Theorem 63.4. *Let $G = (V, E)$ be a forest with at least two vertices and with p vertices of degree 1 and q isolated vertices. Then the minimum size of a 2-edge-connector for G equals $\lceil \frac{1}{2}p \rceil + q$.*

Proof. Each vertex of degree 1 should be incident with at least one new edge, and each vertex of degree 0 should be incident with at least two new edges. So any 2-edge-connector has size at least $\frac{1}{2}p + q$.

To see that $\lceil\frac{1}{2}p\rceil + q$ can be attained, first assume that G is not connected. Choose vertices u and v in different components, with $\deg(u) \leq 1$ and $\deg(v) \leq 1$. Adding edge uv, reduces $\frac{1}{2}p + q$ by 1, as one easily checks.

So we can assume that G is a tree. If $p \leq 3$, the graph is a path or a subdivision of $K_{1,3}$, and the theorem is easy.

If $p \geq 4$, there is a pair of end vertices u, v such that at least two edges of G leave the $u - v$ path P in G. Let G' be the tree obtained from G by contracting P to one vertex. Then G' has $p - 2$ end vertices. Applying induction shows that G' has a 2-edge-connector F of size $\lceil\frac{1}{2}p\rceil - 1$. By adding edge uv we obtain a 2-edge-connector of G, proving the theorem. ∎

This implies, for not necessarily forests:

Corollary 63.4a. *Let $G = (V, E)$ be a non-2-edge-connected undirected graph. For $i = 0, 1$, let p_i be the number of 2-edge-connected components K with $d_E(K) = i$. Then the minimum size of a 2-edge-connector equals $\lceil\frac{1}{2}p_1\rceil + p_0$.*

Proof. Directly from Theorem 63.4, by contracting each 2-edge-connected component to one vertex. ∎

These proofs give polynomial-time algorithms to find a minimum-size 2-edge-connector for a given undirected graph. Eswaran and Tarjan [1976] gave a linear-time algorithm.

63.3. Making an undirected graph k-edge-connected

Watanabe and Nakamura [1987] gave a min-max formula and a polynomial-time algorithm for the minimum size of a k-edge-connector for any undirected graph. Cai and Sun [1989] and Frank [1992a] showed that the min-max relation can be derived from the following lemma (given, in a different, 'vertex-splitting' terminology, by Mader [1978a] and Lovász [1979a] (Problem 6.53); the proof below follows Frank [1992a]):

Lemma 63.5α. *Let $G = (V, E)$ be a graph, let $k \in \mathbb{Z}_+$, with $k \geq 2$, and let $x : V \to \mathbb{Z}_+$. Then G has a k-edge-connector F with $\deg_F(v) = x_v$ for each $v \in V$ if and only if $x(V)$ is even and*

(63.18) $$x(U) \geq k - d_E(U)$$

for each nonempty proper subset U of V.

Proof. Necessity is easy, since for each nonempty $U \subset V$,

(63.19) $$k \leq d_{E \cup F}(U) = d_F(U) + d_E(U) \leq x(U) + d_E(U).$$

To see sufficiency, choose a counterexample with $x(V)$ minimal. Trivially, $x(V) \geq 2$.

Let $S := \{v \in V \mid x_v \geq 1\}$, and fix $s \in S$. Let $\mathcal{U}$ be the collection of inclusionwise maximal sets $U \subset V$ containing s and satisfying $x(U)+d_E(U) \leq k+1$. Note that

(63.20) $\quad x(U) \leq \frac{1}{2}x(V)$ for each $U \in \mathcal{U}$,

since otherwise $x(V \setminus U) \leq x(U) - 2$, implying the contradiction $k \leq x(V \setminus U) + d_E(V \setminus U) \leq x(U) - 2 + d_E(U) \leq k-1$.

Moreover,

(63.21) $\quad$ for all $t \in S \setminus \{s\}$, there exists a $U \in \mathcal{U}$ containing t.

Otherwise, we could augment G by a new edge st and decrease both x_s and x_t by 1. Then (63.18) is maintained, and we obtain a smaller counterexample, contradicting our assumption. This shows (63.21).

Next:

(63.22) $\quad$ for any two distinct $T, U \in \mathcal{U}$, G has an edge leaving $T \cap U$, and no edge connecting $T \cap U$ and $V \setminus (T \cup U)$.

Consider:

(63.23)
$$\begin{aligned}
&2(k+1) \geq x(T) + d_E(T) + x(U) + d_E(U)\\
&= x(T \setminus U) + d_E(T \setminus U) + x(U \setminus T) + d_E(U \setminus T)\\
&+2|E[T \cap U, V \setminus (T \cup U)]| + 2x(T \cap U) \geq 2k+2,
\end{aligned}$$

implying equality throughout. So $x(T \cap U) = 1$ and $|E[T \cap U, V \setminus (T \cup U)] = \emptyset$. Since $d_E(T \cap U) \geq k - x(T \cap U) = k-1 \geq 1$, this proves (63.22).

Now by (63.21) and (63.20) we can choose three sets $T, U, W \in \mathcal{U}$. Then

(63.24) $\quad T \cap U = T \cap W = U \cap W.$

Indeed, by symmetry it suffices to prove that $T \cap U \cap W = U \cap W$. Let $M := U \cap W$. Suppose $T \cap M \neq M$; so $M \not\subseteq T$, and hence $T \cup M \neq T$. Defining $\phi(X) := x(X) + d_E(X)$ for $X \subseteq V$, we obtain the contradiction

(63.25)
$$\begin{aligned}
&k \leq \phi(T \cap M) \leq \phi(T) + \phi(M) - \phi(T \cup M)\\
&\leq \phi(T) + \phi(U) + \phi(W) - \phi(U \cup W) - \phi(T \cup M)\\
&\leq 3(k+1) - 2(k+2) = k-1,
\end{aligned}$$

since the maximality of T, U, and W gives $\phi(U \cup W) \geq k+2$ and $\phi(T \cup M) \geq k+2$. This shows (63.24).

Now by (63.22), G has an edge leaving $T \cap U$, while the other end should be in each of $T \cup U$, $T \cup W$, and $U \cup W$, and hence in $T \cap U$, a contradiction. ∎

From this, the min-max result for minimum-size k-edge-connectors of Watanabe and Nakamura [1987] follows:

Theorem 63.5. *Let $G = (V, E)$ be an undirected graph and let $k, \gamma \in \mathbb{Z}_+$, with $k \geq 2$. Then G has a k-edge-connector of size at most γ if and only if*

$$(63.26) \qquad 2\gamma \geq \sum_{U \in \mathcal{P}} (k - d(U))$$

for each collection $\mathcal{P}$ of disjoint nonempty proper subsets of V.

Proof. Necessity follows since for each nonempty proper subset U of V, at least $k - d(U)$ edges entering U must be in any k-edge-connector. As any new edge can enter at most two sets in $\mathcal{P}$, we have (63.26).

To see sufficiency, choose $x : V \to \mathbb{Z}_+$ satisfying (63.18), with $x(V)$ as small as possible. By Lemma 63.5α it suffices to show that $x(V) \leq 2\gamma$.

Let $\mathcal{P}$ be the collection of inclusionwise maximal subsets U of V satisfying $x(U) = k - d(U)$. Any two distinct sets $T, U \in \mathcal{P}$ satisfy $T \cup U \neq V$, since otherwise we obtain the contradiction

$$(63.27) \qquad \begin{aligned} 2\gamma &< x(V) = x(T \cup U) \leq x(T) + x(U) = k - d(T) + k - d(U) \\ &= k - d(V \setminus T) + k - d(V \setminus U) \leq 2\gamma, \end{aligned}$$

using (63.26). Moreover, any two distinct $T, U \in \mathcal{P}$ are disjoint, since otherwise we obtain the contradiction

$$(63.28) \qquad \begin{aligned} x(T) + x(U) &= 2k - d(T) - d(U) \leq 2k - d(T \cap U) - d(T \cup U) \\ &< x(T \cap U) + x(T \cup U) = x(T) + x(U), \end{aligned}$$

by the maximality of T. Now each $v \in V$ with $x_v \geq 1$ is contained in some $U \in \mathcal{P}$, as otherwise we could decrease x_v. This gives

$$(63.29) \qquad x(V) = \sum_{U \in \mathcal{P}} x(U) = \sum_{U \in \mathcal{P}} (k - d(U)) \leq 2\gamma,$$

which proves the theorem. ∎

Similarly to the directed case, the proof implies that a minimum-size k-edge-connector can be found in polynomial time (Watanabe and Nakamura [1987]):

Theorem 63.6. *Given an undirected graph G and $k \in \mathbb{Z}_+$, a minimum-size k-edge-connector can be found in strongly polynomial time.*

Proof. The proof method reduces to a polynomially bounded number of tests of (63.18), which can be performed in strongly polynomial time by reducing it to maximum flow computations. ∎

Notes. Also Naor, Gusfield, and Martel [1990,1997], and Gabow [1991b] gave polynomial-time algorithms to find a minimum-size k-edge-connector. Frank [1990a, 1992a] and Benczúr [1994,1999] gave strongly polynomial-time algorithms for the (integer) capacitated version of the problem. More and related results can be found in Gabow [1994], Benczúr [1995], Nagamochi and Ibaraki [1995,1996,1997,1999c], Nagamochi, Shiraki, and Ibaraki [1997], Benczúr and Karger [1998,2000], Nagamochi and Eades [1998], Bang-Jensen and Jordán [2000], and Nagamochi, Nakamura, and Ibaraki [2000].

63.3a. k-edge-connectors with bounds on degrees

Frank [1990a,1992a] derived similarly characterizations of the existence of k-edge-connectors of given size and satisfying given lower and upper bounds on the degrees:

Theorem 63.7. *Let $G = (V, E)$ be an undirected graph, let $k, \gamma \in \mathbb{Z}_+$, with $k \geq 2$, and let $l, u \in \mathbb{Z}_+^V$ with $l \leq u$. Then G has a k-edge-connector F of size at most γ satisfying $l(v) \leq \deg_F(v) \leq u(v)$ for each $v \in V$ if and only if $2\gamma \leq u(V)$,*

(63.30) $$k - d_E(U) \leq u(U)$$

for each nonempty proper subset U of V, and

(63.31) $$2\gamma \geq l(V \setminus \bigcup\mathcal{P}) + \sum_{U \in \mathcal{P}} (k - d_E(U)).$$

for each collection $\mathcal{P}$ of disjoint nonempty proper subsets of V.

Proof. The conditions can be easily seen to be necessary.

To see sufficiency, let $x : V \to \mathbb{Z}_+$ satisfy $l \leq x \leq u$, $x(V) \geq 2\gamma$, $x(U) \geq k - d_E(U)$ for each nonempty $U \subset V$, and with $x(V)$ as small as possible. Such an x exists, by (63.30). By Lemma 63.5α, it suffices to show that $x(V) \leq 2\gamma$.

Let $\mathcal{P}$ be the collection of inclusionwise maximal proper subsets U of V satisfying $x(U) = k - d(U)$. Any two distinct sets $T, U \in \mathcal{P}$ satisfy $T \cup U \neq V$, since otherwise we obtain the contradiction

(63.32) $$\begin{aligned} 2\gamma < x(V) = x(T \cup U) \leq x(T) + x(U) = k - d(T) + k - d(U) \\ = k - d(V \setminus T) + k - d(V \setminus U) \leq 2\gamma, \end{aligned}$$

by (63.31). Moreover, any two distinct $T, U \in \mathcal{P}$ are disjoint, since otherwise we obtain the contradiction

(63.33) $$\begin{aligned} x(T) + x(U) = 2k - d(T) - d(U) \leq 2k - d(T \cap U) - d(T \cup U) \\ < x(T \cap U) + x(T \cup U) = x(T) + x(U), \end{aligned}$$

by the maximality of T. Now each $v \in V$ with $x_v > l(v)$ is contained in some $U \in \mathcal{P}$, as otherwise we could decrease x_v. This gives

(63.34) $$x(V) = l(V \setminus \bigcup\mathcal{P}) + \sum_{U \in \mathcal{P}} x(U) = l(V \setminus \bigcup\mathcal{P}) + \sum_{U \in \mathcal{P}} (k - d(U)) \leq 2\gamma,$$

as required. ∎

Notes. T. Jordán (cf. Bang-Jensen and Jordán [1997]) showed that finding a minimum number of edges that makes a given simple graph k-edge-connected and keeps it simple, is NP-complete. On the other hand, Bang-Jensen and Jordán [1997,1998] gave, for any fixed k, an $O(n^4)$-time algorithm for this problem. Taoka, Watanabe, and Takafuji [1994] gave an $O(m + n \log n)$-time algorithm for $k = 4$ and an $O(n^2 + m)$-time algorithm for $k = 5$ (assuming the input graph is $k-1$-edge-connected). Other fast algorithms for undirected edge-connectivity augmentation were given by Benczúr [1999].

Ueno, Kajitani, and Wada [1988] gave a polynomial-time algorithm for finding a minimum-size k-edge-connector for a tree.

63.4. r-edge-connectivity and r-edge-connectors

Let $G = (V, E)$ be an undirected graph and let $r : V \times V \to \mathbb{Z}_+$. G is called *r-edge-connected* if for all $u, v \in V$ there exist $r(u, v)$ edge-disjoint paths connecting u and v. So, by Menger's theorem, G is r-edge-connected if and only if $d_E(U) \geq r(u, v)$ for all $U \subseteq V$ and $u \in U$, $v \in V \setminus U$.

An *r-edge-connector* for G is a set F of edges on V such that the graph $G' := (V, E \cup F)$ satisfies $\lambda_{G'}(u, v) \geq r(u, v)$ for all $u, v \in V$. (Again, $E \cup F$ is the disjoint union, allowing parallel edges.) Define $\gamma(G, r)$ as the minimum size of an r-edge-connector for G.

Given an undirected graph $G = (V, E)$, a function $r : V \times V \to \mathbb{Z}_+$, and a cost function $k : V \times V \to \mathbb{Q}_+$, it is NP-complete to find a minimum-cost r-edge-connector (since for $E = \emptyset$, $r = \mathbf{2}$, it is the traveling salesman problem).

Frank [1990a,1992a] gave a polynomial-time algorithm and a min-max formula for the cardinality case: given a graph $G = (V, E)$ and $r : V \times V \to \mathbb{Z}_+$, find the minimum number of edges to be added to make G r-edge-connected. We describe the method in this section.

It is based on the following theorem of Mader [1978a] (conjectured by Lovász [1976a]; we follow the proof of Frank [1992b]):

Lemma 63.8α. *Let $G = (V \cup \{s\}, E)$ be an undirected graph, where s has even and positive degree, and s is not incident with a bridge of G. Then s has two neighbours u and v such that the graph G' obtained from G by replacing su and sv by one new edge uv satisfies*

(63.35) $$\lambda_{G'}(x, y) = \lambda_G(x, y)$$

for all $x, y \in V$.

Proof. By induction on $|V| + \deg(s)$. For any $U \subseteq V$ with $\emptyset \neq U \neq V$, define

(63.36) $$R(U) := \max_{u \in U, v \in V \setminus U} \lambda_G(u, v),$$

and set $R(\emptyset) := R(V) := 0$. So $R(U) \leq d(U)$ for each $U \subseteq V$.

Let $\mathcal{P}$ be the collection of nonempty proper subsets U of V with $d(U) = R(U)$, and let $\mathcal{U}$ be the collection of nonempty proper subsets U of V with $d(U) \leq R(U) + 1$ (hence $\mathcal{P} \subseteq \mathcal{U}$).

Note that $u, v \in N(s)$ are as required in the lemma if and only if there is no $U \in \mathcal{U}$ containing both u and v. So we can assume that

(63.37) for each pair $u, v \in N(s)$ there is a $U \in \mathcal{U}$ containing u and v.

We first show:

(63.38) $|T| = 1$ for each $T \in \mathcal{P}$.

Suppose not. Consider the graph G/T obtained from G by contracting T (where T also denotes the vertex obtained by contracting T). By induction,

G/T has two edges su' and sv such that for the graph H obtained from G/T by replacing su' and sv by a new edge $u'v$, one has

(63.39) $$\lambda_H(x,y) = \lambda_{G/T}(x,y)$$

for all $x,y \in V(G/T) \setminus \{s\}$. By symmetry of u' and v, we may assume that $v \neq T$, that is, $v \in V \setminus T$. Let $u := u'$ if $u' \neq T$ and choose $u \in T \cap N(s)$ if $u' = T$.

Then for all $Z \in \mathcal{U}$:

(63.40) if $T \subseteq Z$ or $T \cap Z = \emptyset$ then $u \notin Z$ or $v \notin Z$.

Indeed, as $R(Z) \geq d(Z) - 1$, there exist $x,y \in V$ such that Z splits x,y and $\lambda_G(x,y) \geq d(Z) - 1$. Since $T \subseteq Z$ or $T \cap Z = \emptyset$, we may assume that $x \notin T$. Define $y' := y$ if $y \notin T$, and $y' := T$ if $y \in T$. Define $Z' := Z$ if $T \cap Z = \emptyset$, and $Z' := (Z \setminus T) \cup \{T\}$ if $T \subseteq Z$. Suppose now $u,v \in Z$. Then $d_H(Z') = d_G(Z) - 2$. This gives the contradiction

(63.41) $$\lambda_{G/T}(x,y') \geq \lambda_G(x,y) \geq d_G(Z) - 1 > d_H(Z') \geq \lambda_H(x,y') \\ = \lambda_{G/T}(x,y'),$$

proving (63.40).

Now let $U \in \mathcal{U}$ contain u and v. By Lemma 61.6α, $R(T) + R(U)$ is at most $R(T \cap U) + R(T \cup U)$ or at most $R(T \setminus U) + R(U \setminus T)$.

If $R(T) + R(U) \leq R(T \cap U) + R(T \cup U)$, then

(63.42) $$d(T) + d(U) \geq d(T \cap U) + d(T \cup U) \geq R(T \cap U) + R(T \cup U) \\ \geq R(T) + R(U) \geq d(T) + d(U) - 1,$$

implying $R(T \cup U) \geq d(T \cup U) - 1$. So $T \cup U \in \mathcal{U}$ and $u,v \in T \cup U$, contradicting (63.40).

So $R(T) + R(U) \leq R(T \setminus U) + R(U \setminus T)$. Hence

(63.43) $$d(T) + d(U) \geq d(T \setminus U) + d(U \setminus T) \geq R(T \setminus U) + R(U \setminus T) \\ \geq R(T) + R(U) \geq d(T) + d(U) - 1.$$

So $d(T) + d(U) = d(T \setminus U) + d(U \setminus T)$, and hence $T \cap U$ contains no neighbours of s. So $u' \neq T$ (otherwise $u \in T \cap U \cap N(s)$). Hence $u' = u \in U \setminus T$. By (63.43) we also know $R(U \setminus T) \geq d(U \setminus T) - 1$. So $U \setminus T \in \mathcal{U}$ and $u,v \in U \setminus T$, contradicting (63.40). This proves (63.38).

Note that (63.38) implies

(63.44) $\lambda_G(u,v) = \min\{\deg(u), \deg(v)\}$ for all $u,v \in V$,

since $\lambda_G(u,v) = d_E(U)$ for some $U \subseteq V$ splitting $\{u,v\}$. So $U \in \mathcal{P}$, and hence $|U| = 1$, implying (63.44).

Choose a vertex $t \in N(s)$ of minimum degree. Let $\mathcal{U}'$ be a minimal collection of inclusionwise maximal sets in $\mathcal{U}$ containing t such that $\bigcup \mathcal{U}' \supseteq N(s)$ (this exists by (63.37)). Note that for each $U \in \mathcal{U}$ one has $|E[U,s]| \leq \frac{1}{2}\deg(s)$, since otherwise $d(V \setminus U) \leq d(U) - 2$ (since $\deg(s)$ is even), and hence

(63.45) $$R(V \setminus U) \leq d(V \setminus U) \leq d(U) - 2 \leq R(U) - 1 = R(V \setminus U) - 1,$$

a contradiction. Hence $|\mathcal{U}'| \geq 3$ (as $t \in U$ for each $U \in \mathcal{U}'$). Moreover,

(63.46) for each $U \in \mathcal{U}'$, there is a $v \in N(s)$ such that U is the only set in $\mathcal{U}'$ containing v.

(Otherwise we could delete U from $\mathcal{U}'$.)

Also,

(63.47) $R(U \setminus \{t\}) \geq R(U)$ for each $U \in \mathcal{U}'$.

Indeed, choose $x \in U$ and $y \in V \setminus U$ with $R(U) = \lambda_G(x, y)$. If $x \neq t$, then $R(U \setminus \{t\}) \geq \lambda_G(x, y) = R(U)$, as required. If $x = t$, then for any $u \in N(s) \cap (U \setminus \{t\})$,

(63.48) $$R(U) = \lambda_G(t, y) = \min\{\deg(t), \deg(y)\} \leq \min\{\deg(u), \deg(y)\} = \lambda_G(u, y) \leq R(U \setminus \{t\}).$$

This shows (63.47).

Moreover, for any distinct $X, Y \in \mathcal{U}'$ one has

(63.49) $R(X) + R(Y) \leq R(X \setminus Y) + R(Y \setminus X)$.

Suppose not. Then, by Lemma 61.6α we know $R(X) + R(Y) \leq R(X \cap Y) + R(X \cup Y)$, and by symmetry we can assume that $R(X) > R(X \setminus Y)$. Hence by (63.47), $X \cap Y \neq \{t\}$, and hence by (63.38), $X \cap Y \notin \mathcal{P}$. By the maximality of X and Y, $R(X \cup Y) \leq d(X \cup Y) - 2$. This gives the contradiction

(63.50) $$\begin{aligned} R(X \cap Y) + R(X \cup Y) &\leq (d(X \cap Y) - 1) + (d(X \cup Y) - 2) \\ &\leq d(X) + d(Y) - 3 \leq R(X) + R(Y) - 1 \\ &\leq R(X \cap Y) + R(X \cup Y) - 1, \end{aligned}$$

proving (63.49).

This implies that for any distinct $X, Y \in \mathcal{U}'$ one has

(63.51) $|X \setminus Y| = |Y \setminus X| = 1$, and st is the only edge connecting $X \cap Y$ and $(V \cup \{s\}) \setminus (X \cup Y)$.

Indeed, by (63.49) (as st connects $X \cap Y$ and $X \cup Y$),

(63.52) $$\begin{aligned} &d(X) + d(Y) \\ &= d(X \setminus Y) + d(Y \setminus X) + 2|E[X \cap Y, (V \cup \{s\}) \setminus (X \cup Y)]| \\ &\geq d(X \setminus Y) + d(Y \setminus X) + 2 \geq R(X \setminus Y) + R(Y \setminus X) + 2 \\ &\geq R(X) + R(Y) + 2 \geq d(X) + d(Y). \end{aligned}$$

So we have equality throughout. Hence $X \setminus Y, Y \setminus X \in \mathcal{P}$, and therefore, by (63.38), $|X \setminus Y| = |Y \setminus X| = 1$. Moreover, $d(X \cap Y, V \setminus (X \cup Y)) = 1$, proving (63.51).

Now choose $X, Y, Z \in \mathcal{U}'$. Then (63.51) and (63.46) imply that $X \cap Y = X \cap Z = Y \cap Z$. So st is the only edge leaving $X \cap Y$, and hence st is a bridge. This contradicts the condition given in this lemma. ∎

Note that

(63.53) the graph G' arising in Lemma 63.8α again has no bridge incident with s,

as for any two neighbours x, y of s in G' one has $\lambda_{G'}(x,y) = \lambda_G(x,y) \geq 2$. The lemma therefore can be applied iteratively to yield:

Theorem 63.8. *Let $G = (V,E)$ be an undirected graph and let $r : V \times V \to \mathbb{Z}_+$ be symmetric. Let $x : V \to \mathbb{Z}_+$ be such that $x(K) \neq 1$ for each component K of G. Then G has an r-edge-connector F satisfying $\deg_F(v) = x_v$ for each $v \in V$ if and only if $x(V)$ is even and*

(63.54) $$x(U) + d_E(U) \geq r(u,v)$$

for all $U \subseteq V$ and all $u \in U$, $v \in V \setminus U$.

Proof. Necessity of (63.54) follows from the fact that $x(U) + d_E(U) \geq d_F(U) + d_E(U) \geq r(u,v)$. To see sufficiency, extend V by a new vertex s and, for each $v \in V$, x_v edges connecting s and v (parallel if $x_v \geq 2$). Let H be the extended graph. Then (63.54) implies

(63.55) $$d_H(U) \geq r(u,v)$$

for all $U \subseteq V$ and all $u \in U$, $v \in V \setminus U$. Hence, for all $u, v \in V$,

(63.56) $$\lambda_H(u,v) \geq r(u,v).$$

Now by iteratively splitting s as in Lemma 63.8α (cf. (63.53)), we obtain a set F of new edges such that adding F to G, the new graph G' satisfies

(63.57) $$\lambda_{G'}(u,v) = \lambda_H(u,v) \geq r(u,v)$$

for all $u, v \in V$. As moreover $\deg_F(v) = x_v$ for each $v \in V$, F is an r-edge-connector as required. ∎

The condition that $x(K) \neq 1$ for each component K cannot be deleted, as can be seen by taking $G = (V, \emptyset)$, $r := \mathbf{1}$, $x := \mathbf{1}$, with $|V| \geq 4$.

We next give the theorem of Frank [1990a,1992a] characterizing the minimum size $\gamma(G,r)$ of an r-edge-connector. To this end we can assume that r satisfies:

(63.58) $$\begin{aligned} &\text{(i) } r(u,v) = r(v,u) \geq \lambda_G(u,v) \text{ for all } u,v \in V;\\ &\text{(ii) } r(u,w) \geq \min\{r(u,v), r(v,w)\} \text{ for all } u,v,w \in V. \end{aligned}$$

Define

(63.59) $$\begin{aligned} &R(U) := \max_{u \in U, v \in V \setminus U} r(u,v) \text{ if } \emptyset \subset U \subset V, \text{ and}\\ &R(\emptyset) := R(V) := 0. \end{aligned}$$

Call a component K of G *marginal* if $K \neq V$, $r(u,v) = \lambda_G(u,v)$ for all $u, v \in K$, and $r(u,v) \leq 1$ for all $u \in K$ and $v \in V \setminus K$.

Theorem 63.9. *Let $G = (V, E)$ be an undirected graph and let $r : V \times V \to \mathbb{Z}_+$ satisfy* (63.58).

(i) *If K is a marginal component of G, then*

(63.60) $$\gamma(G, r) = \gamma(G - K, r') + R(K),$$

where r' is the restriction of r to $(V \setminus K) \times (V \setminus K)$.

(ii) *If G has no marginal components, then $\gamma(G, r)$ is equal to the maximum value of*

(63.61) $$\lceil \tfrac{1}{2} \sum_{U \in \mathcal{P}} (R(U) - d_E(U)) \rceil$$

taken over all collections $\mathcal{P}$ of disjoint nonempty proper subsets of V.

Proof. We first show (i). Let K be a marginal component of G and define $\alpha := R(K)$. As K is marginal, $\alpha \leq 1$. The inequality

(63.62) $$\gamma(G, r) \leq \gamma(G - K, r') + \alpha$$

is easy, since an r-edge-connector for G can be obtained from an r'-edge-connector F for $G - K$: if $\alpha = 0$, then F is an r-edge-connector, and if $\alpha = 1$, we obtain an r-edge-connector by adding to F one edge connecting some pair $u \in K$, $v \in V \setminus K$ with $r(u, v) = 1$.

To see the reverse inequality, let F be a minimum-size r-edge-connector for G. Let $G' := (V, E \cup F)$. So G' is r-edge-connected.

If F contains no edges connecting K and $V \setminus K$, then $\alpha = 0$ and F contains an r'-edge-connector for $G - K$. Hence $\gamma(G, r) = |F| \geq \gamma(G - K, r') = \gamma(G - K, r') + \alpha$.

If F contains an edge uv with $u \in K$, $v \in V \setminus K$, then the graph H obtained from G' by contracting $(K \cup \{v\})$ to one vertex, is r'-edge-connected. Since edge $uv \in F$ is contracted, it implies that $G - K$ has an r'-edge-connector of size at most $|F| - 1$. So $\gamma(G - K, r') \leq |F| - 1 \leq \gamma(G, r) - \alpha$.

We next show (ii). Let G have no marginal components. Choose $x : V \to \mathbb{Z}_+$ such that $x(U) + d_E(U) \geq R(U)$ for each $U \subseteq V$, with $x(V)$ as small as possible. Let μ be the maximum value of (63.61). It suffices to show that $x(V) \leq 2\mu$, since then we can apply Theorem 63.8 (after increasing $x(v)$ by 1 for some $v \in V$ if $x(V)$ is odd). So assume $x(V) > 2\mu$. As $\mu > 0$ (otherwise $x = \mathbf{0}$), we know $x(V) > 2$.

Then

(63.63) $$x(K) \neq 1 \text{ for each component } K \text{ of } G.$$

For suppose $x(K) = 1$. We show that K is marginal, which is a contradiction. First, $K \neq V$, since $x(V) > 2$. Second, for each $u \in K$, $v \in V \setminus K$, we have $r(u, v) \leq x(K) + d_E(K) = x(K) \leq 1$. Third, to prove that $r(u, v) = \lambda_G(u, v)$ for $u, v \in K$, there is a subset U of K with $|U \cap \{u, v\}| = 1$, $\lambda_G(u, v) = d_E(U)$, and $x(U) = 0$. Then $r(u, v) \leq x(U) + d_E(U) = d_E(U) = \lambda_G(u, v)$. So K is marginal, contradicting our assumption. This proves (63.63).

By the minimality of x, there exists a collection $\mathcal{P}$ of nonempty proper subsets U of V satisfying $x(U) = R(U) - d_E(U)$, such that $\mathcal{P}$ covers $\{v \mid x_v \geq 1\}$. Choose $\mathcal{P}$ such that

(63.64) $$\sum_{U \in \mathcal{P}} |U|$$

is as small as possible. Then

(63.65) $T \cap U = \emptyset$ for distinct $T, U \in \mathcal{P}$.

For suppose $T \cap U \neq \emptyset$. Note that $T \not\subseteq U \not\subseteq T$, by the minimality of (63.64). Observe also that $T \cup U \neq V$, since otherwise we obtain the contradiction

(63.66) $$\begin{aligned} 2\mu &< x(V) = x(T \cup U) \leq x(T) + x(U) \\ &= R(T) - d(T) + R(U) - d(U) \\ &= R(V \setminus T) - d(V \setminus T) + R(V \setminus U) - d(V \setminus U) \leq 2\mu. \end{aligned}$$

(by definition of μ, since $V \setminus T$ and $V \setminus U$ are disjoint).

By Lemma 61.6α, $R(T) + R(U)$ is at most $R(T \cap U) + R(T \cup U)$ or at most $R(T \setminus U) + R(U \setminus T)$.

If $R(T) + R(U) \leq R(T \cap U) + R(T \cup U)$, then

(63.67) $$\begin{aligned} x(T) + x(U) &= R(T) - d(T) + R(U) - d(U) \\ &\leq R(T \cap U) - d(T \cap U) + R(T \cup U) - d(T \cup U) \\ &\leq x(T \cap U) + x(T \cup U) = x(T) + x(U), \end{aligned}$$

and hence we have equality throughout. This implies that $x(T \cup U) = R(T \cup U) - d_E(T \cup U)$, and hence replacing T and U by $T \cup U$ would decrease (63.64), a contradiction.

If $R(T) + R(U) \leq R(T \setminus U) + R(U \setminus T)$, then

(63.68) $$\begin{aligned} x(T) + x(U) &= R(T) - d(T) + R(U) - d(U) \\ &\leq R(T \setminus U) - d(T \setminus U) + R(U \setminus T) - d(U \setminus T) \\ &\leq x(T \setminus U) + x(U \setminus T) \leq x(T) + x(U), \end{aligned}$$

implying equality throughout. This implies that $x(T \setminus U) = R(T \setminus U) - d_E(T \setminus U)$, and hence replacing T by $T \setminus U$ would decrease (63.64), a contradiction.

This proves (63.65), yielding the contradiction

(63.69) $$2\mu < x(V) = \sum_{U \in \mathcal{P}} x(U) = \sum_{U \in \mathcal{P}} (R(U) - d(U)) \leq 2\mu,$$

which proves the theorem. ∎

Frank [1990a,1992a] also gave a polynomial-time algorithm to find a minimum-cost r-edge-connector if the cost of any new edge uv is given by $k(u) + k(v)$, for some function $k : V \to \mathbb{Q}_+$. This is done with the help of the following auxiliary result:

Theorem 63.10. *Let $G = (V, E)$ be an undirected graph and let $r : V \times V \to \mathbb{Z}_+$ be symmetric. Define $R(U)$ as in* (63.59). *Then*

(63.70) $$Q := \{x \in \mathbb{R}_+^V \mid x(U) \geq R(U) - d_E(U) \text{ for all } U \subseteq V\}$$

is a contrapolymatroid, with associated supermodular function given by, for $X \subseteq V$*:*

(63.71) $$g(X) := \max_{\mathcal{U}} \sum_{U \in \mathcal{U}} (R(U) - d_E(U)),$$

where the maximum ranges over collections $\mathcal{U}$ *of disjoint nonempty subsets of* X*.*

Proof. Clearly, for any $x \in \mathbb{R}_+^V$ one has $x \in Q$ if and only if $x(U) \geq g(X)$ for each $X \subseteq V$.

To see that g is supermodular, choose $X, Y \subseteq V$. Let

(63.72) $$g(X) = \sum_{U \in \mathcal{U}} (R(U) - d(U)) \text{ and } g(Y) = \sum_{T \in \mathcal{T}} (R(T) - d(T)),$$

where $\mathcal{U}$ and $\mathcal{T}$ are collections of disjoint nonempty subsets of X and of Y, respectively. The collections $\mathcal{U}$ and $\mathcal{T}$ together form a family $\mathcal{S}$ of nonempty subsets of V satisfying

(63.73) $$\sum_{S \in \mathcal{S}} \chi^S \leq \chi^{X \cap Y} + \chi^{X \cup Y} \text{ and } g(X) + g(Y) \leq \sum_{S \in \mathcal{S}} (R(S) - d(S)).$$

We now choose $\mathcal{S}$ such that (63.73) is satisfied and such that

(63.74) $$\sum_{S \in \mathcal{S}} |S|(|V \setminus S| + 1)$$

is as small as possible.

We claim that $\mathcal{S}$ is laminar; that is,

(63.75) if $T, U \in \mathcal{S}$, then $T \subseteq U$ or $U \subseteq T$ or $T \cap U = \emptyset$.

Suppose not. By Lemma 61.6α, $R(T) + R(U)$ is at most $R(T \cap U) + R(T \cup U)$ or at most $R(T \setminus U) + R(U \setminus T)$. If $R(T) + R(U) \leq R(T \cap U) + R(T \cup U)$, then replacing T and U by $T \cap U$ and $T \cup U$ maintains (63.73) but decreases (63.74) (by Theorem 2.1), contradicting the minimality assumption. If $R(T) + R(U) \leq R(T \setminus U) + R(U \setminus T)$, then replacing T and U by $T \setminus U$ and $U \setminus T$ maintains (63.73) but decreases (63.74) (again by Theorem 2.1), again contradicting the minimality condition. This proves (63.75).

Now let $\mathcal{P}$ be the collection of inclusionwise maximal elements in $\mathcal{S}$ and let $\mathcal{Q}$ be the collection of remaining sets in $\mathcal{S}$. (If a set occurs twice in $\mathcal{S}$, it is both in $\mathcal{P}$ and in $\mathcal{Q}$.) Then each set in $\mathcal{P}$ is contained in $X \cup Y$, and each set in $\mathcal{Q}$ is contained in $X \cap Y$. Moreover, both $\mathcal{P}$ and $\mathcal{Q}$ are collections of disjoint sets. Hence

(63.76) $$\begin{aligned} g(X \cup Y) + g(X \cap Y) &\geq \sum_{P \in \mathcal{P}} (R(P) - d(P)) + \sum_{Q \in \mathcal{Q}} (R(Q) - d(Q)) \\ &= \sum_{S \in \mathcal{S}} (R(S) - d(S)) \geq g(X) + g(Y); \end{aligned}$$

that is, g is supermodular. ∎

With this theorem, also good characterizations and polynomial-time algorithms can be obtained for the minimum size of an r-edge-connector satisfying prescribed lower and upper bounds on its degrees — see Frank [1990a,1992a].

Bang-Jensen, Frank, and Jackson [1995] extended these results to mixed graphs.

63.5. Making a directed graph k-vertex-connected

Let (V, A) and (V, B) be directed graphs. The set B is called a *k-vertex-connector* for D if the directed graph $(V, A \cup B)$ is k-vertex-connected. (Note that parallel edges will not help the vertex-connectivity.)

Since, for directed graphs, 1-vertex-connectors and 1-arc-connectors coincide, the problem of finding a minimum-size 1-vertex-connector for a given directed graph is addressed in Section 57.1.

Frank and Jordán [1995b] showed the following min-max relation for minimum-size k-vertex connector in directed graphs (which is a special case of Frank and Jordán's Theorem 60.5 above).

Call a pair (X, Y) of subsets of V a *good pair* if $X \neq \emptyset$, $Y \neq \emptyset$, $X \cap Y = \emptyset$, and D has no arc from X to Y. Call a collection $\mathcal{F}$ of good pairs a *good collection* if $X \cap X' = \emptyset$ or $Y \cap Y' = \emptyset$ for all distinct (X, Y), $(X', Y') \in \mathcal{F}$.

Theorem 63.11. *Let $D = (V, A)$ be a directed graph and let $k \in \mathbb{Z}_+$. Then the minimum size of a k-vertex-connector for D is equal to the maximum value of*

(63.77) $$\sum_{(X,Y)\in\mathcal{F}} (k - |V \setminus (X \cup Y)|),$$

where $\mathcal{F}$ ranges over good collections of good pairs.

Proof. Let γ be the maximum value. The minimum is not less than γ, since for any $(X, Y) \in \mathcal{F}$, at least $k - |V \setminus (X \cup Y)|$ arcs from X to Y should be added, while such arcs do not run from X' to Y' for any other pair (X', Y') in $\mathcal{F}$ (as $X \cap X' = \emptyset$ or $Y \cap Y' = \emptyset$).

To see equality, we can assume that D is not k-vertex-connected. Then there exist disjoint nonempty subsets T and U of V such that D has no arc from T to U and such that $|V \setminus (T \cup U)| < k$.

If there exist $t \in T$ and $u \in U$ such that augmenting D with the arc (t, u), the maximum decreases, we are done by induction. So we can assume that no such pair t, u exists. Hence for each $t \in T$ and $u \in U$, there exists a good collection $\mathcal{F}_{t,u}$ of good pairs, with

(63.78) $$\sum_{(X,Y)\in\mathcal{F}_{t,u}} (k - |V \setminus (X \cup Y)|) = \gamma,$$

and with $t \notin X$ or $u \notin Y$ for all $(X,Y) \in \mathcal{F}_{t,u}$.

Concatenating these collections $\mathcal{F}_{t,u}$ for all $t \in T$, $u \in U$, and adding the pair (T,U), we obtain a family $\mathcal{G}$ of good pairs satisfying:

(63.79) (i) for each $x \in T$, $y \in U$, there are at most $|T||U|$ pairs (X,Y) in $\mathcal{G}$ with $x \in X$ and $y \in Y$;
(ii) $\sum_{(X,Y)\in\mathcal{G}} (k - |V \setminus (X \cup Y)|) > \gamma |T||U|$.

Among all families $\mathcal{G}$ satisfying (63.79), we choose one minimizing

(63.80) $$\sum_{(X,Y)\in\mathcal{G}} (|X| + |V \setminus Y|)(|Y| + |V \setminus X|).$$

Then

(63.81) for all $(X,Y), (X',Y') \in \mathcal{G}$ one has $X \cap X' = \emptyset$ or $Y \cap Y' = \emptyset$ or $X \subseteq X', Y' \subseteq Y$ or $X' \subseteq X, Y \subseteq Y'$.

Suppose not. Replace (X,Y) and (X',Y') by $(X \cap X', Y \cup Y')$ and $(X \cup X', Y \cap Y')$. This maintains (63.79), while (63.80) decreases[19], contradicting our assumption. This proves (63.81).

Now consider the partial order $\leq$ on pairs (X,Y) of subsets of V, defined by $(X,Y) \leq (X',Y')$ if $X \subseteq X', Y' \subseteq Y$. For each pair (X,Y), let its 'weight' $w(X,Y)$ be the number of times (X,Y) occurs in $\mathcal{G}$, and let its 'length' $l(X,Y)$ be equal to $k - |V \setminus (X \cup Y)|$. Then by (63.79)(i), any chain has weight at most $|T||U|$. By (63.79)(ii), the sum of $l(X,Y)w(X,Y)$ over $(X,Y) \in \mathcal{G}$ is more than $\gamma|T||U|$. Hence, by the length-width inequality for partially ordered sets (Theorem 14.5), $\mathcal{G}$ contains an antichain $\mathcal{F}$ of length more than γ. Then $\mathcal{F}$ is a good collection by (63.81). This contradicts the definition of γ. ∎

The theorem implies that the minimum size of a k-vertex-connector for a given directed graph $D = (V,A)$ is equal to the minimum value of

(63.82) $$\sum_{u,v\in V} x_{u,v}$$

subject to

(63.83) (i) $x_{u,v} \geq 0$ for all $u, v \in V$,
(ii) $\sum_{u\in X}\sum_{v\in Y} x_{u,v} \geq k - |V \setminus (X \cup Y)|$ for all disjoint nonempty $X, Y \subseteq V$ with no arc from X to Y.

[19] This can be seen with Theorem 2.1: Make a copy $\widetilde{V}$ of V, and let $\widetilde{Y}$ be the set of copies of elements of Y. Define $Z_{X,Y} := X \cup (\widetilde{V} \setminus \widetilde{Y})$. Then $|X| + |V \setminus Y| = |Z_{X,Y}|$ and $|Y| + |V \setminus X| = |(V \cup \widetilde{V}) \setminus Z_{X,Y}|$. Moreover, for (X,Y) and (X',Y') we have $Z_{X\cap X',Y\cup Y'} = Z_{X,Y} \cap Z_{X',Y'}$ and $Z_{X\cup X',Y\cap Y'} = Z_{X,Y} \cup Z_{X',Y'}$. So the replacements decrease (63.80) by Theorem 2.1.

This can be seen by observing that Theorem 63.11 implies that this LP-problem has integer primal and dual solutions of equal value.

As Frank and Jordán [1995b] pointed out, this implies that a minimum-size k-vertex-connector can be found in polynomial time with the ellipsoid method, as follows.

Since the conditions (63.83) can be checked in polynomial time, the ellipsoid method (as we discuss below) implies that the minimum size of a k-arc-connector can be determined in polynomial time. Then an explicit minimum-size k-vertex-connector can be found by testing, for each pair $u, v \in V$, whether augmenting D by the new arc (u, v) decreases the minimum size of a k-arc-connector. If so, we add (u, v) to D and iterate.

The ellipsoid method applies, since given $x_{u,v} \geq 0$ $(u, v \in V)$, we can test if (63.83)(ii) holds. Indeed, let B be a set of new arcs forming a complete directed graph on V. Define a capacity function c on $A \cup B$ by: $c(a) := \infty$ for each $a \in A$ and $c(b) = x_{u,v}$ for each arc $b \in B$ from u to v. Then (63.83)(ii) is equivalent to: for each $s, t \in V$ there is an $s-t$ flow $f_{s,t}$ in $(V, A \cup B)$ subject to c of value k, such that for any vertex $v \neq s, t$, the amount of flow traversing v is at most 1 (since the set of arcs in B from X to Y, together with the vertices in $V \setminus (X \cup Y)$, form a mixed arc/vertex-cut separating s and t). As this can be tested in polynomial time, we have a polynomial-time test for (63.83).

In fact, we can transform the problem into a linear programming problem of polynomial size, by including the flow variables $f_{s,t}(a)$ (for $s, t \in V$ and $a \in A \cup B$), into the LP-problem. Thus the minimum size of a k-arc-connector can be described as the solution of a linear programming problem of polynomial size.

There is no combinatorial polynomial-time algorithm known to find a minimum-size k-vertex-connector for a given directed graph. (Frank and Jordán [1995a] describe a combinatorial polynomial-time algorithm for finding a minimum-size 2-vertex-connector for a strongly connected directed graph. Frank and Jordán [1999] extended it to a polynomial-time algorithm (for any fixed k) to find a minimum-size k-vertex-connector.)

Notes. Frank and Jordán [1995b] also showed that a directed graph $D = (V, A)$ has a k-vertex-connector B with all in- and outdegrees at most $k - \kappa(D)$ (where $\kappa(D)$ denotes the vertex-connectivity of D).

Frank [1994a] gave the following conjecture:

(63.84) (?) Let $D = (V, A)$ be a simple acyclic directed graph. Then the minimum size of a k-vertex-connector for D is equal to the maximum of $\sum_{v \in V} \max\{0, k - \deg^{\text{in}}(v)\}$ and $\sum_{v \in V} \max\{0, k - \deg^{\text{out}}(v)\}$. (?)

An $O(kn)$-time algorithm finding a minimum-size k-vertex-connector for a rooted tree was given by Masuzawa, Hagihara, and Tokura [1987]. Frank [1994a] observed that this result easily extends to branchings.

Approximation algorithms for the minimum size of a k-vertex-connector for a directed graph were given by Jordán [1993a].

63.6. Making an undirected graph k-vertex-connected

Let (V, E) and (V, F) be undirected graphs. The set F is called a *k-vertex-connector* for G if the graph $(V, E \cup F)$ is k-vertex-connected.

Trivially, the minimum size of a 1-vertex-connector for an undirected graph G is equal to one less than the number of components of G.

The minimum size of a 2-vertex-connector for undirected graphs was given by Eswaran and Tarjan [1976] and Plesník [1976]. To this end, call a block *pendant* if it contains exactly one cut vertex of G. Moreover, call a block *isolated* if it contains no cut vertex of G. So an isolated block is a component of G.

Theorem 63.12. *Let $G = (V, E)$ be a non-2-vertex-connected undirected graph, with p pendant blocks and q isolated blocks. Let d be the maximum number of components of $G - v$, maximized over $v \in V$. Then the minimum size of a 2-vertex-connector for G is equal to*

(63.85) $$k := \max\{d - 1, \lceil \tfrac{1}{2}p \rceil + q\}.$$

Proof. One needs at least $d-1$ edges, since for any $v \in V$, after deleting v the augmented graph should be connected. Any block containing no cut vertex should be incident with at least two new edges, and any block containing one cut vertex should be incident with at least one new edges. Hence the number of new edges is at least $\frac{1}{2}p + q$, and hence at least k.

To show that k can be attained, choose a counterexample G with k minimal. Then G is connected. Otherwise, we can choose two blocks B, B' from different components of G such that each of B, B' is pendant or isolated. We can choose a non-cut vertex from each of B, B', and connect them by a new edge to obtain graph G'. After that, k has decreased by exactly 1, and we can apply induction to G', implying the theorem.

So G is connected, and hence $q = 0$ (as G is not 2-vertex-connected). Moreover, $k \geq 2$, since otherwise $p \leq 2$, and we can add one edge to make G 2-vertex-connected.

Let U be the set of vertices v for which $G-v$ has at least three components and let W be the set of vertices v for which $G - v$ has $k + 1$ components. So $W \subseteq U$. Moreover, $|U| \geq 2$, since otherwise we can add $d - 1$ edges to make G connected.

We show:

(63.86) there exist two distinct pendant blocks B, B' such that each $B-B'$ path traverses all vertices in W and at least two vertices in U.

If $|W| \leq 1$, this is trivial. So we may assume that $|W| \geq 2$. Then, as $W \subseteq U$, it suffices to show that there exists a path traversing all vertices in W. If such a path would not exist, there exists a subset X of W with $|X| = 3$ that is not on a path. Then for each $v \in X$, one component K of $G - v$ contains $X \setminus \{v\}$. So for each $v \in X$, $G - v$ has k components disjoint from

X. Moreover, for distinct $v, v' \in X$, if K and K' are components of $G - v$ and $G - v'$ (respectively) each disjoint from X, then $K \cap K' = \emptyset$. Since for each $v \in X$ and each component K of $G - v$, $K \cup \{v\}$ contains at least one pendant block, we know $p \geq 3k \geq 3\lceil \frac{1}{2}p \rceil$, contradicting the fact that $p > 0$.

This shows (63.86). Now augment G by an edge connecting non-cut vertices in B and B', giving graph G'. As this augmentation decreases k (by the conditions given in (63.86)), we would obtain a counterexample with k smaller. ∎

This proof directly gives a polynomial-time algorithm to find a minimum-size 2-vertex-connector for G. Eswaran and Tarjan [1976] mention that a linear-time implementation of this algorithm was communicated to them in 1973 by R. Pecherer and A. Rosenthal — see Rosenthal and Goldner [1977]. (See also Hsu and Ramachandran [1991,1993].)

An equivalent form of Theorem 63.12 is:

Corollary 63.12a. *Let $G = (V, E)$ be a non-2-vertex-connected graph. Then G has a 2-vertex-connector of size at most γ if and only if for each vertex v, $G - v$ has at most $\gamma + 1$ components and*

(63.87) $$\sum_{U \in \mathcal{P}} (2 - |N(U)|) \leq 2\gamma$$

for each collection $\mathcal{P}$ of disjoint nonempty subsets U of V with $|U| \leq |V| - 3$.

Proof. Directly from Theorem 63.12. ∎

Jackson and Jordán [2001] showed that for each fixed k, a minimum-size k-vertex-connector for an undirected graph can be found in polynomial time.

Notes. Watanabe and Nakamura [1988,1993] give a characterization of the minimum size of a 3-vertex-connector, and Watanabe and Nakamura [1993] describe an $O(n(n+m)^2)$-time algorithm (for a sketch, see Watanabe and Nakamura [1988, 1990]). Hsu and Ramachandran [1991] gave a linear-time algorithm for this problem. Hsu [1992,2000] gave an almost-linear-time algorithm to find a minimum-size 4-vertex-connector for a 3-connected undirected graph.

Note that the natural extensions of Corollary 63.12a does not hold for k-vertex-connectors with $k \geq 4$, as is shown by the complete bipartite graph $K_{3,3}$.

For approximation algorithms, see Jordán [1993b,1995,1997a], Khuller and Thurimella [1993], Cheriyan and Thurimella [1996b,1999], Nutov and Penn [1997], Penn and Shasha-Krupnik [1997], and Jackson and Jordán [2000].

63.6a. Further notes

Corollary 53.6b implies the following characterization for connectivity augmentation, due to Frank [1979b].

Theorem 63.13. *Let $D = (V, A)$ be a digraph, let $r \in V$, and let $k \in \mathbb{Z}_+$ be such that D contains k disjoint r-arborescences. Moreover, let $D' = (V, A')$ and $l \in \mathbb{Z}_+^{A'}$. Then the minimum of $l(C)$ where $C \subseteq A'$ such that the digraph $(V, A \cup C)$ (taking arcs multiple) has $k + 1$ disjoint r-arborescences is equal to the maximum size t of a family of nonempty subsets $U_1, \ldots, U_t$ of $V \setminus \{r\}$ such that $d_D^{\text{in}}(U_j) = k$ for $j = 1, \ldots, t$ and such that each arc a of D' enters at most $l(a)$ of the U_j.*

Proof. Consider the digraph $D'' = (V, A'')$ with $A'' := A \cup A'$ (taking multiple arcs for arcs occurring both in A and in A'). Now the minimum in this corollary is equal to the minimum of $\sum_{a \in A'} l(a)x_a$ where $x \in \mathbb{Z}^{A''}$ satisfies

(63.88)
$$0 \leq x_a \leq 1 \text{ if } a \in A',$$
$$x(\delta_{D'}^{\text{in}}(U)) \geq k + 1 - d_D^{\text{in}}(U) \text{ for each nonempty } U \subseteq V \setminus \{r\}.$$

Since (63.88) is TDI by Corollary 53.6b, this minimum is equal to the maximum described in the present corollary. ∎

The problem of making a bipartite directed graph strongly connected while preserving bipartiteness is considered by Gabow and Jordán [1999,2000a]. Augmenting the arc-connectivity while preserving bipartiteness is studied by Gabow and Jordán [2000b]. Making a bipartite undirected graph k-edge-connected while preserving bipartiteness, and, more generally, edge-connectivity augmentation with partition constraints, is studied by Bang-Jensen, Gabow, Jordan, and Szigeti [1998, 1999].

For the 'successive augmentation problem', see Cheng and Jordán [1999]. For NP-completeness and approximation results for connectivity augmentation, see Frederickson and Ja'Ja' [1981,1982]. Frank and Király [2001] studied problems that combine graph orientation and connectivity augmentation.

Planar graph connectivity augmentation was considered by Provan and Burk [1999].

Ishii, Nagamochi, and Ibaraki [1997,1998b,1998a,1999,2000,2001] considered the problem of making an undirected graph both k-vertex- and l-edge-connected.

For surveys on connectivity augmentation, see Frank [1993a,1994a], Jordán [1994,1997b], and Nagamochi [2000].

Part VI

Cliques, Stable Sets, and Colouring

Part VI: Cliques, Stable Sets, and Colouring

We now arrive at a class of problems that are in general NP-complete: finding a maximum-size clique or stable set or a minimum vertex-colouring in an undirected graph. These problems relate to each other: a stable set in a graph is a clique in the complementary graph, a colouring is a partitioning of the vertex set into stable sets, and the maximum size of a clique is a lower bound for the minimum number of colours.

Graph colouring was motivated originally by the four-colour conjecture formulated in the 1850s, stating that each planar map can be coloured with at most four colours — since 1977 a theorem of Appel and Haken. Later, colouring turned out to have several other applications, like in school scheduling, timetabling, and warehouse planning and in bungalow, terminal, platform, and frequency assignment. Finding optimum cliques of stable sets again can be used in frequency assignment, and in set packing problems, which show up for instance in crew scheduling.

While these problems are in general NP-complete, some are polynomial-time solvable for special classes of graphs: perfect graphs, t-perfect graphs, claw-free graphs. They form the body of this part.

Perfect graphs carry one of the deepest theorems in graph theory, the strong perfect graph theorem — recently proved by Chudnovsky, Robertson, Seymour, and Thomas. The proof is highly complicated, and we cannot give it in this book.

We refer to Part III for stable sets in and colouring of *line graphs* — equivalently, matchings and edge-colouring.

Chapters:

Chapter 64

Cliques, stable sets, and colouring

This chapter studies cliques, stable sets, and colouring for general graphs: complexity, polyhedra, fractional solutions, weighted versions.
In studying later chapters of this part, one can do largely without the results of the present chapter. Only some elementary definitions and terminology will be needed. It suffices to use this chapter just for reference.
In this chapter, all graphs can be assumed to be simple.

64.1. Terminology and notation

Let $G = (V, E)$ be an undirected graph. A *clique* is a set of vertices any two of which are adjacent. The maximum size of a clique in G is the *clique number* of G, and is denoted by $\omega(G)$.

A *stable set* is a set of vertices any two of which are nonadjacent. The maximum size of a stable set in G is called the *stable set number* of G, and is denoted by $\alpha(G)$.

A *vertex cover* is a set of vertices intersecting all edges. The minimum size of a vertex cover in G is called the *vertex cover number* of G, and is denoted by $\tau(G)$.

A *(vertex-)colouring* of G is a partition of V into stable sets $S_1, \ldots, S_k$. The sets $S_1, \ldots, S_k$ are called the *colours* of the colouring. The minimum number of colours in a vertex-colouring of G is called the *(vertex-)colouring number* of G, denoted by $\chi(G)$. A graph G is called k-*(vertex-)colourable* if $\chi(G) \leq k$, and k-*chromatic* if $\chi(G) = k$. A *minimum (vertex-)colouring* is a colouring with $\chi(G)$ colours. A k-*(vertex-)colouring* is a colouring with k colours.

A *clique cover* of G is a partition of V into cliques. The minimum number of cliques in a clique cover of G is called the *clique cover number* of G, and is denoted by $\overline{\chi}(G)$. A *minimum clique cover* is a clique cover with $\overline{\chi}(G)$ cliques.

The following relations between these parameters are immediate:

(64.1) $$\alpha(G) = \omega(\overline{G}),\ \overline{\chi}(G) = \chi(\overline{G}),\ \omega(G) \leq \chi(G),\ \alpha(G) \leq \overline{\chi}(G),$$
$$\tau(G) = |V| - \alpha(G).$$

64.2. NP-completeness

It is NP-complete to find a maximum-size stable set in a graph. To be more precise, the *stable set problem*: given a graph G and a natural number k, decide if $\alpha(G) \geq k$, is NP-complete (according to Karp [1972b] this is implicit in the work of Cook [1971] and was also known to R. Reiter):

Theorem 64.1. *Determining the stable set number is* NP*-complete.*

Proof. We reduce the satisfiability problem to the stable set problem. Let $C_1 \wedge \cdots \wedge C_k$ be a Boolean expression, where each C_i is of the form $y_1 \vee \cdots \vee y_m$, with $y_1, \ldots, y_m \in \{x_1, \neg x_1, \ldots, x_n, \neg x_n\}$. Call $x_1, \neg x_1, \ldots, x_n, \neg x_n$ the *literals*. Consider the graph $G = (V, E)$ with $V := \{(\sigma, i) \mid \sigma$ is a literal in $C_i\}$ and $E := \{\{(\sigma, i), (\tau, j)\} \mid i = j$ or $\sigma = \neg\tau\}$. Then the expression is satisfiable if and only if G has a stable set of size k. ∎

It can be shown that the stable set problem remains NP-complete if the graphs are restricted to 3-regular planar graphs (Garey, Johnson, and Stockmeyer [1976]) or to triangle-free graphs (Poljak [1974]).

Since a subset U of VG is a vertex cover if and only if $VG \setminus U$ is a stable set, we also have:

Corollary 64.1a. *Determining the vertex cover number is* NP*-complete.*

Proof. By Theorem 64.1, since the vertex cover number of a graph G is equal to $|VG|$ minus the stable set number. ∎

A subset C of VG is a clique in a graph G if and only if C is a stable set in the complementary graph $\overline{G}$. So finding a maximum-size clique in G is equivalent to finding a maximum-size stable set in $\overline{G}$, and $\omega(G) = \alpha(\overline{G})$. Hence, as determining $\alpha(G)$ is NP-complete, also determining $\omega(G)$ is NP-complete.

Also, it is NP-complete to decide if a graph is k-colourable (Karp [1972b]):

Theorem 64.2. *Determining the vertex-colouring number is* NP*-complete.*

Proof. We show that the stable set problem can be reduced to the vertex-colouring problem. Let $G = (V, E)$ be an undirected graph and let $k \in \mathbb{Z}_+$. We want to decide if $\alpha(G) \geq k$. To this end, let V' be a copy of V and let C be a set of size k, where V, V', and C are disjoint. Make a graph H with vertex set $V \cup V' \cup C$ as follows. A pair of vertices in V is adjacent in H if and only if it is adjacent in G. The sets V' and C are cliques in H. Each vertex in V is adjacent to each vertex in $V' \cup C$, except to its copy in V'. No vertex in V' is adjacent to any vertex in C.

This defines the graph H. Then $\alpha(G) \geq k$ if and only if $\chi(H) \leq |V| + 1$. ∎

Well-known is the *four-colour conjecture* (or *4CC*), stating that $\chi(G) \leq 4$ for each loopless planar graph G. This conjecture was proved by Appel and Haken [1977] and Appel, Haken, and Koch [1977], and is now called the *four-colour theorem*. (A shorter proof was given by Robertson, Sanders, Seymour, and Thomas [1997], leading to an $O(n^2)$-time 4-colouring algorithm for planar graphs (Robertson, Sanders, Seymour, and Thomas [1996]).)

However, it is NP-complete to decide if a planar graph is 3-colourable, even if the graph has maximum degree 4 (Garey, Johnson, and Stockmeyer [1976]). Moreover, determining the colouring number of a graph G with $\alpha(G) \leq 4$ is NP-complete (cf. Garey and Johnson [1979]). Holyer [1981] showed that deciding if a 3-regular graph is 3-edge-colourable is NP-complete (see Section 28.3). Note that one can decide in polynomial time if a graph G is 2-colourable, since bipartiteness can be checked in polynomial time.

These NP-completeness results imply that if NP$\neq$co-NP, then one may not expect a min-max relation characterizing the stable set number $\alpha(G)$, the vertex cover number $\tau(G)$, the clique number $\omega(G)$, or the colouring number $\chi(G)$ of a graph G.

64.3. Bounds on the colouring number

A lower bound on the colouring number is given by the clique number:

(64.2) $\qquad \omega(G) \leq \chi(G).$

This is easy, since in any clique all vertices should have different colours.

There are several graphs which have strict inequality in (64.2). We mention the odd circuits C_k, with k odd and ≥ 5: then $\omega(C_k) = 2$ and $\chi(C_k) = 3$. Moreover, for the complement $\overline{C}_k$ of any such graph we have: $\omega(\overline{C}_k) = \lfloor k/2 \rfloor$ and $\chi(\overline{C}_k) = \lceil k/2 \rceil$.

It was a conjecture of Berge [1963a] that these graphs are crucial. In May 2002, M. Chudnovsky, N. Robertson, P.D. Seymour, and R. Thomas announced that they have found a proof of this conjecture.

Strong perfect graph theorem: Each graph G with $\omega(G) < \chi(G)$ has C_k or $\overline{C}_k$ as induced subgraph for some odd $k \geq 5$.

It is convenient to define a *hole* of a graph G to be an induced subgraph of G isomorphic to C_k for some $k \geq 4$. Moreover, an *antihole* is an induced subgraph isomorphic to $\overline{C}_k$ for some $k \geq 4$. A hole or antihole is *odd* if it has an odd number of vertices. Then the strong perfect graph theorem can be formulated as: each graph G with $\omega(G) < \chi(G)$ has an odd hole or odd antihole.

For more on this we refer to Chapter 65.

64.3a. Brooks' upper bound on the colouring number

There is a trivial upper bound on the colouring number:

(64.3) $$\chi(G) \leq \Delta(G) + 1,$$

where $\Delta(G)$ denotes the maximum degree of G. This bound follows by colouring the vertices 'greedily' one by one: at any stage, at least one colour (out of $\Delta(G)+1$ colours) is not used by the neighbours.

Brooks [1941] sharpened this inequality as follows. We follow the proof given by Lovász [1975d].

Theorem 64.3 (Brooks' theorem). *For any connected graph G one has $\chi(G) \leq \Delta(G)$, except if G is a complete graph or an odd circuit.*

Proof. We can assume that G is 2-connected, since otherwise we can apply induction. Moreover, we can assume that $\Delta(G) \geq 3$. Let $k := \Delta(G)$.

I. First assume that G has nonadjacent vertices u and w with $G - u - w$ disconnected. Let V_1 and V_2 be proper subsets of V such that $V_1 \cup V_2 = V$, $V_1 \cap V_2 = \{u, w\}$, and no edge connects $V_1 \setminus \{u, w\}$ and $V_2 \setminus \{u, w\}$. Let $G_1 := G[V_1]$ and $G_2 := G[V_2]$.

For $i = 1, 2$, we know by induction that $\chi(G_i) \leq k$, since G_i is not complete (as u and w are nonadjacent), and since $\Delta(G_i) \leq k$ and $k \geq 3$. By symmetry of G_1 and G_2, we can assume that each k-colouring of G_1 gives u and w the same colour (otherwise G_1 and G_2 have k-colourings that coincide on u and w, yielding a k-colouring of G). This implies that both u and w have degree at least $k - 1$ in G_1. Hence they have degree at most 1 in G_2. Therefore, as $k \geq 3$, G_2 has a k-colouring giving u and w the same colour. So G is k-colourable.

II. Now choose a vertex v of maximum degree. As G is not a complete graph, v has two nonadjacent neighbours, say u and w. By part I, we can assume that $G - u - w$ is connected. Hence it has a spanning tree T. Orient T so as to obtain a rooted tree, rooted at v. Hence we can order the vertices of G as $v_1, \ldots, v_n$ such that $v_1 = v$, $v_{n-1} = u$, $v_n = w$, and such that each v_i with $i > 1$ is adjacent to some v_j with $j < i$. Give u and w colour 1. Next successively for $i = n-2, n-1, \ldots, 1$, we can give a colour from $1, \ldots, k$ to v_i different from the colours given to the neighbours v_j of v_i with $j > i$. Such a colour exists, since if $i > 1$, there are less than k neighbours v_j of v_i with $j > i$; and if $i = 1$, there are k such neighbours, but neighbours u and w have the same colour. ∎

(A related proof was given by Ponstein [1969], and a strengthening of Brooks' theorem by Reed [1999a]. For another proof of Brooks' theorem, see Melnikov and Vizing [1969].)

64.3b. Hadwiger's conjecture

Another upper bound on the colouring number is conjectured by Hadwiger [1943]. Since there exist graphs with $\omega(G) < \chi(G)$, it is not true that if $\chi(G) \geq k$, then G contains the complete graph K_k on k vertices as a subgraph. However, Hadwiger conjectured the following, where a graph H is called a *minor* of a graph G if H arises from some subgraph of G by contracting some (possibly none) edges.

Hadwiger's conjecture: If $\chi(G) \geq k$, then G contains K_k as a minor.

In other words, for each k, the graph K_k is the only graph G with the property that G is not $(k-1)$-colourable and each proper minor of G is $(k-1)$-colourable.

Hadwiger's conjecture is trivial for $k = 1, 2, 3$, and was shown by Hadwiger [1943] for $k = 4$ (also by Dirac [1952]):

Theorem 64.4. *If G has no K_4 minor, then $\chi(G) \leq 3$.*

Proof. One may assume that $G = (V, E)$ is not a forest or a circuit. Then G has a circuit C not covering all vertices of G. Choose $v \in V \setminus VC$. If G is 3-connected, there are three paths from v to VC, disjoint except for v. This creates a K_4 minor, a contradiction.

So G is not 3-connected, that is, G has a vertex-cut of size less than 3. Then $\chi(G) \leq 3$ follows by induction: if G is disconnected or has a 1-vertex-cut, this is trivial, and if G is 2-connected and has a 2-vertex-cut $\{u, w\}$, we can apply induction to the graphs $G - K$ after adding an edge uw, for each component K of $G - u - w$. ∎

(For another proof, see Woodall [1992].)

As planar graphs contain no K_5 minor, Hadwiger's conjecture for $k = 5$ implies the four-colour theorem. In fact, Wagner [1937a] showed that his decomposition theorem (Theorem 3.3) implies that Hadwiger's conjecture for $k = 5$ is equivalent to the four-colour conjecture. (Young [1971] gave a 'quick' proof of this equivalence.) The four-colour conjecture was proved by Appel and Haken [1977] and Appel, Haken, and Koch [1977]. (Robertson, Sanders, Seymour, and Thomas [1997] gave a shorter proof.)

Robertson, Seymour, and Thomas [1993] showed that Hadwiger's conjecture is true also for $k = 6$, by reducing it again to the four-colour theorem. For $k \geq 7$, Hadwiger's conjecture is unsettled.

Halin [1964] has proved that if G has no K_k minor, then $\chi(G) \leq 2^{k-2}$ (Wagner [1964] gave a short proof). Further progress on Hadwiger's conjecture was made by Wagner [1960], Mader [1968], Jakobsen [1971], Duchet and Meyniel [1982], Kostochka [1982], Fernandez de la Vega [1983], Thomason [1984], and Reed and Seymour [1998].

Hajós' conjecture. G. Hajós[1] conjectured (more strongly than Hadwiger) that any k-chromatic graph contains a subdivision of K_k as subgraph. For $k \leq 4$, Hajós' conjecture is equivalent to Hadwiger's conjecture.

Hajós' conjecture was refuted by Catlin [1979] for $k = 8$. He showed that the line graph $L(G)$ of the graph G obtained from the 5-circuit C_5 by replacing each

[1] According to Toft [1996], Hajós considered the conjecture already in the 1940s in connection with the four-colour conjecture, but he never published it. (The paper Hajós [1961] commonly referred to, does not give Hajós' conjecture.) An early written record of the conjecture is in the review of Tutte [1961b], in the January 1961 issue of *Mathematical Reviews*, of the book *Färbungsprobleme auf Flächen und Graphen* (Colouring Problems on Surfaces and Graphs) by Ringel [1959]. This book itself however does not mention the conjecture.

edge by three parallel edges, has colouring number 8 (as $L(G)$ has 15 vertices and stable set number 2), but contains no subdivision of K_8.

Catlin in fact gave a counterexample to Hajós' conjecture for each $k \geq 7$. Erdős and Fajtlowicz [1981] showed that almost all graphs are counterexamples to Hajós' conjecture.

Related is the following result of Hajós [1961]: any graph G with $\chi(G) \geq k$ can be obtained from the complete graph K_k by a series of the following operations on graphs (each preserving $\chi \geq k$):

(64.4)
- (i) add vertices or edges;
- (ii) identify two nonadjacent vertices;
- (iii) take two disjoint graphs G_1 and G_2, choose edges $e_1 = u_1v_1$ of G_1 and $e_2 = u_2v_2$ of G_2, identify u_1 and u_2, delete e_1 and e_2, and add edge v_1v_2.

64.4. The stable set, clique, and vertex cover polytope

The *stable set polytope* $P_{\text{stable set}}(G)$ of a graph $G = (V, E)$ is the convex hull of the incidence vectors of the stable sets in G. Since finding a maximum-size stable set is NP-complete, one may not expect a polynomial-time checkable system of linear inequalities describing the stable set polytope (Corollary 5.16a). More precisely, if NP≠co-NP, then there do not exist inequalities satisfied by the stable set polytope such that their validity can be certified in polynomial time and such that the inequality $\mathbf{1}^{\mathsf{T}}x \leq \alpha(G)$ is a nonnegative linear combination of them.

The *clique polytope* $P_{\text{clique}}(G)$ of a graph $G = (V, E)$ is the convex hull of the incidence vectors of cliques. Trivially

(64.5) $$P_{\text{clique}}(G) = P_{\text{stable set}}(\overline{G}).$$

Hence, similar observations hold for the clique polytope.

Another related polytope is the *vertex cover polytope* $P_{\text{vertex cover}}(G)$ of G, being the convex hull of the incidence vectors of vertex covers in G. Since a subset U of V is a vertex cover if and only if $V \setminus U$ is a stable set, we have

(64.6) $$x \in P_{\text{vertex cover}}(G) \iff \mathbf{1} - x \in P_{\text{stable set}}(G).$$

This shows that problems on the two types of polytopes can be reduced to each other.

64.4a. Facets and adjacency on the stable set polytope

Padberg [1973] (for facets induced by odd circuits) and Nemhauser and Trotter [1974] observed that

(64.7) each facet of the stable set polytope of an induced subgraph $G[U]$ of G, is the restriction to U of some unique facet of $P_{\text{stable set}}(G)$.

More precisely, for each facet F of $P_{\text{stable set}}(G[U])$ there is a unique facet F' of $P_{\text{stable set}}(G)$ with the property that $F = \{x \in \mathbb{R}^U \mid x' \in F'\}$, where $x'_v = x_v$ if $v \in U$ and $x'_v = 0$ if $v \in V \setminus U$.

To prove (64.7), it suffices to prove it for $U = V \setminus \{v\}$ for some $v \in V$. Let F be a facet of $P_{\text{stable set}}(G - v)$. We can consider F as a face of codimension 2 of $P_{\text{stable set}}(G)$ (by extending F with a 0 at coordinate v). Define $H := \{x \in \mathbb{R}^V \mid x_v = 0\}$. As F is on the facet $F'' := P_{\text{stable set}}(G) \cap H$ of $P_{\text{stable set}}(G)$, there is a unique facet F' of $P_{\text{stable set}}(G)$ with $F = F'' \cap F'$. This implies $F = F' \cap H$, since

(64.8) $$F = F' \cap F'' = F' \cap P_{\text{stable set}}(G) \cap H = F' \cap H.$$

Suppose now that $P_{\text{stable set}}(G)$ has another facet F''' with $F = F''' \cap H$. Then $F \subseteq F''' \cap F'' \subseteq F''' \cap H = F$, and hence $F = F'' \cap F'''$, contradicting the unicity of F'. This proves (64.7).

Padberg [1973] also showed the following:

Theorem 64.5. *Let $G = (V, E)$ be a graph and let $a \in \mathbb{Z}_+^V$. Then the inequality*

(64.9) $$a^{\mathsf{T}} x \leq 1$$

is valid for the stable set polytope of G if and only if a is the incidence vector of a clique C. Moreover, (64.9) *determines a facet if and only if C is an inclusionwise maximal clique.*

Proof. Trivially, inequality (64.9) is valid if $a = \chi^C$ for some clique C. Conversely, if (64.9) is valid, then a is a $0, 1$ vector, and hence the incidence vector of a subset C of V. Then C is a clique, since otherwise C contains a stable set S of size 2, implying that (64.9) is not valid for $x := \chi^S$.

In proving the second statement, we can assume that $a = \chi^C$ for some clique C. Suppose that (64.9) determines a facet, and that C is not an inclusionwise maximal clique. Then there is a clique C' properly containing C. Hence for each $x \in P_{\text{stable set}}(G)$, if $x(C) = 1$, then $x(C') = 1$. This implies that the inequality $x(C) \leq 1$ is not facet-inducing, a contradiction.

Finally suppose that C is an inclusionwise maximal clique. To see that (64.9) determines a facet, let $a^{\mathsf{T}} x = \beta$ be satisfied by all x in the stable set polytope with $x(C) = 1$. So $a(S) = \beta$ for each stable set S with $|S \cap C| = 1$. Then $a_v = \beta$ for each $v \in C$, as $S := \{v\}$ is stable. Also, $a_u = 0$ for each $u \in V \setminus C$, since by the maximality of C, there is a vertex $v \in C$ that is not adjacent to u. So $S := \{u, v\}$ is stable, and hence $a_u + a_v = \beta$. So $a_u = 0$. Concluding, $a^{\mathsf{T}} x = \beta$ is some multiple of $x(C) = 1$, and hence $x(C) \leq 1$ determines a facet. ∎

Graphs for which the nonnegativity and clique inequalities determine all facets, are precisely the *perfect* graphs — see Chapter 65.

Trivially, the vertices of the stable set polytope are precisely the incidence vectors of the stable sets. Chvátal [1975a] characterized adjacency:

Theorem 64.6. *The incidence vectors of two different stable sets R, S are adjacent vertices of the stable set polytope if and only if $R \triangle S$ induces a connected subgraph of G.*

Proof. To see necessity, if $G[R \triangle S]$ is not connected, then (as it is bipartite) it has two colour classes U and W with $\{U, W\} \neq \{R \setminus S, S \setminus R\}$. Let $U' := U \cup (R \cap S)$ and

$W' := W \cup (R \cap S)$. Then U' and W' are stable sets and $\frac{1}{2}(\chi^R + \chi^S) = \frac{1}{2}(\chi^{U'} + \chi^{W'})$, contradicting the adjacency of χ^R and χ^S.

To see sufficiency, if χ^R and χ^S are not adjacent, then there exist stable sets U and W, and $\lambda, \mu \in (0,1)$ such that $\lambda\chi^R + (1-\lambda)\chi^S = \mu\chi^U + (1-\mu)\chi^W$ and $\{U, W\} \neq \{R, S\}$. So $U \cap W = R \cap S$. Hence $U \setminus W, W \setminus U$ forms a bipartition of $G[R \triangle S]$ different from the bipartition $R \setminus S, S \setminus R$. This contradicts the connectedness of $G[R \triangle S]$. ∎

64.5. Fractional stable sets

The incidence vectors of stable sets in an undirected graph $G = (V, E)$ are precisely the integer vectors $x \in \mathbb{R}^V$ satisfying

(64.10)
$$\begin{array}{lll} \text{(i)} & 0 \leq x_v \leq 1 & \text{for } v \in V, \\ \text{(ii)} & x_u + x_v \leq 1 & \text{for } \{u, v\} \in E. \end{array}$$

(The inequalities (64.10)(ii) are called the *edge inequalities*.) Any (not necessarily integer) solution x of (64.10) is called a *fractional stable set*. By definition, its *size* is equal to $x(V)$.

The maximum size of a fractional stable set is called the *fractional stable set number* and is denoted by $\alpha^*(G)$. By linear programming duality, $\alpha^*(G)$ is equal to the *fractional edge cover number* $\rho^*(G)$ (assuming that G has no isolated vertices), which is the minimum value of $y(E)$ over all $y \in \mathbb{R}^E$ satisfying

(64.11)
$$\begin{array}{lll} \text{(i)} & 0 \leq y_e \leq 1 & \text{for } e \in E, \\ \text{(ii)} & y(\delta(v)) \geq 1 & \text{for } v \in V. \end{array}$$

Any solution y of (64.11) is called a *fractional edge cover*.

This was also discussed in Section 30.11, where it was shown that each vertex of the polytope determined by (64.11) (the fractional edge cover polytope) is half-integer. A similar result holds for the *fractional stable set polytope*, which is the polytope determined by (64.10) (the result is implicit in Balinski [1965]):

Theorem 64.7. *Each vertex of the fractional stable set polytope P is half-integer.*

Proof. Let x be a vertex of P. Let $U := \{v \in V \mid 0 < x_v < \frac{1}{2}\}$ and let $W := \{v \in V \mid \frac{1}{2} < x_v < 1\}$. Then there is an $\varepsilon > 0$ such that both $x + \varepsilon(\chi^U - \chi^W)$ and $x - \varepsilon(\chi^U - \chi^W)$ belong to P. As x is a vertex, it follows that $\chi^U - \chi^W = 0$. So $U = W = \emptyset$. ∎

(This proof was provided to Nemhauser and Trotter [1974] by a referee of their paper.)

The theorem also follows from the observation of Balinski [1965] that each nonsingular submatrix of the incidence matrix of a graph has a half-integer inverse.

Theorem 64.7 implies that $\alpha^*(G) = \frac{1}{2}\alpha_2(G)$, where $\alpha_2(G)$ is the maximum size of a 2-*stable set*, which is an integer vector $x \in \mathbb{R}^V$ satisfying

(64.12) (i) $x_v \geq 0$ for $v \in V$,
(ii) $x_u + x_v \leq 2$ for $\{u, v\} \in E$

(cf. Section 30.9).

Moreover, it implies a characterization of the 2-*stable set polyhedron*, which is the convex hull of the 2-stable sets:

Corollary 64.7a. *The* 2*-stable set polyhedron is determined by* (64.12).

Proof. Directly from Theorem 64.7. ∎

With the following construction, the problem of finding a maximum-weight fractional stable set (and similarly, a maximum-weight 2-stable set), can be reduced to the problem of finding a maximum-weight stable set in a bipartite graph. The latter problem is strongly polynomial-time solvable, by Theorem 21.10.

Let $G = (V, E)$ be a graph. Let V' be a copy of V. For any $v \in V$, let v' denote the copy of V in V'. Define $\widetilde{V} := V \cup V'$. Let $\widetilde{E}$ be the set of pairs $u'v$ and uv', over all edges uv of G. Then $\widetilde{G} := (\widetilde{V}, \widetilde{E})$ is a bipartite graph.

For any weight function $w : V \to \mathbb{R}_+$, define $\tilde{w} : \widetilde{V} \to \mathbb{R}_+$ by $\tilde{w}(v) := \tilde{w}(v') := w(v)$ for $v \in V$. Then any stable set S in $\widetilde{G}$ maximizing $\tilde{w}(S)$ gives a 2-stable set x in G maximizing $w^\mathsf{T} x$, by defining $x_v := |S \cap \{v, v'\}|$. Indeed, for any 2-stable set x' in G we can define a stable set S' in $\widetilde{G}$ by

(64.13) $$S' := \{v \in V \mid x'_v \geq 1\} \cup \{v \in V' \mid x'_v \geq 2\}.$$

Then $w^\mathsf{T} x' = \tilde{w}(S') \leq \tilde{w}(S) = w^\mathsf{T} x$. (Here we assume without loss of generality that G has no isolated vertices.)

64.5a. Further on the fractional stable set polytope

Nemhauser and Trotter [1974] characterized the vertices of the fractional stable set polytope:

Theorem 64.8. *A vector $x \in \mathbb{R}^V$ is a vertex of the fractional stable set polytope P of G if and only if $x = \chi^{U_2} + \frac{1}{2}\chi^{U_1}$, where U_2 is a stable set of G, where U_1 is disjoint from $U_2 \cup N(U_2)$, and where each component of $G[U_1]$ is nonbipartite.*

Proof. *Necessity.* Let x be a vertex of P, and define $U_2 := \{v \in V \mid x_v = 1\}$ and $U_1 := \{v \in V \mid x_v = \frac{1}{2}\}$. Then U_2 is a stable set and no vertex in U_1 is adjacent to any vertex in U_2. So U_1 is disjoint from $U_2 \cup N(U_2)$.

If some component of $G[U_1]$ would be bipartite, say with colour classes S and T, then $x \pm \varepsilon(\chi^S - \chi^T)$ would belong to P for some $\varepsilon \neq 0$. This contradicts the fact that x is a vertex of P.

Sufficiency. Suppose that x satisfies the condition, and that x is not a vertex of P. Then there is a nonzero vector y such that both $x + y$ and $x - y$ belong to P. Necessarily, $y_v = 0$ if $v \notin U_1$. Moreover, for each edge uw of $G[U_1]$ one has $y_u + y_w = 0$, since $x_u + x_w = 1$. As each component of $G[U_1]$ contains an odd circuit, this implies $y_v = 0$ for each $v \in U_1$. So $y = \mathbf{0}$, a contradiction. ∎

A useful condition was given by Nemhauser and Trotter [1975]:

Theorem 64.9. *Let $G = (V, E)$ be a graph, let $w : V \to \mathbb{R}$ be a weight function, and let $S \subseteq V$ be a stable set. If S is a maximum-weight stable set in the subgraph of G induced by $S \cup N(S)$, then S is contained in some maximum-weight stable set of G.*

Proof. Let T be a maximum-weight stable set of G. Define $U := (S \cup T) \setminus N(S)$. Trivially, U is stable. Also, $w(N(S) \cap T) \leq w(S \setminus T)$, since $w((S \cup N(S)) \cap T) \leq w(S)$, as S has maximum weight in $G[S \cup N(S)]$. Hence

(64.14) $$w(U) = w(T) + w(S \setminus T) - w(N(S) \cap T) \geq w(T),$$

implying that U is a maximum-weight stable set in G. ∎

This implies (Nemhauser and Trotter [1975]):

Corollary 64.9a. *Let $G = (V, E)$ be a graph, let $w : V \to \mathbb{R}$ be a weight function, and let x be a maximum-weight fractional stable set. Then $S := \{v \mid x_v = 1\}$ is contained in a maximum-weight stable set.*

Proof. This follows from Theorem 64.9, since S is a maximum-weight stable set in $G[S \cup N(S)]$. For if T would be a stable set in $G[S \cup N(S)]$ with $w(T) > w(S)$, then $x + \varepsilon(\chi^T - \chi^S)$ would belong to the fractional stable set polytope for some $\varepsilon > 0$, while it has weight larger than x, a contradiction. ∎

Picard and Queyranne [1977] showed that, for any graph $G = (V, E)$ and any weight function $w : V \to \mathbb{R}$, there is a unique minimal subset of vertices that has fractional values in some optimum fractional stable set (solving a problem posed by Nemhauser and Trotter [1975]):

Theorem 64.10. *Let $G = (V, E)$ be a graph, let $w : V \to \mathbb{R}$ be a weight function, and let x and y be maximum-weight fractional stable sets. Then there is a maximum-weight fractional stable set z such that, for each vertex v, z_v is integer if x_v or y_v integer.*

Proof. We can assume that x and y are half-integer (as we can assume that x and y are vertices of the fractional stable set polytope). For $i = 0, 1, 2$, let $X_i := \{v \mid x_v = i/2\}$ and $Y_i := \{v \mid y_v = i/2\}$. Then

(64.15) $$w(Y_0 \cap X_2) \leq w(X_0 \cap Y_2),$$

since

$$(64.16) \qquad y + \tfrac{1}{2}(\chi^{Y_0 \cap X_2} - \chi^{X_0 \cap Y_2})$$

is a fractional stable set. Otherwise, since X_2 is stable, there is an edge uv with $y_u + y_v = 1$, $u \in Y_0 \cap X_2$, and $v \notin X_0 \cap Y_2$. So $y_u = 0$, and hence $y_v = 1$. Also, $x_u = 1$, and hence $x_v = 0$. So $v \in X_0 \cap Y_2$, a contradiction. This shows (64.15).

Moreover,

$$(64.17) \qquad w(X_0 \setminus Y_0) \leq w(X_2 \setminus Y_2),$$

since

$$(64.18) \qquad x + \tfrac{1}{2}(\chi^{X_0 \setminus Y_0} - \chi^{X_2 \setminus Y_2})$$

is a fractional stable set. Otherwise there is an edge uv with $x_u + x_v = 1$, $u \in X_0 \setminus Y_0$, and $v \notin X_2 \setminus Y_2$. So $x_u = 0$, and hence $x_v = 1$. Also, $y_u > 0$, and hence $y_v < 1$. So $v \in X_2 \setminus Y_2$, a contradiction. This shows (64.17).

(64.15) and (64.17) imply that

$$(64.19) \qquad \begin{aligned} w(Y_1 \cap X_2) &= w(X_2 \setminus Y_2) - w(X_2 \cap Y_0) \geq w(X_0 \setminus Y_0) - w(Y_2 \cap X_0) \\ &= w(Y_1 \cap X_0). \end{aligned}$$

Hence

$$(64.20) \qquad z := y + \tfrac{1}{2}(\chi^{Y_1 \cap X_2} - \chi^{Y_1 \cap X_0})$$

has weight at least that of y. Moreover, z is a fractional stable set. Otherwise, as X_2 is stable, there is an edge uv with $y_u + y_v = 1$, $u \in Y_1 \cap X_2$ and $v \notin Y_1 \cap X_0$. So $y_u = y_v = \frac{1}{2}$, $x_u = 1$, hence $x_v = 0$. So $v \in Y_1 \cap X_0$, a contradiction. Hence z is a fractional stable set as required. ∎

Nemhauser and Trotter [1975] and Picard and Queyranne [1977] gave a polynomial-time algorithms to find a half-integer maximum-weight fractional stable set attaining the minimum number of fractional values. (This can be derived from the uniqueness of the minimal set of fractional vertices: just try $x_v = 0$ and $x_v = 1$ for each $v \in V$, and see if the fractional stable set number drops.)

Pulleyblank [1979a] and Bourjolly and Pulleyblank [1989] characterized the minimal set of fractional values. Related results were given by Grimmett [1986].

64.6. Fractional vertex covers

Similar results hold for *fractional vertex covers*, which are vectors $x \in \mathbb{R}^V$ satisfying

$$(64.21) \qquad \begin{array}{lll} \text{(i)} & 0 \leq x_v \leq 1 & \text{for } v \in V, \\ \text{(ii)} & x_u + x_v \geq 1 & \text{for } \{u, v\} \in E. \end{array}$$

Trivially, a vector x is a fractional vertex cover if and only if $\mathbf{1} - x$ is a fractional stable set.

The minimum size of a fractional vertex cover is called the *fractional vertex cover number*, and is denoted by $\tau^*(G)$. So

(64.22) $\tau^*(G) + \alpha^*(G) = |V|$.

Again, by linear programming duality, $\tau^*(G)$ is equal to the *fractional matching number* $\nu^*(G)$, which is the maximum value of $y(E)$ over all $y \in \mathbb{R}^E$ satisfying

(64.23)
$$\begin{array}{lll} \text{(i)} & 0 \leq y_e \leq 1 & \text{for } e \in E, \\ \text{(ii)} & y(\delta(v)) \leq 1 & \text{for } v \in V. \end{array}$$

Any solution y of (64.23) is called a *fractional matching*. This was also discussed in Section 30.3, where it was shown that each vertex of the polytope determined by (64.23) (the fractional matching polytope) is half-integer. A similar result holds for the *fractional vertex cover polytope*, which is the polytope determined by (64.21):

Theorem 64.11. *Each vertex of the fractional vertex cover polytope P is half-integer.*

Proof. Directly from Theorem 64.7, since x belongs to the fractional vertex cover polytope if and only if $\mathbf{1}-x$ belongs to the fractional stable set polytope. ∎

Theorem 64.11 implies that $\tau^*(G) = \frac{1}{2}\tau_2(G)$, where $\tau_2(G)$ is the minimum size of a 2-*vertex cover*, which is an integer vector $x \in \mathbb{R}^V$ satisfying

(64.24)
$$\begin{array}{lll} \text{(i)} & x_v \geq 0 & \text{for } v \in V, \\ \text{(ii)} & x_u + x_v \geq 2 & \text{for } \{u,v\} \in E \end{array}$$

(cf. Section 30.10).

It also implies a characterization of the 2-*vertex cover polyhedron*, which is the convex hull of the 2-vertex covers:

Corollary 64.11a. *The 2-vertex cover polyhedron is determined by* (64.24).

Proof. Directly from Theorem 64.11. ∎

By the results on fractional stable sets and 2-stable sets given in Section 64.5, and using the reductions described above, a minimum-weight fractional vertex cover and a minimum-weight 2-vertex cover can be found in strongly polynomial time.

Notes. Corollary 64.9a and Theorem 64.10 have direct analogues for vertex covers: given a graph $G = (V, E)$ and a weight function $w : V \to \mathbb{R}$,

(64.25) for each minimum-weight fractional vertex cover x there is a minimum-weight vertex cover contained in $\{v \mid x_v \neq 0\}$,

and

(64.26) for any two minimum-weight fractional vertex covers x and y there is a minimum-weight fractional vertex cover z such that for each $v \in V$: $x_v \in \mathbb{Z}$ or $y_v \in \mathbb{Z} \Rightarrow z_v \in \mathbb{Z}$.

These statements can be derived from Corollary 64.9a and Theorem 64.10 by again observing that a vector x is a (fractional) stable set if and only if $\mathbf{1} - x$ is a (fractional) vertex cover. Similarly, Theorem 64.8 implies a characterization of the vertices of the fractional vertex cover polytope.

64.6a. A bound of Lorentzen

The fractional stable set and vertex cover numbers give upper and lower bounds on the stable set and vertex cover number, respectively. These bounds are computable in polynomial time. A better polynomial-time computable bound was given by Lorentzen [1966]:

Theorem 64.12. *For each graph $G = (V, E)$:*

(64.27) $$2\nu^*(G) - \nu(G) \leq \tau(G).$$

Proof. Since $\nu^*(G) = 2\nu_2(G)$ (cf. Section 30.2), there is a half-integer fractional matching $x : E \to \mathbb{R}_+$ with $x(E) = \nu^*(G)$, such that the support of x is the disjoint union of a matching and a number t of odd circuits. We can assume that each edge of G belongs to the support of x (as deleting edges increases neither $\nu(G)$ nor $\tau(G)$). Also we can assume that G has no isolated vertices. Then $\nu(G) = \frac{1}{2}(|V| - t)$, $\tau(G) = \frac{1}{2}(|V| + t)$, and $\nu^*(G) = \frac{1}{2}|V|$. ∎

Bound (64.27) is generally a better lower bound on $\tau(G)$ than $\tau^*(G)$ (for example, for $G = K_3$). It implies an upper bound for $\alpha(G)$, generally better than $\alpha(G) \leq \rho^*(G)$:

Corollary 64.12a. *For each graph $G = (V, E)$ without isolated vertices:*

(64.28) $$\alpha(G) \leq 2\rho^*(G) - \rho(G).$$

Proof. Using Theorem 30.9, we have $\alpha(G) = |V| - \tau(G) \leq |V| - 2\nu^*(G) + \nu(G) = 2(|V| - \nu^*(G)) - (|V| - \nu(G)) = 2\rho^*(G) - \rho(G)$. ∎

64.7. The clique inequalities

A set of constraints stronger than the edge inequalities (64.10)(ii) is obtained by the 'clique inequalities'. Let $P(G)$ be the polytope in $\mathbb{R}^V$ determined by

(64.29) $$\begin{array}{lll} \text{(i)} & x_v \geq 0 & \text{for each } v \in V, \\ \text{(ii)} & x(C) \leq 1 & \text{for each clique } C. \end{array}$$

The inequalities (64.29)(ii) are called the *clique inequalities.*

Since the integer solutions of (64.29) are exactly the incidence vectors of stable sets, the stable set polytope of G is equal to the integer hull of $P(G)$ (the convex hull of the integer vectors in $P(G)$).

We call any vector x satisfying (64.29) a *strong fractional stable set*. We denote

(64.30) $\alpha^{**}(G)$:= *strong fractional stable set number* := the maximum size of a strong fractional stable set.

Since each strong fractional stable set is a fractional stable set, we know

(64.31) $\alpha(G) \leq \alpha^{**}(G) \leq \alpha^*(G)$.

So $\alpha^{**}(G)$ gives a better upper bound on $\alpha(G)$ than $\alpha^*(G)$ gives — however, $\alpha^{**}(G)$ is generally more difficult to compute.

Note that $P(G)$ is the antiblocking polyhedron of the clique polytope of G:

(64.32) $P(G) = A(P_{\text{clique}}(G))$.

(For background on antiblocking polyhedra, see Section 5.9.)

64.8. Fractional and weighted colouring numbers

For any graph $G = (V, E)$, the *fractional colouring number* $\chi^*(G)$ is the minimum value of $\lambda_1 + \cdots + \lambda_k$ with $\lambda_1, \ldots, \lambda_k \in \mathbb{R}_+$ such that there exist stable sets $S_1, \ldots, S_k$ with

(64.33) $\lambda_1 \chi^{S_1} + \cdots + \lambda_k \chi^{S_k} = \mathbf{1}$.

So if the λ_i are required to be integer, we have the colouring number.

By linear programming duality, the fractional colouring number is equal to the maximum of $\mathbf{1}^{\mathsf{T}} x$ over the polytope $\overline{P}(G)$ in $\mathbb{R}^V_+$ determined by

(64.34)
$$\begin{array}{ll} x_v \geq 0 & \text{for each } v \in V, \\ x(S) \leq 1 & \text{for each stable set } S. \end{array}$$

(So $\overline{P}(G) = P(\overline{G})$ and $\overline{P}(G) = A(P_{\text{stable set}}(G))$.) Hence we have:

(64.35) $\chi^*(\overline{G}) = \alpha^{**}(G)$.

We denote

(64.36) $\overline{\chi}^*(G) := \chi^*(\overline{G})$,

which is called the *fractional clique cover number* of G.

No polynomial-time algorithm is known to calculate $\chi^*(G)$. Note that the separation problem for $\overline{P}(G)$ is NP-complete, since the optimization problem over $P_{\text{stable set}}(G)$ is NP-complete.

Given a graph $G = (V, E)$ and a weight function $w : V \to \mathbb{Z}_+$, the *weighted colouring number* $\chi_w(G)$ is the minimum value of $\lambda_1 + \cdots + \lambda_k$ with $\lambda_1, \ldots, \lambda_k \in \mathbb{Z}_+$ such that there exist stable sets $S_1, \ldots, S_k$ with

(64.37) $\lambda_1 \chi^{S_1} + \cdots + \lambda_k \chi^{S_k} = w$.

So if $w = \mathbf{1}$, then $\chi_w(G)$ is equal to the colouring number $\chi(G)$ of G. Hence determining $\chi_w(G)$ is NP-complete.

For $w : V \to \mathbb{Z}_+$, let graph G^w arise from G by replacing each vertex by a clique C_v of size $w(v)$, two vertices in different cliques C_u,C_v being adjacent if and only if u and v are adjacent. Then

(64.38) $\qquad \chi_w(G) = \chi(G^w).$

We denote

(64.39) $\qquad \overline{\chi}_w(G) := \chi_w(\overline{G}),$

called the *weighted clique cover number* of G.

The fractional version is the *fractional weighted colouring number* $\chi_w^*(G)$, defined as the minimum value of $\lambda_1 + \cdots + \lambda_k$ with $\lambda_1, \ldots, \lambda_k \in \mathbb{R}_+$ such that there exist stable sets $S_1, \ldots, S_k$ with

(64.40) $\qquad \lambda_1\chi^{S_1} + \cdots + \lambda_k\chi^{S_k} = w.$

This value is equal to the maximum value of $w^{\mathsf{T}}x$ over the antiblocking polytope $A(P_{\text{stable set}}(G))$ pf $P_{\text{stable set}}(G)$. Since the optimization problem over $P_{\text{stable set}}(G)$ is NP-complete, determining $\chi_w^*(G)$ is NP-hard.

We denote

(64.41) $\qquad \overline{\chi}_w^*(G) := \chi_w^*(\overline{G}),$

called the *fractional weighted clique cover number* of G.

The complexity results above can be specialized to classes of graphs. By the results of Grötschel, Lovász, and Schrijver [1981,1984c]:

(64.42) For any collection $\mathcal{G}$ of graphs: there is a polynomial-time algorithm to find the fractional weighted colouring number for any graph in $\mathcal{G}$ and any weight function if and only there is a polynomial-time algorithm to find a maximum-weight stable set in any graph in $\mathcal{G}$ and for any weight function.

Since the problem of determining $\alpha(G)$ is NP-complete even if we restrict ourselves to planar cubic graphs, determining $\chi_w^*(G)$ for such graphs is NP-hard. As noticed in Grötschel, Lovász, and Schrijver [1981], determining $\chi_w^*(G)$ and $\chi(G)$ seem incomparable with respect to complexity. For cubic graphs G, $\chi(G)$ can be easily found in polynomial time (using Brooks' theorem (Theorem 64.3)), while determining $\chi_w^*(G)$ is NP-hard. In contrast to this, for the line graph G of a cubic graph H, $\chi(G)$ is NP-complete to compute by Holyer's theorem that 3-edge colourability is NP-complete (see Section 28.3), whereas $\chi_w^*(G)$ can be computed in polynomial time, since the separation problem over $A(P_{\text{stable set}}(G))$ is polynomial-time solvable, as the optimization problem over $P_{\text{stable set}}(G)$ is polynomial-time solvable (as it amounts to finding a maximum-weight matching in H).

64.8a. The ratio of $\chi(G)$ and $\chi^*(G)$

For later purposes we prove the following upper bound for the colouring number in terms of the fractional colouring number, obtained by applying a greedy-type algorithm (Johnson [1974a], Lovász [1975c]):

Theorem 64.13. *For any graph $G = (V, E)$:*

(64.43) $$\chi(G) \leq (1 + \ln \alpha(G))\chi^*(G).$$

Proof. Set $k := \alpha(G)$. Iteratively choose a maximum-size stable set S in G and reset G to $G - S$. We stop if VG is empty.

The stable sets found form a colouring $\mathcal{C}$ of the (original) vertex set V. So $\chi(G) \leq |\mathcal{C}|$.

For each $v \in V$, define

(64.44) $$x_v := \frac{1}{|S|},$$

where S is the set in $\mathcal{C}$ containing v. Then $x(V) = |\mathcal{C}|$, and hence

(64.45) $$\chi(G) \leq x(V).$$

Consider any stable set S' of G. Let S' consist of vertices $v_1, \ldots, v_k$, in the order by which they are covered by stable sets S in the algorithm. Then for each $i = 1, \ldots, k$, we have

(64.46) $$x_{v_i} \leq \frac{1}{k - i + 1}.$$

Indeed, let v_i be covered by $S \in \mathcal{C}$. When we selected S, the vertices $v_i, v_{i+1}, \ldots, v_k$ were uncovered yet. As we chose S, we know $|S| \geq |\{v_i, v_{i+1}, \ldots, v_k\}| = k - i + 1$, implying (64.46).

(64.46) implies

(64.47) $$x(S') \leq \sum_{i=1}^{k} \frac{1}{k - i + 1} = \sum_{i=1}^{k} \frac{1}{i} \leq 1 + \ln k \leq 1 + \ln \alpha(G).$$

So $(1 + \ln \alpha(G))^{-1} \cdot x$ satisfies (64.34), and hence

(64.48) $$(1 + \ln \alpha(G))^{-1} \cdot x(V) \leq \chi^*(G).$$

Together with (64.45), this implies (64.43). ∎

This theorem will be used in proving Theorem 67.17.

64.8b. The Chvátal rank

In Section 36.7a we defined the polyhedron P' for any rational polyhedron P and the notion of the Chvátal rank of a polyhedron P.

Let $P(G)$ denote the polytope of strong fractional stable sets, that is, the polytope determined by (64.29) (the nonnegativity and clique constraints). For any polyhedron P, let P_{I} denote the *integer hull* of P, that is, the convex hull of the integer vectors in P.

Chvátal [1973a] showed that there is no fixed t such that $P(G)^{(t)} = P(G)_{\mathrm{I}}$ for each graph G, even if we restrict G to graphs with $\alpha(G) = 2$. Chvátal, Cook, and Hartmann [1989] showed that t can be at least $\frac{1}{3}\log n$ for such graphs (where n is the number of vertices).

We will see in Corollary 65.2e that the class of graphs G with $P(G)_{\mathrm{I}} = P(G)$ is exactly the class of perfect graphs. By Edmonds' matching polytope theorem (Corollary 25.1a) if G is the line graph of some graph H, then $P(G)' = P(G)_{\mathrm{I}}$, which is the matching polytope of H.

The smallest t for which $P(G)^{(t)} = P(G)_{\mathrm{I}}$ might be an indication of the computational complexity of the stable set number $\alpha(G)$. For each fixed t, the stable set problem for graphs with $P(G)^{(t)} = P(G)_{\mathrm{I}}$ belongs to NP∩co-NP. Chvátal [1973a] raised the question whether it belongs to P. (A negative indication is the result of Eisenbrand [1999] that given a polytope P by linear inequalities and given x, deciding if x belongs to P' is co-NP-complete.)

Another (weaker, but easier to compute) relaxation is: $Q(G)$ is the polytope of fractional stable sets; that is, the polytope in $\mathbb{R}^V$ determined by

(64.49) (i) $x_v \geq 0$ for each $v \in V$,
(ii) $x_v + x_w \leq 1$ for each $vw \in E$.

Again $Q(G)_{\mathrm{I}} = P_{\text{stable set}}(G)$. Since $Q(G) \supseteq P(G)$, there is no fixed t with $Q(G)^{(t)} = Q(G)_{\mathrm{I}}$ for each graph G. Chvátal [1973a] noticed that for $G = K_n$ the smallest t with $Q(G)^{(t)} = P_{\text{stable set}}(G)$ is about $\log n$.

It is not difficult to see that $Q(G)'$ is the polytope determined by (64.49) together with

(64.50) (iii) $x(VC) \leq \lfloor \frac{1}{2}|VC| \rfloor$ for each odd circuit C.

Graphs G with $Q(G)' = P_{\text{stable set}}(G)$ are called *t-perfect*. More on t-perfect graphs can be found in Chapter 68.

Chvátal [1975b] conjectures that there is no polynomial $p(n)$ such that for each graph G with n vertices we can obtain the inequality $x(V) \leq \alpha(G)$ from system (64.49) by adding at most $p(n)$ cutting planes. (That is, a list of at most $p(n)$ inequalities $a_i^{\mathsf{T}}x \leq \lfloor \beta_i \rfloor$ such that, for each i, a_i is an integer vector and the inequality $a_i^{\mathsf{T}}x \leq \beta_i$ is a nonnegative combination of inequalities from (64.49) and inequalities occurring earlier in the list.)

Chvátal, Cook, and Hartmann [1989] showed that the Chvátal rank of the following relaxation of the stable set polytope:

(64.51) $x_v \geq 0$ for $v \in V$,
$x(U) \leq \alpha(G[U])$ for $U \subseteq V$,

is $\Omega((n/\log n)^{\frac{1}{2}})$, where G is a graph with n vertices. This relaxation is stronger than the polytope determined by just the nonnegativity and clique constraints.

64.9. Further results and notes

64.9a. Graphs with polynomial-time stable set algorithm

In the remaining chapters of this part we will see that a maximum-weight stable set can be found in strongly polynomial time in perfect graphs and their complements, in t-perfect graphs, and in claw-free graphs. In perfect graphs and their complements, also a minimum vertex-colouring can be found in polynomial time. In this section we list some other classes of graphs where a maximum-size stable set or a minimum vertex-colouring can be found in polynomial time.

A graph is a *circular-arc graph* if it is the intersection graph of a set of intervals on a circle. Gavril [1974a] gave polynomial-time algorithms for finding a maximum-size clique, a maximum-size stable set, and a minimum clique cover in these graphs. Karapetyan [1980] showed that $\chi(G) \leq \frac{3}{2}\omega(G)$ for any circular-arc graph G (proving a conjecture of Tucker [1975]). More on circular-arc graphs can be found in Klee [1969], Tucker [1971,1974,1975,1978,1980], Trotter and Moore [1976], Garey, Johnson, Miller, and Papadimitriou [1980], Golumbic [1980], Orlin, Bonuccelli, and Bovet [1981], Gupta, Lee, and Leung [1982], Skrien [1982], Leung [1984], Hsu [1985, 1995], Teng and Tucker [1985], Apostolico and Hambrusch [1987], Golumbic and Hammer [1988], Masuda and Nakajima [1988], Spinrad [1988], Shih and Hsu [1989a, 1989b], Bertossi and Moretti [1990], Hell, Bang-Jensen, and Huang [1990], Hsu and Tsai [1991], Deng, Hell, and Huang [1992,1996], Eschen and Spinrad [1993], Hsu and Spinrad [1995], Bhattacharya, Hell, and Huang [1996], Bhattacharya and Kaller [1997], Hell and Huang [1997], Feder, Hell, and Huang [1999], and McConnell [2001]. See also Section 65.6d.

A graph is a *circle graph* if its vertex set is a set of chords of the circle, two chords being adjacent if they intersect or cross. For these graphs, Gavril [1973] gave polynomial-time algorithms for finding a maximum-size clique and a maximum-size stable set. Bouchet [1985,1987b,1994], Naji [1985], and Gabor, Supowit, and Hsu [1989] showed that circle graphs can be recognized in polynomial time; this was improved to quadratic time by Spinrad [1994]. (Related results can be found in Fournier [1978], Garey, Johnson, Miller, and Papadimitriou [1980], Golumbic [1980], Rotem and Urrutia [1981], de Fraysseix [1984], Hsu [1985], Naji [1985], Dagan, Golumbic, and Pinter [1988], Gabor, Supowit, and Hsu [1989], Masuda, Nakajima, Kashiwabara, and Fujisawa [1990], Felsner, Müller, and Wernisch [1994], Ma and Spinrad [1994], Spinrad [1994], and Elmallah and Stewart [1998]. See also Section 65.6d.)

The weighted stable set problem was shown to be polynomial-time solvable for graphs without $K_5 - e$ minor by Barahona and Mahjoub [1994b]. (The graph $K_5 - e$ is obtained from K_5 by deleting one edge.) Descriptions of the corresponding polytopes are given by Barahona and Mahjoub [1994b,1994c].

Hsu, Ikura, and Nemhauser [1981] gave, for each fixed k, a polynomial-time algorithm for the weighted stable set problem for graphs without odd circuits of length larger than $2k + 1$. A 'nice class for the vertex packing problem' (obtained from bipartite graphs and claw-free graphs by repeated substitution) was given by Bertolazzi, De Simone, and Galluccio [1997]. Another nice class was given by De Simone [1993].

In Section 60.3d (Corollary 60.5b) we gave a proof of Győri's theorem (Győri [1984]), stating that the following class of graphs G satisfies $\alpha(G) = \overline{\chi}(G)$. Let A be a $\{0, 1\}$ matrix such that the 1's in each row form a contiguous interval. Then G has vertex set $\{(i, j) \mid a_{i,j} = 1\}$, where two pairs (i, j) and (i', j') are adjacent if and only if $a_{i,j'} = a_{i',j} = 1$. The method of Frank and Jordán [1995b] also yields a polynomial-time algorithm to find a maximum-size stable set and a minimum clique cover. Frank [1999a] gave an alternative algorithmic proof. This class of graphs is not closed under taking induced subgraphs, and they need not be perfect.

Hammer, Mahadev, and de Werra [1985], Balas, Chvátal, and Nešetřil [1987], Balas and Yu [1989], De Simone and Sassano [1993], Hertz and de Werra [1993], Hertz [1995,1997], Brandstädt and Hammer [1999], Mosca [1999], and Lozin [2000] gave further classes of graphs for which the maximum-size or maximum-weight clique problem is polynomial-time solvable.

64.9b. Colourings and orientations

Let $D = (V, A)$ be an orientation of an undirected graph $G = (V, E)$. The following was shown by Gallai [1968a] and Roy [1967] (referring to conjectures by P. Erdős and C. Berge, respectively):

(64.52) $\chi(G) \leq \lambda(D)$,

where

(64.53) $\lambda(D) :=$ the maximum number of vertices on a directed path in D.

To see this, consider an inclusionwise maximal subset A' of A with the property that $D' = (V, A')$ is acyclic. For any $v \in V$, let $h(v)$ be the number of vertices in a longest directed path in D' ending at v. If $h(u) = h(v)$ for distinct vertices u and v, then u and v are nonadjacent, since otherwise we can add the arc joining u and v to A'. So h defines a colouring of V, with no more colours than the number of vertices in a longest directed path in D'.

This proves (64.52). Note that (64.52) implies that each tournament ($\equiv$ orientation of a complete graph) has a Hamiltonian path (a theorem of Rédei [1934] (Corollary 14.14a)).

Roy [1967] also observed that each undirected graph $G = (V, E)$ has an acyclic orientation in which the number of vertices in a longest directed path is equal to the colouring number of G. (This follows by colouring the vertices with colours $1, \ldots, \chi(G)$, and orienting any edge from u to v if the colour of u is smaller than that of v, which gives a digraph D with $\lambda(D) \leq \chi(G)$.)

This result is equivalent to the fact that for any undirected graph $G = (V, E)$:

(64.54) $\chi(G) = \min\limits_{D} \lambda(D)$,

where D ranges over all acyclic orientations of G.

These results are essentially based on the (easy) fact that the minimum number of antichains needed to cover a partially ordered set is equal to the size of a maximum chain (Theorem 14.1).

Minty [1967] showed that for each graph $G = (V, E)$:

(64.55) $\chi(G) \leq k \iff G$ has an orientation such that each undirected circuit has at least $\frac{1}{k}|VC|$ forward arcs.

Necessity follows by colouring the vertices with colours $1, \ldots, k$, and orienting any edge from u to v if $\text{colour}(u) < \text{colour}(v)$. To see sufficiency, let D be an orientation as described. Give each arc a length $k - 1$, and add an arc in the reverse direction of length -1. Then each directed circuit in the extended digraph has nonnegative length. Hence there is a 'potential' $p : V \to \mathbb{Z}$ with $1 \leq p(v) - p(u) \leq k - 1$ for each arc (u, v) of D. Reducing p mod k gives a k-colouring as required.

Note that each orientation as in (64.55) is acyclic, and that any orientation D with $\lambda(D) \leq k$ is as in (64.55). The equivalence (64.55) gives a vertex-free description of the colouring number, and implies that $\chi(G)$ only depends on the cycle matroid of G.

Deming [1979a] showed that dual statements can be derived from Dilworth's decomposition theorem (Theorem 14.2), where 'chain' and 'antichain' are interchanged.

First one has, as a dual to (64.52), that for any orientation $D = (V, A)$ of an undirected graph $G = (V, E)$:

(64.56) $\qquad \alpha(G) \geq \xi(D),$

where

(64.57) $\qquad \xi(D) :=$ the minimum number of directed paths in D needed to cover V.

To see (64.56), again consider an inclusionwise maximal subset A' of A with $D' = (V, A')$ acyclic. By Dilworth's decomposition theorem, V has a subset U of size $\xi(D)$ such that no two vertices in U are connected by a directed path in D. Then U is a stable set in G, since if two distinct $u, v \in U$ are adjacent in G, say $(u, v) \in A$, then $(u, v) \notin A'$, and hence $A' \cup \{(u, v)\}$ is not acyclic. But then A' contains a directed path from v to u, a contradiction.

This shows (64.56). Deming [1979a] showed also a dual form of (64.54):

(64.58) $\qquad \alpha(G) = \max_{D} \xi(D),$

where D ranges over all acyclic orientations of G. Indeed, $\geq$ in (64.58) follows from (64.56). To see $\leq$, let U be a maximum-size stable set in G. Let D be any acyclic orientation of G in which each vertex in U is a source. Then $\xi(D) \geq |U| = \alpha(G)$.

64.9c. Algebraic methods

Lovász [1994] gave the following relations between stable sets, cliques, and colourings, using Hilbert's Nullstellensatz (extending Li and Li [1981] and unpublished work of D.J. Kleitman and L. Lovász). For any graph $G = (V, E)$, define the polynomial p_G in the variables x_v ($v \in V$) by:

(64.59) $\qquad p_G := \prod_{uv \in E} (x_u - x_v)$

(fixing some orientation of the edges). Then $\alpha(G) \leq k$ if and only if there are graphs $H_1, \ldots, H_t$ on V satisfying

(64.60) $\qquad p_G = p_{H_1} + \cdots + p_{H_t},$

with $\overline{\chi}(H_i) \leq k$ for $i = 1, \ldots, t$. The number t can be exponentially large — hence (64.60) gives no good characterization for the stable set number. Similarly, $\chi(G) \geq k$ if and only if there are graphs satisfying (64.60) with $\omega(H_i) \geq k$ for $i = 1, \ldots, t$.

Let $G = (V, E)$ be a (simple) graph, with adjacency matrix A_G. Motzkin and Straus [1965] showed that the maximum value of $x^{\mathsf{T}} A_G x$ over $x : V \to \mathbb{R}_+$ satisfying $x(V) = 1$, is equal to $1 - \omega(G)^{-1}$.

The proof of this is easy: for any two nonadjacent vertices u, v with $x_u > 0$ and $x_v > 0$, we can reset $x_u := x_u + \varepsilon$, $x_v := x_v - \varepsilon$ for some $\varepsilon \neq 0$ without decreasing $x^{\mathsf{T}} A_G x$. Hence the maximum value is attained by a vector x whose support is a clique C. As x takes the maximum value, we should have $x_v = 1/|C|$ for each $v \in C$. Then $x^{\mathsf{T}} A_G x$ is maximized if C is a maximum-size clique.

Motzkin and Straus' theorem implies the result of Korn [1968] that the minimum value of $x^{\mathsf{T}}(I + A_G)x$ over $x : V \to \mathbb{R}_+$ with $x(V) = 1$, is equal to $\alpha(G)^{-1}$. Indeed,

(64.61) $$\min_x x^{\mathsf{T}}(I + A_G)x = \min_x x^{\mathsf{T}}(J - A_{\overline{G}})x = 1 - \max_x x^{\mathsf{T}} A_{\overline{G}} x = \omega(\overline{G})^{-1} = \alpha(G)^{-1}.$$

More on this can be found in Gibbons, Hearn, Pardalos, and Ramana [1997].

Lovász [1982,1994] gave surveys of algebraic, topological, and other methods for the stable set and the vertex colouring problem.

64.9d. Approximation algorithms

Lund and Yannakakis [1993,1994] showed that unless NP=P, there do not exist a constant c and a polynomial-time algorithm that finds a vertex-colouring of any graph G using at most $c\chi(G)$ colours. (This was proved for $c < 2$ by Garey and Johnson [1976].)

More generally, Lund and Yannakakis [1993,1994] showed that there exists an $\varepsilon > 0$ such that, unless NP=P, there is no polynomial-time algorithm to find the colouring number of a graph up to a factor of n^{ε} (where n is the number of vertices).

A similar result for maximum-size stable sets was proved by Arora, Lund, Motwani, Sudan, and Szegedy [1992,1998]. Håstad [1996,1999] showed that, if NP$\neq$P, then there is no $\varepsilon > 0$ and a polynomial-time algorithm that finds a clique that is maximum-size up to a factor $n^{1/2-\varepsilon}$. Under a slightly stronger complexity assumption (NP$\neq$ZPP), Håstad proved a factor of $n^{1-\varepsilon}$.

For background, see Johnson [1992] and Papadimitriou [1994]. Related results can be found in Hochbaum [1983a], Wigderson [1983], Berger and Rompel [1990], Feige, Goldwasser, Lovász, Safra, and Szegedy [1991,1996], Berman and Schnitger [1992], Boppana and Halldórsson [1992], Bellare, Goldwasser, Lund, and Russell [1993], Khanna, Linial, and Safra [1993,2000], Bellare and Sudan [1994], Feige and Kilian [1994,1996,1998a,1998b,2000], Karger, Motwani, and Sudan [1994,1998], Bellare, Goldreich, and Sudan [1995,1998], Feige [1995,1997], Fürer [1995], Håstad [1996,1999], Alon and Kahale [1998], Arora and Safra [1998], Engebretsen and Holmerin [2000], Srinivasan [2000], and Khot [2001].

In contrast, there is an easy algorithm to obtain a vertex cover in a graph $G = (V, E)$ of size at most $2\tau(G)$ (F. Gavril 1974 (cf. Garey and Johnson [1979])): choose any inclusionwise maximal matching M (greedily); then the set of vertices covered by M is a vertex cover of size $2|M|$. Since $\tau(G) \geq |M|$, this is a vertex cover as described.

No polynomial-time algorithm yielding a factor better than 2 is known. Håstad [1997,2001] showed that, if NP$\neq$P, no factor better than $\frac{7}{6}$ is achievable in polynomial time.

See also Section 67.4f below.

64.9e. Further notes

Yannakakis [1988,1991] showed that the stable set polytope of the line graph $L(K_n)$ of a complete graph K_n cannot be represented as the projection of a polytope in higher dimensions that is symmetric under the automorphism group of $L(K_n)$. Cao and Nemhauser [1998] characterized line graphs as those graphs whose stable set polytope is determined by the inequalities corresponding to the matching polytope constraints.

Euler, Jünger, and Reinelt [1987] extended results of Padberg [1973] on facets of the stable set polytope, to more general 'independence' polytopes.

More on the stable set polytope can be found in Fulkerson [1971a], Chvátal [1973a,1975a,1985a], Padberg [1973,1974b,1977,1979,1980,1984], Nemhauser and Trotter [1974], Trotter [1975], Wolsey [1976], Balas and Zemel [1977], Naddef and Pulleyblank [1981a], Sekiguchi [1983], Ikura and Nemhauser [1985], Grötschel, Lovász, and Schrijver [1986], Lovász and Schrijver [1989,1991], Cheng and Cunningham [1995,1997], Cánovas, Landete, and Marín [2000], Lipták and Lovász [2000, 2001], and Cheng and de Vries [2002a,2002b].

The convex hull of the incidence vectors of the stable sets of size at most a given k is studied by Janssen and Kilakos [1999]. Generalizations of the stable set polytope to more general $0, \pm 1$ programming and satisfiability problems were studied by Johnson and Padberg [1982], Hooker [1996], and Sewell [1996].

Methods for and computational results on the stable set problem (or the equivalent clique, vertex cover, and set packing problems) are given by Balas and Samuelsson [1977], Chvátal [1977], Houck and Vemuganti [1977], Tarjan and Trojanowski [1977], Geoffroy and Sumner [1978], Gerhards and Lindenberg [1979], Hansen [1980b], Bar-Yehuda and Even [1981,1982,1985], Billionnet [1981], Chiba, Nishizeki, and Saito [1982] (planar graphs), Hochbaum [1982,1983a], Loukakis and Tsouros [1982], Baker [1983,1994], Clarkson [1983], Monien and Speckenmeyer [1983,1985], Balas and Yu [1986], Jian [1986], Robson [1986], Shindo and Tomita [1988], Hurkens and Schrijver [1989], Carraghan and Pardalos [1990], Nemhauser and Sigismondi [1992], Balas and Xue [1991,1996], Boppana and Halldórsson [1992], Pardalos and Rodgers [1992], Paschos [1992], Khuller, Vishkin, and Young [1993,1994], Berman and Fürer [1994], Mannino and Sassano [1994], Halldórsson [1995], Balas, Ceria, Cornuéjols, and Pataki [1996], Bourjolly, Laporte, and Mercure [1997], Halldórsson and Radhakrishnan [1997], Alon and Kahale [1998], Arkin and Hassin [1998], Feige and Kilian [1998a], Kleinberg and Goemans [1998], Chandra and Halldórsson [1999, 2001], Nagamochi and Ibaraki [1999b], Bar-Yehuda [2000], Halperin [2000,2002], Krivelevich and Vu [2000], Chen, Kanj, and Jia [2001], Krivelevich, Nathaniel, and Sudakov [2001a,2001b], and Guha, Hassin, Khuller, and Or [2002].

Methods for graph colouring are proposed and investigated by Christofides [1971], Brown [1972], Matula, Marble, and Isaacson [1972], Corneil and Graham [1973], Johnson [1974b], Wang [1974], Lawler [1976a], McDiarmid [1979], Matula and Beck [1983], Sysło, Deo, and Kowalik [1983], Wigderson [1983], Edwards [1986], Berger and Rompel [1990], Hertz [1991], Halldórsson [1993], Blum [1994], Demange, Grisoni, and Paschos [1994], Karger, Motwani, and Sudan [1994,1998], Schiermeyer [1994], Beigel and Eppstein [1995], Blum and Karger [1997], Krivelevich and Vu [2000], Eppstein [2001], Halperin, Nathaniel, and Zwick [2001], Molloy and Reed [2001], Stacho [2001], Alon and Krivelevich [2002], and Charikar [2002].

For computational results on clique, stable set, and colouring problems, consult also Johnson and Trick [1996].

A survey of graph colouring algorithms was given by Matula, Marble, and Isaacson [1972]. Chiba, Nishizeki, and Saito [1981], Thomassen [1994], and Robertson, Sanders, Seymour, and Thomas [1996] gave linear-time 5-colouring algorithms for planar graphs. The worst-case behaviour of graph colouring algorithms was investigated by Johnson [1974b].

Mycielski [1955] showed that triangle-free graphs can have arbitrarily large colouring number. King and Nemhauser [1974] and Gyárfás [1987] and Fouquet, Giakoumakis, Maire, and Thuillier [1995] studied classes of graphs for which the colouring number can be bounded by a function of the clique number.

Gyárfás [1987] conjectures that there exists a function $g : \mathbb{Z}_+ \to \mathbb{Z}_+$ such that $\chi(G) \leq g(\omega(G))$ for each graph G without odd holes. Equivalently, for $\omega \in \mathbb{Z}_+$, let $g(\omega)$ be the maximum colouring number of a graph without odd holes and cliques of size $> \omega$. Then Gyárfás' conjectures that g is finite. It is easy to see that $g(2) = 2$. N. Robertson, P.D. Seymour, and R. Thomas announced that they proved $g(3) = 4$ (this was conjectured by G. Ding).

Upper bounds for the stable set number of a graph in terms of the degrees were presented by Hansen [1979,1980b]. Relations between the colouring number and the fractional colouring number are investigated by Kilakos and Marcotte [1997]. Reed [1998] discussed bounding the chromatic number of a graph by a convex combination of its clique number and its maximum degree plus 1. Gerke and McDiarmid [2001a,2001b] investigated the ratio of the weighted colouring and the weighted clique number.

A theorem of Turán [1941] implies that any simple graph G with n vertices and m edges satisfies:

(64.62) $$\alpha(G) \geq \frac{n^2}{n + 2m}.$$

Bondy [1978] showed that $m \geq 2\tau(G) - 1$ if G is connected. A study of the relations between several parameters derived from stability and colouring was given by Hell and Roberts [1982].

A survey on the stable set problem is given by Padberg [1979], on approximation methods for the stable set problem by Halldórsson [1998], and on colourings by Jensen and Toft [1995] and Toft [1995]. Colouring is also discussed in most graph theory books mentioned in Chapter 1.

Chapter 65

Perfect graphs: general theory

In this and the next two chapters, we consider the 'perfect' graphs, introduced by C. Berge in the 1960s. They turn out to unify several results in combinatorial optimization, in particular, min-max relations and polyhedral characterizations.
Berge proposed two conjectures, the *weak* and the *strong* perfect graph conjecture. The second implies the first.
The weak perfect graph conjecture says that perfection is maintained under taking the complementary graph. This was proved by Lovász [1972c]: the perfect graph theorem.
The strong perfect graph conjecture characterizes perfect graphs by excluding odd holes and odd antiholes. A proof of this was announced in May 2002 by Chudnovsky, Robertson, Seymour, and Thomas, resulting in the strong perfect graph theorem. The announced proof is highly complicated, and we cannot give it here.
Many of the results described in this and the next chapter follow directly as a consequence of the strong perfect graph theorem (while some of them are used in the proof). Where possible and appropriate, we give direct proofs of these consequences.
In this chapter, we give general theory, in Chapter 66 we discuss classes of perfect graphs, and in Chapter 67 we show the polynomial-time solvability of the maximum-weight clique and minimum colouring problems for perfect graphs.

65.1. Introduction to perfect graphs

As we saw before, the clique number $\omega(G)$ and the colouring number $\chi(G)$ of a graph $G = (V, E)$ are related by the inequality

(65.1) $\qquad \omega(G) \leq \chi(G).$

Strict inequality can occur, for instance, for any odd circuit of length at least five, and its complement.

Having equality in (65.1) does not say that much about the internal structure of a graph: any graph $G = (V, E)$ can be extended to a graph $G' = (V', E')$ satisfying $\omega(G') = \chi(G')$, simply by adding to G a clique of size $\chi(G)$, disjoint from V.

However, the condition becomes much more powerful if we require that equality in (65.1) holds for each induced subgraph of G. The idea for this was formulated by Berge [1963a]. He defined a graph $G = (V, E)$ te be *perfect* if $\omega(G') = \chi(G')$ holds for each induced subgraph G' of G.

Various classes of graphs could be shown to be perfect, like the bipartite graphs (trivially) and the line graphs of bipartite graphs (by Kőnig's edge-colouring theorem).

Berge [1960a,1963a] observed the important phenomenon that for several of these classes, also the complementary graphs are perfect. Berge therefore conjectured that the complement of any perfect graph is perfect again — the *weak perfect graph conjecture*. This conjecture was proved by Lovász [1972c], by proving an equivalent form of the conjecture given by Fulkerson [1972a] (the replication lemma — see Corollary 65.2c below).

As mentioned, obvious examples of imperfect graphs are the odd circuits of length at least five, and their complements. Berge [1963a] and P.C. Gilmore (cf. Berge [1966]) made the conjecture that this characterizes perfect graphs, which is the strong perfect graph conjecture. A proof was announced in May 2002 by Chudnovsky, Robertson, Seymour, and Thomas.

To simplify formulation, it is convenient to introduce the notions of 'hole' and 'antihole'. A *hole* in a graph G is an induced subgraph of G isomorphic to a circuit with at least four vertices. An *antihole* in G is an induced subgraph of G isomorphic to the complement of a circuit with at least four vertices. A hole or antihole is *odd* if it has an odd number of vertices.

Theorem 65.1 (Strong perfect graph theorem)**.** *A graph G is perfect if and only if G contains no odd hole and no odd antihole.*

A graph containing no odd hole or odd antihole is called a *Berge graph*[2]. So the strong perfect graph theorem says that Berge graphs are precisely the perfect graphs.

An alternative formulation is in terms of minimally imperfect graphs. A *minimally imperfect* (or *critically imperfect*) graph is an imperfect graph such that each proper induced subgraph is perfect. Then the strong perfect graph theorem says that the only minimally imperfect graphs are the odd circuits of length at least five, and their complements.

It is (as yet) unknown if perfection of a graph can be tested in polynomial time. (Lovász [1986] 'would guess' that such an algorithm exists.) The clique number of a perfect graph can be determined in polynomial time, with the help of the ellipsoid method — see Chapter 67. However, no combinatorial polynomial-time algorithm is known.

We will next discuss perfect graph theory in greater detail (although we cannot give a proof of the strong perfect graph theorem). Let us make a useful observation:

[2] This term was introduced by Chvátal and Sbihi [1987].

(65.2) any minimally imperfect graph $G = (V, E)$ has no stable set S with $\omega(G - S) < \omega(G)$.

Otherwise, $\omega(G) \geq \omega(G - S) + 1 = \chi(G - S) + 1 \geq \chi(G)$, since we can use S as colour.

Similarly, for any class $\mathcal{G}$ of graphs closed under taking induced subgraphs:

(65.3) each graph $G \in \mathcal{G}$ is perfect $\iff$ each graph $G \in \mathcal{G}$ with $VG \neq \emptyset$ has a stable set S with $\omega(G - S) < \omega(G)$.

Here necessity follows from the fact that we can take for S any of the colours in a minimum colouring of G. Sufficiency follows by induction on $|VG|$: $\chi(G) \leq \chi(G - S) + 1 = \omega(G - S) + 1 \leq \omega(G)$.

65.2. The perfect graph theorem

Lovász [1972a] proved the weak perfect graph conjecture in the following stronger form (suggested by A. Hajnal), which we show with the elegant linear-algebraic proof found by Gasparian [1996].

Theorem 65.2. *A graph G is perfect if and only if $\omega(G')\alpha(G') \geq |VG'|$ for each induced subgraph G' of G.*

Proof. Necessity is easy, since if G is perfect, then $\omega(G') = \chi(G')$ for each induced subgraph G' of G, and since $\chi(G')\alpha(G') \geq |VG'|$ for any graph G'.

To see sufficiency, it suffices to show that each minimally imperfect graph G satisfies $|VG| \geq \alpha(G)\omega(G) + 1$. We can assume that $VG = \{1, \ldots, n\}$. Define $\omega := \omega(G)$ and $\alpha := \alpha(G)$.

We first construct

(65.4) stable sets $S_0, \ldots, S_{\alpha\omega}$ such that each vertex is covered by exactly α of the S_i.

Let S_0 be a stable set in G of size α. By the minimality of G, we know that for each $v \in S_0$, the graph $G - v$ is perfect, and that hence $\chi(G - v) = \omega(G - v) \leq \omega$. Therefore, $V \setminus \{v\}$ can be partitioned into ω stable sets. Doing this for each $v \in S_0$, we obtain stable sets as in (65.4).

Now for each $i = 0, \ldots, \alpha\omega$, there exists a clique C_i of size ω with $C_i \cap S_i = \emptyset$ (by (65.2)). Then, for distinct i, j with $0 \leq i, j \leq \alpha\omega$, we have $|C_i \cap S_j| = 1$. This follows from the fact that C_i has size ω and intersects each S_j in at most one vertex, and hence, by (65.4), it intersects $\alpha\omega$ of the S_j. As $C_i \cap S_i = \emptyset$, we have that $|C_i \cap S_j| = 1$ if $i \neq j$.

Now consider the $(\alpha\omega+1) \times n$ incidence matrices M and N of $S_0, \ldots, S_{\alpha\omega}$ and $C_0, \ldots, C_{\alpha\omega}$ respectively. So M and N are $\{0, 1\}$ matrices, with $M_{i,j} = 1 \iff j \in S_i$, and $N_{i,j} = 1 \iff j \in C_i$, for $i = 0, \ldots, \alpha\omega$ and $j = 1, \ldots, n$. By the above, $MN^{\mathsf{T}} = J - I$, where J is the $(\alpha\omega+1) \times (\alpha\omega+1)$ all-1 matrix, and I the $(\alpha\omega+1)\times(\alpha\omega+1)$ identity matrix. As $J-I$ has rank $\alpha\omega+1$, we have $n \geq \alpha\omega+1$. ∎

Theorem 65.2 implies (Lovász [1972c]):

Corollary 65.2a (perfect graph theorem)**.** *The complement of a perfect graph is perfect again.*

Proof. Directly from Theorem 65.2, as the condition given in it is invariant under taking the complementary graph. ∎

As was observed by Cameron [1982], Theorem 65.2 implies that the question 'Given a graph, is it perfect?' belongs to co-NP. Indeed, to certify imperfection of a graph, it is sufficient, and possible, to specify:

(65.5) (i) an induced subgraph $G=(V,E)$,
(ii) integers $\alpha,\omega \geq 2$ with $|V|=\alpha\omega+1$, and
(iii) for each $v \in V$, an ω-colouring of $G-v$ and an α-colouring of $\overline{G}-v$.

This is possible, since, by Theorem 65.2, a minimally imperfect subgraph G has these properties for $\omega := \omega(G)$ and $\alpha := \alpha(G)$. It is also sufficient to certify imperfection, since (65.5)(iii) implies that $\omega(G) \leq \omega$ and $\alpha(G) \leq \alpha$, and hence by (65.5)(ii), that G is not perfect.

Theorem 65.2 implies:

Corollary 65.2b. *Each minimally imperfect graph G satisfies*

(65.6) $$|VG| = \alpha(G)\omega(G)+1.$$

Proof. We have $|VG| \leq \alpha(G)\omega(G)+1$, since for any vertex v of G, the graph $G-v$ is perfect, and hence

(65.7) $$|VG|-1 = |V(G-v)| \leq \alpha(G-v)\omega(G-v) \leq \alpha(G)\omega(G).$$

Conversely, $|VG| \geq \alpha(G)\omega(G)+1$, since if $|VG| \leq \alpha(G)\omega(G)$, then $|VG'| \leq \alpha(G')\omega(G')$ for each induced subgraph G' of G (by the minimal imperfection of G). This implies with Theorem 65.2 that G is perfect, a contradiction. ∎

65.3. Replication

Let $G=(V,E)$ be a graph and let $v \in V$. Extend G with some new vertex, v' say, which is adjacent to v and to all vertices adjacent to v in G. In this way we obtain a new graph H, which we say is obtained from G by *duplicating* v. Repeated duplicating a vertex is called *replicating*. *Replicating* a vertex v *by a factor* k means duplicating v $k-1$ times if $k \geq 1$, and deleting v if $k=0$.

Corollary 65.2c (replication lemma)**.** *Let H arise from G by duplicating vertex v. Then if G is perfect, also H is perfect.*

Proof. By the perfect graph theorem, it suffices to show that $\overline{H}$ is perfect, and hence (as we can apply induction) that $\omega(\overline{H}) = \chi(\overline{H})$.

By the perfect graph theorem, if G is perfect, then $\overline{G}$ is perfect. Hence $\omega(\overline{H}) = \omega(\overline{G}) = \chi(\overline{G}) = \chi(\overline{H})$. ∎

Repeated application of Corollary 65.2c implies the following (the weighted colouring number is defined in Section 64.8):

Corollary 65.2d. *Let G be a perfect graph and let $w : V \to \mathbb{Z}_+$ be a 'weight' function. Then the maximum weight of a clique is equal to the weighted colouring number $\chi_w(G)$ of G.*

Proof. Let G^w be the graph arising from G by replicating any vertex v by a factor $w(v)$. By Corollary 65.2c, G^w is perfect, and so $\omega(G^w) = \chi(G^w)$. Since $\omega(G^w)$ is equal to the maximum weight of a clique in G and since $\chi(G^w) = \chi_w(G)$, the corollary follows. ∎

65.4. Perfect graphs and polyhedra

The *clique polytope* of a graph $G = (V, E)$ is the convex hull of the incidence vectors of the cliques. Clearly, any vector x in the clique polytope satisfies:

(65.8) (i) $x_v \geq 0$ for each $v \in V$,
(ii) $x(S) \leq 1$ for each stable set S.

Fulkerson [1972a] and Chvátal [1975a] showed that Corollary 65.2d implies a polyhedral characterization of perfect graphs:

Corollary 65.2e. *A graph G is perfect if and only if its clique polytope is determined by* (65.8).

Proof. *Necessity.* Let G be perfect. To prove that the clique polytope is determined by (65.8), it suffices to show that for each weight function $w : V \to \mathbb{Z}_+$, the maximum weight t of a clique in G is not less than the maximum of $w^{\mathsf{T}}x$ over (65.8). By Corollary 65.2d, there exist stable sets $S_1, \ldots, S_t$ with

(65.9) $$w = \chi^{S_1} + \cdots + \chi^{S_t}.$$

Hence for each x satisfying (65.8) we have

(65.10) $$w^{\mathsf{T}}x = x(S_1) + \cdots + x(S_t) \leq t.$$

Sufficiency. Let the clique polytope of G be determined by (65.8). Suppose that G is not perfect. Choose a minimal set U with $\omega(G[U]) < \chi(G[U])$. Let

$w := \chi^U$. The function $w^{\mathsf{T}}x$ is maximized over $P_{\text{clique}}(G)$ by the incidence vector of each maximum-size clique of $G[U]$. Moreover, by linear programming duality, there exists a stable set S with $x(S) = 1$ for each optimum solution x. So S intersects each maximum-size clique of $G[U]$, and hence

(65.11) $$\omega(G[U \setminus S]) \leq \omega(G[U]) - 1 < \chi(G[U]) - 1 \leq \chi(G[U \setminus S]),$$

contradicting the minimality of U. ∎

Corollary 65.2e is equivalent to: G is perfect if and only if $P_{\text{clique}}(G) = A(P_{\text{stable set}}(G))$. (Here $A(P)$ is the antiblocking polyhedron of P.) Hence it implies the perfect graph theorem (using the theory of antiblocking polyhedra (cf. Section 5.9)):

(65.12) $$\begin{aligned} & G \text{ is perfect } \iff P_{\text{clique}}(G) = A(P_{\text{stable set}}(G)) \\ & \iff P_{\text{stable set}}(G) = A(P_{\text{clique}}(G)) \\ & \iff P_{\text{clique}}(\overline{G}) = A(P_{\text{stable set}}(\overline{G})) \iff \overline{G} \text{ is perfect.} \end{aligned}$$

Corollary 65.2d also implies that perfect graphs can be characterized by total dual integrality:

Corollary 65.2f. *A graph G is perfect if and only if system* (65.8) *is totally dual integral.*

Proof. Directly from Corollaries 65.2d and 65.2e. ∎

So for any graph G we have that (65.8) determines an integer polytope if *and only if* it is totally dual integral.

65.4a. Lovász's proof of the replication lemma

The proof of Lovász [1972c] of the weak perfect graph theorem is based on proving the 'replication lemma' (Corollary 65.2c above), as follows.

By (65.2), it suffices to find a stable set S in H intersecting all maximum-size cliques of H, since any induced subgraph of H is an induced subgraph of G or arises from it by replication.

Consider an $\omega(G)$-colouring of G, and let S be the colour containing v. Then S intersects each maximum-size clique C of H. Indeed, if $v' \notin C$, then C is a maximum-size clique of G, and so it intersects S. If $v' \in C$, then also $v \in C$ (as $C \cup \{v\}$ is a clique), and so C intersects S.

This proves the replication lemma, which by repeated application gives Corollary 65.2d. Since the proof of Corollary 65.2e given above only uses Corollary 65.2d, this shows (with (65.12)) that the replication lemma implies the perfect graph theorem. This is Fulkerson's proof of the equivalence of the replication lemma and the weak perfect graph conjecture ($\equiv$ perfect graph theorem).

65.5. Decomposition of Berge graphs

The proof of the strong perfect graph conjecture is based on a decomposition theorem of Berge graphs, stating that each Berge graph can be decomposed into 'basic' graphs: bipartite graphs and their complements, and line graphs of bipartite graphs and their complements. We formulate the decomposition rules.

Let $G = (V, E)$ be a graph. A *2-join* of G is a partition of V into sets V_1 and V_2 such that for $i = 1, 2$, $|V_i| \geq 3$ and V_i contains disjoint nonempty subsets A_i, B_i with the property that for all $v_1 \in V_1$ and $v_2 \in V_2$:

(65.13) v_1 and v_2 are adjacent $\iff$ $v_1 \in A_1$, $v_2 \in A_2$, or $v_1 \in B_1$, $v_2 \in B_2$.

A *skew partition* of G is a partition V_1, V_2 of V such that $G[V_1]$ and $\overline{G}[V_2]$ are disconnected. An *homogeneous pair* of G is a pair A, B of disjoint subsets of V such that $3 \leq |A| + |B| \leq |V| - 2$ and such that for all $x, y \in A \cup B$ and $z \in V \setminus (A \cup B)$, if $xz \in E$ and $yz \notin E$, then x and y belong to distinct sets A, B.

M. Chudnovsky, N. Robertson, P.D. Seymour, and R. Thomas announced in May 2002 that they proved the following[3]:

Theorem 65.3. *Let G be a Berge graph. Then G or $\overline{G}$ is bipartite or the line graph of a bipartite graph, or has a 2-join, a skew partition, or a homogeneous pair.*

Unfortunately, we cannot give the (highly complicated) proof of this theorem. M. Chudnovsky, N. Robertson, P.D. Seymour, and R. Thomas also showed that any minimum-size imperfect Berge graph has no skew partition[4]. Since such a graph has no 2-join (Cornuéjols and Cunningham [1985] and Kapoor [1994] — see Corollary 65.7a below) and no homogeneous pair (Chvátal and Sbihi [1987]), and since bipartite graphs and their line graphs are perfect (Kőnig [1916] — see Section 66.1), this implies:

Theorem 65.4 (strong perfect graph theorem)**.** *A graph is perfect if and only if it is a Berge graph.*

65.5a. 0- and 1-joins

A *0-join* of a graph $G = (V, E)$ is a partition of V into nonempty sets V_1 and V_2 such that no edge connects V_1 and V_2. Let $G_1 := G[V_1]$ and $G_2 = G[V_2]$. Then G is called the *0-join* of G_1 and G_2. Trivially:

---

[3] This was conjectured by M. Conforti, G. Cornuéjols, N. Robertson, P.D. Seymour, R. Thomas, and K. Vušković (cf. Cornuéjols [2002]). It builds on work of Roussel and Rubio [2001], and it was stimulated by interaction with concurrent work of Conforti, Cornuéjols, Vušković, and Zambelli [2002] and Conforti, Cornuéjols, and Zambelli [2002b].

[4] conjectured by Chvátal [1985c].

Theorem 65.5. *G is perfect $\iff$ G_1 and G_2 are perfect.*

Proof. This follows from the facts that $\omega(G) = \max\{\omega(G_1), \omega(G_2)\}$ and $\chi(G) = \max\{\chi(G_1), \chi(G_2)\}$, and that induced subgraphs of G arise by the same construction from induced subgraphs of G_1 and G_2. ∎

Hence

(65.14) no minimally imperfect graph has a 0-join.

A 1-*join* (or *join*) of a graph $G = (V, E)$ is a partition of V into subsets V_1 and V_2 such that $|V_1| \geq 2$, $|V_2| \geq 2$, and such that there exist nonempty $A_1 \subseteq V_1$ and $A_2 \subseteq V_2$ with the property that for all $v_1 \in V_1$ and $v_2 \in V_2$:

(65.15) v_1 and v_2 are adjacent $\iff$ $v_1 \in A_1$ and $v_2 \in A_2$.

Choose $v_1 \in A_1$ and $v_2 \in A_2$, and define $G_1 := G[V_1 \cup \{v_2\}]$ and $G_2 := G[V_2 \cup \{v_1\}]$. Then G is called the 1-*join* of G_1 and G_2.

Bixby [1984] proved (generalizing a result of Lovász [1972c]):

Theorem 65.6. *G is perfect $\iff$ G_1 and G_2 are perfect.*

Proof. Necessity follows from the fact that G_1 and G_2 are induced subgraphs of G. To prove sufficiency, it suffices to show $\omega(G) = \chi(G)$, since each induced subgraph of G arises by the same construction, or by a 0-join from induced subgraphs of G_1 and G_2. Let $\omega := \omega(G)$ and $a_i := \omega(G[A_i])$ for $i = 1, 2$. It suffices to show that for each $i = 1, 2$,

(65.16) $G[V_i]$ has an ω-colouring such that A_i uses a_i colours only,

since then we can assume that we use different colours for A_1 and A_2 (as $a_1 + a_2 \leq \omega$), yielding an ω-colouring of G.

To prove (65.16), we may assume that $i = 1$. Let G_1' be the graph obtained from G_1 by replicating v_2 by a factor $\omega - a_1$. So $\omega(G_1') = \omega$. By the replication lemma, G_1' is perfect. Hence $\omega(G_1') = \chi(G_1')$. As the clique of vertices obtained from v_2 has size $\omega - a_1$, we use only a_1 colours for A_1, as required. ∎

An alternative proof follows from Cunningham [1982b]. Cunningham [1982a] described an $O(n^3)$-time algorithm to find a 1-join (if any).

Theorem 65.6 implies:

(65.17) no minimally imperfect graph has a 1-join,

since it has no 0-join, and hence G_1 and G_2 as above are proper induced subgraphs of G, implying that they are perfect. Therefore, by Theorem 65.6, G is perfect, a contradiction.

65.5b. The 2-join

We next show that a minimally imperfect graph has no 2-join, except if it is an odd circuit. This was shown by Cornuéjols and Cunningham [1985] (for a special case) and Kapoor [1994].

The proof uses the following 'special replication lemma' (Cornuéjols and Cunningham [1985]). Let $e = uv$ be an edge of a graph G. Let G' be the graph obtained from replicating v and deleting edge uv', where v' is the new vertex.

Lemma 65.7α (special replication lemma)**.** *If G is perfect and uv is not contained in a triangle of G, then G' is again perfect.*

Proof. It suffices to show that G' has a stable set S' such that $\omega(G' - S') < \omega(G')$. If $\omega(G') > \omega(G)$, we can take $S' = \{v'\}$. So we may assume $\omega(G') = \omega(G)$. Let S be the colour of an $\omega(G)$-colouring of G with $v \in S$. Let $S' := (S \setminus \{v\}) \cup \{v'\}$. Then S' is a stable set in G'. If $\omega(G' - S') < \omega(G')$ we are done. So assume that $\omega(G'-S') = \omega(G')$. Let C be a clique in $G'-S'$ of size $\omega(G)$. Since $\omega(G-S) < \omega(G)$ and since $G - S = G' - S' - v$, we know $v \in C$. Since $\omega(G') = \omega(G)$, we know $u \in C$. Hence, $C = \{u, v\}$ (since uv is not in a triangle). So $\omega(G') = 2$, and hence vv' is not contained in a triangle of G'. But then v' has degree 1 in G', implying $\chi(G') = \chi(G) = \omega(G) = \omega(G')$. ∎

Next we consider a *special 2-join*, namely where the sets A_i and B_i in the definition of 2-join are connected by a path in $G[V_i]$ (for $i = 1, 2$). For $i = 1, 2$, let P_i be a shortest $A_i - B_i$ path in $G[V_i]$. Define $G_1 := G[V_1 \cup VP_2]$ and $G_2 := G[V_2 \cup VP_1]$.

Theorem 65.7. *G is perfect $\iff$ G_1 and G_2 are perfect.*

Proof. Necessity follows from the fact that G_1 and G_2 are induced subgraphs of G. To prove sufficiency, it is enough to prove $\omega(G) = \chi(G)$, since each induced subgraph of G arises by the same construction, or by 1- or 0-joins, from induced subgraphs of G_1 and G_2. Define $\omega := \omega(G)$, and

(65.18) $\quad a_i := \omega(G[A_i])$ and $b_i := \omega(G[B_i])$ for $i = 1, 2$.

Note that perfection of G_1 implies that $|EP_1| \equiv |EP_2| \pmod 2$, since $VP_1 \cup VP_2$ induces a hole in G_1.

For any colouring ϕ of a graph and any set X of vertices, let $\phi(X)$ denote the set of colours used by X. We show that, for each $i = 1, 2$, $G[V_i]$ has an ω-colouring $\phi : V \to \{1, \ldots, \omega\}$ such that

(65.19)
(i) $\phi(A_i) = \{1, \ldots, a_i\}$;
(ii) if $|EP_i|$ is even, then $\phi(B_i) = \{1, \ldots, b_i\}$;
(iii) if $|EP_i|$ is odd, then $\phi(B_i) = \{\omega - b_i + 1, \ldots, \omega\}$.

This yields an ω-colouring of G, by replacing the colour, i say, of any vertex in V_2 by $\omega - i + 1$. (The correctness follows from $a_1 + a_2 \leq \omega$ and $b_1 + b_2 \leq \omega$.)

To prove the existence of a colouring satisfying (65.19), we may assume $i = 1$. Let $v_0, v_1, \ldots, v_k$ be the vertices (in order) of the $A_2 - B_2$ path P_2.

First assume that $k > 1$ or $a_1 + b_1 \geq \omega$. Let G_1' be the graph arising from G_1 by replicating v_j by a factor

(65.20)
$$\begin{array}{ll} \omega - a_1 & \text{if } j < k-1 \text{ and } j \text{ is even,} \\ a_1 & \text{if } j < k-1 \text{ and } j \text{ is odd,} \\ \min\{\omega - a_1, b_1\} & \text{if } j = k-1 \text{ and } j \text{ is even,} \\ \min\{a_1, b_1\} & \text{if } j = k-1 \text{ and } j \text{ is odd,} \\ \omega - b_1 & \text{if } j = k. \end{array}$$

Then $\omega(G_1') = \omega$, and any ω-colouring of G_1' yields a colouring satisfying (65.19). Indeed, if k is even, then (65.20) implies that the set of colours used by the copies of v_0 and the set of colours used by the copies of v_k are comparable[5]. If k is odd, then (65.20) implies that the set of colours used by the copies of v_0 and the set of colours *not* used by the copies of v_k are comparable.

Next assume that $k = 1$ and $a_1 + b_1 < \omega$. Extend G_1 by a new vertex v', adjacent to all vertices in B_1 and to v_1. By the special replication lemma (Lemma 65.7α), the new graph G_1'' is again perfect. Let G_1' be the graph arising from G_1'' by replicating v_0 by a factor $\omega - a_1$, v_1 by a factor a_1, and v' by a factor $\omega - a_1 - b_1$. Again, $\omega(G_1') = \omega$, and any ω-colouring of G_1' yields a colouring satisfying (65.19). ∎

This implies:

Corollary 65.7a. *Any minimally imperfect graph having a 2-join is an odd circuit.*

Proof. Let G be a minimally imperfect graph, and let V_i, A_i, B_i (for $i = 1, 2$) be as in the definition of 2-join. If for some i, the graph $G[V_i]$ has no $A_i - B_i$ path, then G has a 0- or 1-join, contradicting (65.14) or (65.17). So we can assume that, for $i = 1, 2$, $G[V_i]$ has an $A_i - B_i$ path. Let P_i be a shortest such path.

By Theorem 65.7 and by symmetry, we may assume that $G[V_1 \cup VP_2]$ is not perfect. Hence, by the minimal imperfection of G, $G = G[V_1 \cup VP_2]$.

We first show $\omega(G) = 2$. Choose an internal vertex u on P_2. (This exists, since $|V_2| \geq 3$.) Choose $v \in V \setminus \{u\}$. By the minimal imperfection of G, we know $\chi(\overline{G} - v) = \alpha(G - v)$. Therefore, $VG \setminus \{v\}$ can be partitioned into $\alpha(G - v)$ cliques. Since $|VG| = \alpha(G)\omega(G) + 1$ (by (65.6)), each of these cliques has size $\omega(G)$. In particular, u is in a clique of size $\omega(G)$. Hence, since u is an internal vertex of P_2, $\omega(G) = 2$.

As $\omega(G) = 2$, $\chi(G - v) \leq 2$ for each $v \in VG$; that is, $G - v$ is bipartite for each $v \in VG$. So each odd circuit is Hamiltonian. As G is not bipartite, G has an odd circuit. This circuit has no chords, as otherwise there exists a shorter odd circuit. ∎

Cornuéjols and Cunningham [1985] gave an $O(n^2m^2)$-time algorithm to find a 2-join in a given graph (if any).

65.6. Pre-proof work on the strong perfect graph conjecture

In this section we survey research done on the strong perfect graph conjecture before it was proved in general. Many of the results follow as a consequence of the strong perfect graph theorem. Since the proof of this theorem is very complicated, we will include proofs not based on the strong perfect graph theorem.

[5] Sets X and Y are called *comparable* if $X \subseteq Y$ or $Y \subseteq X$.

65.6a. Partitionable graphs

The strong perfect graph theorem implies that each minimally imperfect graph is a circuit or its complement, and hence is highly symmetric. Before the strong perfect graph theorem was proved, several regularity properties of minimally imperfect graphs were shown, initiated by the work of Padberg [1974a].

A graph $G = (V, E)$ is called *partitionable* if $|V| = \alpha(G)\omega(G)+1$ and $\chi(G-v) = \omega(G)$ and $\overline{\chi}(G - v) = \alpha(G)$ for each $v \in V$. By Corollary 65.2b, each minimally imperfect graph is partitionable. As each partitionable graph is imperfect, the strong perfect graph theorem is equivalent to: each partitionable graph has an odd hole or odd antihole.

Partitionable graphs are characterized as follows[6]. Our proof of necessity is based on Gasparian [1996] (and is similar to the proof of Theorem 65.2).

Theorem 65.8. *A graph G is partitionable if and only if $|VG| = \alpha(G)\omega(G) + 1$ and each vertex is contained in exactly $\alpha(G)$ stable sets of size $\alpha(G)$ and in exactly $\omega(G)$ cliques of size $\omega(G)$.*

Proof. Define $n := |VG|$, $\alpha := \alpha(G)$, and $\omega := \omega(G)$.

I. To see necessity, let G be partitionable. Then the proof method of Theorem 65.2 applies: We again construct

(65.21) stable sets $S_0, \ldots, S_{\alpha\omega}$ such that each vertex is covered by exactly α of the S_i.

Indeed, let S_0 be a stable set in G of size α. For each vertex v, as G is partitionable, we know $\chi(G - v) = \omega$. Therefore, $VG \setminus \{v\}$ can be partitioned into ω stable sets. Doing this for each $v \in S_0$, we obtain stable sets as in (65.21).

Next, for each $i = 0, \ldots, \alpha\omega$, there exists a clique C_i of size ω with $C_i \cap S_i = \emptyset$. To see this, choose $v \in S_i$. As G is partitionable, $\chi(\overline{G}-v) = \alpha$, and hence $VG\setminus\{v\}$ can be partitioned into α cliques. Since $n = \alpha\omega + 1$, each clique has size ω. Since $|S_i \setminus \{v\}| \leq \alpha - 1$, at least one of these cliques is disjoint from S_i.

Then, for distinct i, j with $0 \leq i, j \leq \alpha\omega$, we have $|C_i \cap S_j| = 1$. This follows from the fact that C_i has size ω and intersects each S_j in at most one vertex, and hence, by (65.21), C_i intersects $\alpha\omega$ of the S_j. As $C_i \cap S_i = \emptyset$, we have that $|C_i \cap S_j| = 1$ if $i \neq j$.

Now consider the $(\alpha\omega+1) \times n$ incidence matrices M and N of $S_0, \ldots, S_{\alpha\omega}$ and $C_0, \ldots, C_{\alpha\omega}$ respectively. So M and N are $\{0, 1\}$ matrices, with $M_{i,j} = 1 \iff j \in S_i$, and $N_{i,j} = 1 \iff j \in C_i$, for $i = 0, \ldots, \alpha\omega$ and $j = 1, \ldots, n$. By the above, $MN^{\mathsf{T}} = J - I$, where J is the $(\alpha\omega + 1) \times (\alpha\omega + 1)$ all-1 matrix, and I the $(\alpha\omega + 1) \times (\alpha\omega + 1)$ identity matrix. So M and N are nonsingular.

It then suffices (by symmetry) to show that each maximum-size clique C occurs among $C_0, \ldots, C_n$. Now $(M\chi^C)_i$ is 1 if $|C \cap S_i| = 1$, and is 0 otherwise. As $|C| = \omega$ and as each $v \in V$ belongs to exactly α of the S_i, C intersects precisely $\alpha\omega$ of the S_i. That is, there is exactly one, say S_j, disjoint from C. Hence $M\chi^C = M\chi^{C_j}$, and therefore $C = C_j$, as M is nonsingular.

[6] Necessity of the condition for minimally imperfect graphs was shown by Padberg [1974a], and for partitionable graphs in general by Bland, Huang, and Trotter [1979]. As to sufficiency, Cameron [1982] referred to private communication with A. Lubiw in 1981, and Whitesides [1982] called it ‘well known’.

II. To see sufficiency, let G satisfy the condition. As each vertex of G is in exactly α stable sets of size α, there are exactly n maximum-size stable sets. Similarly, there are exactly n maximum-size cliques.

Let M and N be the incidence matrix of the maximum-size stable sets and maximum-size cliques, respectively. We can order the rows such that $MN^{\mathsf{T}} = J - I$, where J is the all-one $n \times n$-matrix, and I the identity matrix of order n. To see this, each maximum-size stable set S intersects precisely $\alpha\omega$ maximum-size cliques, since $|S| = \alpha$ and each vertex $v \in S$ is in precisely ω maximum-size cliques. Hence there is a unique maximum-size clique C disjoint from S. Similarly, for each maximum-size clique C there is a unique maximum-size stable set S disjoint from C.

So $MN^{\mathsf{T}} = J - I$, implying

(65.22)
$$\begin{aligned} M(J-I)N^{\mathsf{T}} &= MJN^{\mathsf{T}} - MN^{\mathsf{T}} = \alpha JN^{\mathsf{T}} - (J-I) = \alpha\omega J - J + I \\ &= nJ - 2J + I = (J-I)(J-I) = MN^{\mathsf{T}}MN^{\mathsf{T}}. \end{aligned}$$

Since M and N^{T} are nonsingular, this implies $N^{\mathsf{T}}M = J - I$.

Now choose $v \in V$. As $N^{\mathsf{T}}M = J - I$, for each $u \in V \setminus \{v\}$ there exists a unique pair of a maximum-size clique C_u and a maximum-size stable set S_u with $u \in C_u$, $v \in S_u$, and $C_u \cap S_u = \emptyset$. Then for each $w \in C_u$ we have $C_w = C_u$, since $w \in C_u$ and $v \in S_u$. So the C_u partition $V \setminus \{v\}$, and hence $\chi(\overline{G} - v) = \alpha$. Then also $\chi(G - v) = \omega$ by symmetry. ∎

A partitionable graph G with $\alpha(G) = \alpha$ and $\omega(G) = \omega$, is also called an (α, ω)-*graph.*

The proof of Theorem 65.8 also implies the following further properties of partitionable graphs (properties (i)-(iii) were proved for minimally imperfect graphs by Padberg [1974a] and for partitionable graphs by Bland, Huang, and Trotter [1979]; property (iv) was shown by Whitesides [1982]):

Theorem 65.9. *Let G be a partitionable graph with n vertices. Then:*

(65.23)
(i) *G contains exactly n maximum-size cliques and exactly n maximum-size stable sets;*
(ii) *the matrix N formed by the incidence vectors of the maximum-size cliques is nonsingular, and the matrix M formed by the incidence vectors of the maximum-size stable sets is nonsingular;*
(iii) *each maximum-size clique intersects all but one maximum-size stable sets, and each maximum-size stable set intersects all but one maximum-size cliques;*
(iv) *for any two distinct vertices u, v of G there is a unique pair of a maximum-size clique C and a maximum-size stable set S with $u \in C$, $v \in S$, and $C \cap S = \emptyset$.*

Proof. See the proof of Theorem 65.8. ∎

Notes. One may show that $|\det M| = \alpha(G)$ and $|\det N| = \omega(G)$ for any partitionable graph. Indeed, since $M\mathbf{1} = \alpha(G) \cdot \mathbf{1}$, we have that $M^{-1}\mathbf{1} = \alpha(G)^{-1} \cdot \mathbf{1}$. Hence $\alpha(G)$ divides $\det M$ (as $(\det M) \cdot M^{-1}$ is an integer matrix). Similarly, $\omega(G)$ divides $\det N$. Now $|\det M \cdot \det N| = |\det(MN^{\mathsf{T}})| = |\det(J - I)| = |VG| - 1 = \alpha(G)\omega(G)$. So $|\det M| = \alpha(G)$ and $|\det N| = \omega(G)$.

Shepherd [1994b] showed that a graph G is partitionable if and only if for some $p, q \geq 2$ with $|VG| = pq + 1$: (i) G has a family of $|VG|$ stable sets of size p such that each vertex is in precisely p of them, and (ii) G has no stable set S of size p that intersects each clique of size q. A polynomial-time recognition algorithm of partitionable graphs was given by Shepherd [2001].

65.6b. More characterizations of perfect graphs

It is not difficult to show that for any partitionable graph G one has:

(65.24) $$\chi^*(G) = \omega(G) + \frac{1}{\alpha(G)}.$$

Indeed, let $n := |VG|$, $\alpha := \alpha(G)$, $\omega := \omega(G)$, $\chi^* := \chi^*(G)$. To see $\geq$, observe that the vector $\alpha^{-1} \cdot \mathbf{1}$ satisfies all stable set inequalities (64.34), and hence $\chi^* \geq n\alpha^{-1} = \omega + \alpha^{-1}$. To see $\leq$, give each stable set of size α a value α^{-1}. This gives a fractional colouring of size $\omega + \alpha^{-1}$. So $\chi^* \leq \omega + \alpha^{-1}$, proving (65.24).

Hence perfect graphs can be characterized by:

Theorem 65.10. *A graph G is perfect $\iff$ $\chi^*(G')$ is an integer for each induced subgraph G' of G.*

Proof. See above. ∎

Berge [1973a] gave the following further characterization of perfect graphs. For any graph $G = (V, E)$, let $\chi_2(G)$ denote the *bicolouring number* of G, being the minimum number of stable sets $S_1, \ldots, S_t$ such that each vertex is in two of the S_i. Alternatively, it is the minimum number of colours such that we can assign to each vertex a pair of colours in such a way that any two adjacent vertices get two disjoint pairs of colours.

Theorem 65.11. *A graph G is perfect if and only if $\chi_2(G') = 2\chi(G')$ for each induced subgraph G' of G.*

Proof. To see necessity, we have $2\omega(G) \leq \chi_2(G) \leq 2\chi(G)$ for each graph G. Hence if G is perfect, then $\omega(G) = \chi(G)$, and hence $\chi_2(G) = 2\chi(G)$. As perfection is closed under taking induced subgraphs, necessity of the condition follows.

To see sufficiency, let G be a minimally imperfect graph. Consider two nonadjacent vertices u and v. Then $\chi_2(G) \leq \chi(G - u) + \chi(G - v) + 1$ (as we can take $\{u, v\}$ as a colour). Since, by the condition, $\chi_2(G) = 2\chi(G)$, we can assume, by symmetry, that $\chi(G) \leq \chi(G - u)$. Hence $\chi(G) \leq \chi(G - u) \leq \omega(G - u) \leq \omega(G)$, contradicting the fact that G is minimally imperfect. ∎

(This proof does not use the perfect graph theorem.)

65.6c. The stable set polytope of minimally imperfect graphs

The following theorem of Padberg [1976] is a direct consequence of the strong perfect graph conjecture, but we give a direct proof (we adapt the proof of Seymour [1990b]):

Theorem 65.12. *Let $G = (V, E)$ be a minimally imperfect graph. Then the polytope determined by*

(65.25) (i) $x_v \geq 0$ for $v \in V$,
(ii) $x(C) \leq 1$ for each clique C,

has precisely one noninteger vertex, namely $\omega^{-1} \cdot \mathbf{1}$, where $\omega := \omega(G)$.

Proof. Let $G = (V, E)$ be a minimally imperfect graph, and let x^* be a noninteger vertex of the polytope determined by (65.25). Set $n := |V|$.

First we have that

(65.26) $x^*_v > 0$ for each vertex v.

For suppose that $x^*_v = 0$. Then $x^*|V \setminus \{v\}$ is a noninteger vertex of the polytope (65.25) for $G - v$, contradicting the perfection of $G - v$ (by Corollary 65.2e). This proves (65.26).

Let $\mathcal{C}$ be a collection of cliques C such that $x^*(C) = 1$ for each $C \in \mathcal{C}$ and such that $\{\chi^C \mid C \in \mathcal{C}\}$ is a set of n linearly independent vectors. For $v \in V$, let $\mathcal{C}_v$ denote the collection of $C \in \mathcal{C}$ with $v \in C$. Then:

(65.27) $|\mathcal{C}_v| \leq \omega$ for each $v \in V$.

To see this, consider any $v \in V$ and any $C \in \mathcal{C} \setminus \mathcal{C}_v$. Since $G - v$ is perfect, the vector $x^*|V \setminus \{v\}$ is a convex combination $\sum_S \lambda_S \chi^S$ of stable sets S in $G - v$. For each $u \in C$, choose a stable set S_u with $u \in S_u$ and $\lambda_{S_u} > 0$. Then $|C' \cap S_u| = 1$ for each $C' \in \mathcal{C} \setminus \mathcal{C}_v$ (since $(x^*|V \setminus \{v\})(C') = 1$). So the incidence vectors χ^{S_u} for $u \in C$ are linearly independent. This implies that the vectors $\chi^{S_u} - x^*$ for $u \in C$ have rank at least $|C| - 1$. As each of these vectors is orthogonal to $\chi^{C'}$ for each $C' \in \mathcal{C} \setminus \mathcal{C}_v$, we have

(65.28) $|\mathcal{C} \setminus \mathcal{C}_v| \leq (n - 1) - (|C| - 1) = n - |C|$.

Let U be the set of vertices not covered by all cliques in $\mathcal{C}$. Then:

(65.29)
$$\begin{aligned} n &= \sum_{C \in \mathcal{C}} 1 = \sum_{C \in \mathcal{C}} \sum_{v \in V \setminus C} \frac{1}{n - |C|} = \sum_{v \in U} \sum_{C \in \mathcal{C} \setminus \mathcal{C}_v} \frac{1}{n - |C|} \\ &\leq \sum_{v \in U} \sum_{C \in \mathcal{C} \setminus \mathcal{C}_v} \frac{1}{|\mathcal{C} \setminus \mathcal{C}_v|} = \sum_{v \in U} 1 = |U| \leq n. \end{aligned}$$

So we have equality throughout; that is, $U = V$ and $|\mathcal{C} \setminus \mathcal{C}_v| = |V| - |C|$ for each $v \in V$ and each $C \in \mathcal{C} \setminus \mathcal{C}_v$. This gives equality in (65.28). So $|\mathcal{C}_v| = |C| \leq \omega$, proving (65.27).

Let $\mathcal{C}'$ denote the collection of maximum-size cliques in G. By Theorem 65.9, each $v \in V$ is in precisely ω sets in $\mathcal{C}'$. Hence

(65.30)
$$\begin{aligned} n &= \sum_{C \in \mathcal{C}} 1 = \sum_{C \in \mathcal{C}} x^*(C) = \sum_{v \in V} |\mathcal{C}_v| x^*_v \leq \omega \sum_{v \in V} x^*_v = \sum_{C \in \mathcal{C}'} x^*(C) \\ &\leq \sum_{C \in \mathcal{C}'} 1 = n. \end{aligned}$$

Hence we have equality throughout. Therefore, x^* satisfies $x^*(C) = 1$ for each maximum-size clique C. Hence $x^* = \omega^{-1} \cdot \mathbf{1}$. ∎

By the antiblocking relation, Theorem 65.12 implies that the stable set polytope of a minimally imperfect graph has precisely one facet not given by the clique and nonnegative constraints:

Corollary 65.12a. *Let $G = (V, E)$ be a minimally imperfect graph. Then the stable set polytope of G is determined by:*

(65.31)
$$\begin{aligned} &x_v \geq 0 &&\text{for } v \in V,\\ &x(C) \leq 1 &&\text{for each clique } C,\\ &x(V) \leq \alpha(G). && \end{aligned}$$

Proof. Directly from Theorem 65.12 applied to the antiblocking polytope of the polytope determined by (65.25) (for $\overline{G}$). ∎

Shepherd [1990,1994b] calls a graph *near-perfect* if its stable set polytope is determined by (65.31), and he showed that a graph G is minimally imperfect if and only if both G and its complement $\overline{G}$ are near-perfect.

65.6d. Graph classes

Before a proof of the strong perfect graph theorem in general was announced in 2002, it had been proved for several classes of graphs. Next to the classes to be discussed in Chapter 66, it was shown for (among other):

- *claw-free graphs*, that is, graphs not having $K_{1,3}$ (a *claw*) as induced subgraph (Parthasarathy and Ravindra [1976] (cf. Tucker [1979] and Maffray and Reed [1999], and Giles and Trotter [1981] for a simpler proof)).
  It follows that the line graph $L(G)$ of a graph G is perfect if and only if G contains no odd circuit with at least five vertices as (not necessarily induced) subgraph. So these graphs have edge-colouring number $\chi'(G)$ equal to the maximum degree $\Delta(G)$ (if $\Delta(G) \geq 3$); moreover, the matching number $\nu(G)$ is equal to the minimum number of stars and triangles needed to cover the edges of G; this extends Kőnig's edge-colouring and matching theorems (cf. Trotter [1977] and de Werra [1978]).
  Sbihi [1978,1980] and Minty [1980] showed that the weighted stable set problem is solvable in strongly polynomial time for claw-free graphs (see Chapter 69). A combinatorial polynomial-time algorithm for the colouring problem for claw-free perfect graphs was given by Hsu [1981], and for the weighted clique and clique cover problems by Hsu and Nemhauser [1981,1982,1984].
  Chvátal and Sbihi [1988] gave a polynomial-time algorithm to recognize claw-free perfect graphs, based on decomposition (cf. Maffray and Reed [1999]). Koch [1979] gave a polynomial-time algorithm which for any claw-free graph either finds a maximum-size stable set and a minimum-size clique cover of equal cardinalities, or else finds an odd hole or odd antihole.
  Perfection of line graphs was also studied by Cao and Nemhauser [1998]. The validity of the strong perfect graph conjecture for claw-free graphs was extended to 'pan-free' graphs by Olariu [1989b].
- *K_4-free graphs* — graphs not having K_4 as subgraph (Tucker [1977b], cf. Tucker [1979,1987a]).

- *diamond-free graphs* (Tucker [1987b][7]) — graphs not having $K_4 - e$ (a *diamond*) as induced subgraph (where $K_4 - e$ is the graph obtained from K_4 by deleting an edge) (Conforti [1989] gave an alternative proof). Tucker [1987b] gave an $O(n^2m)$-time algorithm to colour such graphs optimally. Fonlupt and Zemirline [1987] and Conforti and Rao [1993] gave polynomial-time perfection tests for diamond-free graphs. Related results can be found in Conforti and Rao [1989, 1992a,1992b] and Fonlupt and Zemirline [1992,1993].
- *paw-free graphs* — graphs not having a *paw* (a K_4 with two incident edges deleted) as induced subgraph. This follows from the perfection of Meyniel graphs (Theorem 66.6). It also follows from a characterization of Olariu [1988e] of paw-free graphs.
- *square-free graphs* (Conforti, Cornuéjols, and Vušković [2002]) — graphs not having a C_4 (a *square*) as induced subgraph.
- *bull-free graphs* (Chvátal and Sbihi [1987]) — graphs not having a *bull* as induced subgraph, where a bull is the (self-complementary) graph on five vertices a, b, c, d, e and edges ab, ac, bc, bd, ce (see Figure 65.1). Reed and Sbihi [1995] gave a polynomial-time perfection test for bull-free graphs. More on bull-free graphs can be found in de Figueiredo [1995], de Figueiredo, Maffray, and Porto [1997,2001], and Hayward [2001].
- *chair-free graphs* (Sassano [1997]) — graphs not having a *chair* as induced subgraph, where a chair is the graph on five vertices a, b, c, d, e and edges ab, bc, cd, be (see Figure 65.1).
- *dart-free graphs* (Sun [1991]) — graphs not having a *dart* as induced subgraph (a dart is a graph with vertices a, b, c, d, e and edges ab, ac, ad, ae, bc, cd (see Figure 65.1)); Chvátal, Fonlupt, Sun, and Zemirline [2000,2002] gave a polynomial-time recognition algorithm for dart-free perfect graphs.
- graphs having neither P_5 nor K_5 as induced subgraph (Maffray and Preissmann [1994], Barré and Fouquet [1999]).
- *circular-arc graphs* (Tucker [1975]) — these are the intersection graphs of families of intervals on a circle (cf. Section 64.9a).
- *circle graphs* (Buckingham and Golumbic [1984]) — these are the intersection graphs of families of chords of a circle (cf. Section 64.9a).
- planar graphs (Tucker [1973b]). Tucker [1984b] showed that this can be derived (without appealing to the four-colour theorem) from the validity of the strong perfect graph conjecture for K_4-free graphs: a K_4 subgraph in a planar graph $G \neq K_4$ contains a triangle that is a vertex-cut of G; hence one can apply induction to find a 4-colouring of G.
  Tucker and Wilson [1984] gave an $O(n^2)$ algorithm for finding a minimum colouring of a planar perfect graph, Hsu [1987b] gave an $O(n^3)$-time perfection test for planar graphs, and Hsu [1988] described strongly polynomial-time algorithms for the maximum-weight stable set, the weighted colouring, and the weighted clique cover problems for planar perfect graphs.
- graphs embeddable in the torus or in the Klein bottle (Grinstead [1980,1981]).
- *checked graphs* (Gurvich and Temkin [1992]) — graphs whose vertex set is a subset of $\mathbb{R}^2$, two vertices being adjacent if and only the line segment connecting them is horizontal or vertical.

[7] An partial proof was given by Parthasarathy and Ravindra [1979], cf. Tucker [1987b].

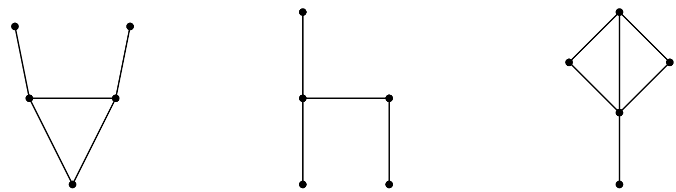

Figure 65.1

The perfect graph theorem implies that the strong perfect graph conjecture is true also for the classes of graphs complementary to those listed above.

Since C_k and $\overline{C}_k$ (for odd $k \geq 5$) are claw-free, the result of Parthasarathy and Ravindra [1976] implies that, to show the strong perfect graph theorem, it suffices to show that each minimally imperfect graph is claw-free.

Other classes of graphs for which the strong perfect graph conjecture holds were found by Rao and Ravindra [1977], Olariu [1988d], Jamison and Olariu [1989b], Carducci [1992], Galeana-Sánchez [1993], Lê [1993b], De Simone and Galluccio [1994], Maire [1994b], Maffray and Preissmann [1995], Xue [1995,1996], Ait Haddadene and Gravier [1996], Maffray, Porto, and Preissmann [1996], Aït Haddadène and Maffray [1997], Kroon, Sen, Deng, and Roy [1997], Babaĭtsev [1998], Hoàng and Le [2000b, 2001], and Gerber and Hertz [2001].

65.6e. The P_4-structure of a graph and a semi-strong perfect graph theorem

V. Chvátal noticed that the collection of 4-sets inducing the 4-vertex path P_4 as a subgraph, provides a useful tool in studying perfection. (Note that $\overline{P_4}$ is isomorphic to P_4.) It led Chvátal [1984a] to conjecture the following 'semi-strong perfect graph theorem', which was proved by Reed [1987] (announced in Reed [1985]).

Call two graphs G and H, with $VG = VH$, *P_4-equivalent* if for each $U \subseteq V$ one has: U induces a P_4-subgraph of G if and only if U induces a P_4-subgraph of H. Then Reed's theorem states that

(65.32) if G and H are P_4-equivalent and G is perfect, then H is perfect.

This theorem implies the perfect graph theorem, since G and $\overline{G}$ are P_4-equivalent. On the other hand, the theorem is implied by the strong perfect graph theorem, since any graph P_4-equivalent to an odd circuit of length at least 5 is equal to that circuit or to its complement.

Other relations between the P_4-structure and perfection were proved by Chvátal and Hoang [1985] and Chvátal, Lenhart, and Sbihi [1990]. Let $G = (V, E)$ be a graph and let V be partitioned into classes V_0 and V_1, with both $G[V_0]$ and $G[V_1]$ perfect. For each word $x = x_1x_2x_3x_4$ of length 4 over the alphabet $\{0, 1\}$, let $\mathcal{Q}_x$ denote the set of chordless paths in G with vertices v_1, v_2, v_3, v_4 (in order) with $v_i \in V_{x_i}$ for $i = 1, 2, 3, 4$. Then G is perfect if:

(65.33) (i) $\mathcal{Q}_{1000} = \mathcal{Q}_{0100} = \mathcal{Q}_{0111} = \mathcal{Q}_{1011} = \emptyset$, or

(ii) $\mathcal{Q}_{0000} = \mathcal{Q}_{0110} = \mathcal{Q}_{1001} = \mathcal{Q}_{1111} = \emptyset$, or
(iii) $\mathcal{Q}_{1000} = \mathcal{Q}_{0100} = \mathcal{Q}_{0110} = \mathcal{Q}_{1001} = \mathcal{Q}_{1111} = \emptyset$, or
(iv) $\mathcal{Q}_{1000} = \mathcal{Q}_{0101} = \mathcal{Q}_{0110} = \mathcal{Q}_{1001} = \mathcal{Q}_{1111} = \emptyset$, or
(v) $\mathcal{Q}_{1000} = \mathcal{Q}_{0101} = \mathcal{Q}_{0110} = \mathcal{Q}_{1001} = \mathcal{Q}_{0111} = \emptyset$, or
(vi) $\mathcal{Q}_{1000} = \mathcal{Q}_{1001} = \mathcal{Q}_{1011} = \emptyset$.

Sufficiency of (i) was shown by Chvátal and Hoang [1985], and of the other cases by Chvátal, Lenhart, and Sbihi [1990] ((ii) also by Gurvich [1993a,1993b]), who also showed that (65.33) essentially covers all cases where perfection of G follows from perfection of its constituents and the 'colouring' of the P_4-subgraphs. In fact, (65.33) and its symmetrical cases (interchanging V_0 and V_1 and/or replacing G by $\overline{G}$) describe exactly the cases excluded by G or $\overline{G}$ being an odd chordless circuit of length ≥ 5 or its complement.

A theorem of Seinsche [1974] states that each graph without an induced P_4 subgraph is perfect. (This follows from the perfection of Meyniel graphs (Theorem 66.6).[8])

Hence, case (65.33)(ii) implies the result of Hoang [1985] that any graph is perfect if there is a set U of vertices having an odd intersection with each chordless path with 4 vertices. More generally, it implies perfection of any graph if there is a set U of vertices such that each induced P_4 subgraph has exactly one of its two middle vertices in U or has exactly one of its ends in U.

Related (and more general than the results of Chvátal and Hoang quoted above) is the following theorem of Chvátal [1987a]. Let $G = (V, E)$ be a graph and let V be partitioned into two classes X and Y such that there are no $x \in X$, $y \in Y$, and $U \subseteq V$ such that both $U \cup \{x\}$ and $U \cup \{y\}$ induce a P_4 subgraph. Then G is perfect if and only if $G[X]$ and $G[Y]$ are perfect.

More work on the P_4-structure related to perfection is reported in Jung [1978], Jamison and Olariu [1989c,1992a,1992b,1995a,1995b], Hayward and Lenhart [1990], Hoàng [1990,1995,1999], Olariu [1991], Ding [1994], Rusu [1995a,1999b], Giakoumakis [1996], Hoàng, Hougardy, and Maffray [1996], Hougardy [1996b,1997,1999, 2001], Babel and Olariu [1997,1998,1999], Giakoumakis, Roussel, and Thuillier [1997], Giakoumakis and Vanherpe [1997], Hougardy, Le, and Wagler [1997], Babel [1998a,1998b], Babel, Brandstädt, and Le [1999], Brandstädt and Le [1999,2000], Roussel, Rusu, and Thuillier [1999], Brandstädt, Le, and Olariu [2000], Hoàng and Le [2000a,2001], Barré [2001], and Hayward, Hougardy, and Reed [2002].

65.6f. Further notes on the strong perfect graph conjecture

Markosyan and Karapetyan [1984] showed that the strong perfect graph conjecture is equivalent to: each minimally imperfect graph G is regular of degree $2\omega(G) - 2$.

For $k, n \in \mathbb{Z}_+$, let $C_{n,k}$ be the graph obtained from the circuit C_n (with n vertices) by adding all edges connecting two vertices at distance less than k. If $n \equiv 1 \pmod{k+1}$ and $n \geq 2k + 3$, then $C_{n,k}$ is partitionable. Chvátal [1976] showed that the strong perfect graph conjecture is equivalent to: each minimally imperfect graph G has $C_{|VG|,\omega(G)}$ as *spanning* subgraph (not necessarily induced).

[8] Arditti and de Werra [1976] claimed that Seinsche's result also follows from the 'fact' that any graph without induced P_4 subgraph is the comparability graph of a branching, therewith overlooking C_4.

Bland, Huang, and Trotter [1979] and Chvátal, Graham, Perold, and Whitesides [1979] gave examples of partitionable graphs G not containing $C_{|VG|,\omega(G)}$ as a spanning subgraph. Sebő [1996a] and Bacsó, Boros, Gurvich, Maffray, and Preissmann [1998] showed that these constructions give no counterexamples to the strong perfect graph conjecture. Related results are given by Chvátal [1984b]. A computer search for partitionable graphs was reported by Lam, Swiercz, Thiel, and Regener [1980].

Call a pair of vertices u, v in a graph an *even pair* if each induced $u - v$ path has even length. Meyniel [1987] showed that a minimally imperfect graph has no even pair. (This was extended to partitionable graphs by Bertschi and Reed [1987].) Hougardy [1996a] proved that the strong perfect graph conjecture is equivalent to: each properly induced subgraph of a minimally imperfect graph has an even pair or is a clique. Bienstock [1991] showed that it is NP-complete to test if a graph has no even pair. More on even pairs can be found in Hoàng and Maffray [1989], Bertschi [1990], Hougardy [1995], Rusu [1995c], Everett, de Figueiredo, Linhares-Sales, Maffray, Porto, and Reed [1997] (survey), Linhares Sales, Maffray, and Reed [1997], Linhares Sales and Maffray [1998], de Figueiredo, Gimbel, Mello, and Szwarcfiter [1999], Rusu [2000], and Everett, de Figueiredo, Linhares Sales, Maffray, Porto, and Reed [2001] (survey).

Prömel and Steger [1992] showed that 'almost all Berge graphs are perfect': the ratio of the number of n-vertex perfect graphs and the number of n-vertex Berge graphs, tends to 1 if $n \to \infty$.

The role of uniquely colourable perfect graphs for the strong perfect graph conjecture was investigated by Tucker [1983b]. Bacsó [1997] studied the conjecture that a uniquely colourable perfect graph G is either a clique or contains two maximum-size cliques intersecting each other in $\omega(G) - 1$ vertices. This is implied by the strong perfect graph theorem. Related work was given by Sakuma [2000].

Corneil [1986] investigated families of graphs 'complete' for the strong perfect graph conjecture (that is, proving the conjecture for these graphs suffices to prove the conjecture in general).

Equivalent versions of the strong perfect graph conjecture were given by Olaru [1972,1973b], Ravindra [1975], Markosyan [1981], Markosyan and Gasparyan [1987], Olariu [1990b], Huang [1991], Markosian, Gasparian, and Markosian [1992], Galeana-Sánchez [1993], De Simone and Galluccio [1994], Lonc and Zaremba [1995], and Padberg [2001].

Giles, Trotter, and Tucker [1984], Hsu [1984], Fonlupt and Sebő [1990], Croitoru and Radu [1992b], Sebő [1992], Panda and Mohanty [1997], and Rusu [1997] gave further techniques for proving the strong perfect graph conjecture.

Several other properties of minimally imperfect and partitionable graphs were derived by Olaru [1969,1972,1973a,1973b,1977,1980,1993,1998], Sachs [1970], Padberg [1974a,1974b,1975,1976], Parthasarathy and Ravindra [1976], Tucker [1977b, 1983a], Olaru and Suciu [1979], Markosyan [1981,1985], Sridharan and George [1982], Whitesides [1982], Buckingham and Golumbic [1983], Chvátal [1984c,1985c], Grinstead [1984], Olaru and Sachs [1984], Chvátal and Sbihi [1987], Meyniel [1987], Olariu [1988b,1988c,1990a,1991], Meyniel and Olariu [1989], Preissmann [1990], Sebő [1992,1996a,1996b], Cornuéjols and Reed [1993], Hougardy [1993], Maffray [1993], Olariu and Stewart [1993], Hayward [1995], Hoàng [1996c], Perz and Zaremba [1996], Fouquet, Maire, Rusu, and Thuillier [1997], Gasparyan [1998], Barré and Fouquet [1999,2001], Croitoru [1999], de Figueiredo, Klein, Kohayakawa, and Reed [2000], Barré [2001], Roussel and Rubio [2001], and Conforti, Cornuéjols, Gasparyan, and Vušković [2002]. Surveys were given by Preissmann and Sebő [2001] and Cornuéjols [2002].

65.7. Further results and notes

65.7a. Perz and Rolewicz's proof of the perfect graph theorem

An interesting proof of the perfect graph theorem was given by Perz and Rolewicz [1990]. It does not use the replication lemma, and is based on linear algebra, in a manner different from the proof of Gasparian given in Section 65.2, namely on the value of determinants.

In fact, Perz and Rolewicz [1990] show (in a different but equivalent terminology) that a graph $G = (V, E)$ is perfect if and only if $P_{\text{stable set}}(G)$ and $P_{\text{clique}}(G)$ form an antiblocking pair of polytopes. They prove sufficiency in a way similar to the proof of Fulkerson given for sufficiency in Corollary 65.2e above.

They proved necessity as follows. Choose a counterexample with $|V|$ minimal. So G is perfect, and $P_{\text{stable set}}(G)$ and $P_{\text{clique}}(G)$ do not form an antiblocking pair. Hence there exist $x \in A(P_{\text{stable set}}(G))$ and $y \in A(P_{\text{clique}}(G))$ with $x^{\mathsf{T}}y > 1$. Choose such x, y with $x^{\mathsf{T}}y$ maximal. Let $\nu := x^{\mathsf{T}}y$.

We first show

(65.34) $$\nu \leq \frac{n}{n-1},$$

where $n := |V|$. Indeed, for each $u \in V$, deleting the uth component of x and y, we obtain vectors in $A(P_{\text{stable set}}(G - u))$ and $A(P_{\text{clique}}(G - u))$, respectively. By the minimality of G, we have $\sum_{v \neq u} x_v y_v \leq 1$. Hence

(65.35) $$\nu = \sum_v x_v y_v = \frac{1}{n-1} \sum_u \Big(\sum_{v \neq u} x_v y_v \Big) \leq \frac{n}{n-1}.$$

This proves (65.34). By the minimality of G, we also have $x_v > 0$ and $y_v > 0$ for each v.

Now $\nu^{-1} \cdot x \in P_{\text{clique}}(G)$, since otherwise there is a $z \in A(P_{\text{clique}}(G))$ with $\nu^{-1}x^{\mathsf{T}}z > 1$, contradicting the maximality of $x^{\mathsf{T}}y$. So there exist cliques $C_1, \ldots, C_n$ and $\lambda_1, \ldots, \lambda_n > 0$ such that

(65.36) $$x = \sum_{i=1}^{n} \lambda_i \chi^{C_i} \text{ and } \sum_{i=1}^{n} \lambda_i = \nu.$$

Similarly, there exist stable sets $S_1, \ldots, S_n$ and $\mu_1, \ldots, \mu_n > 0$ such that

(65.37) $$y = \sum_{j=1}^{n} \mu_j \chi^{S_j} \text{ and } \sum_{j=1}^{n} \mu_j = \nu.$$

Then $y(C_i) = 1$ for $i = 1, \ldots, n$, since $y(C_i) \leq 1$ (as $y \in A(P_{\text{clique}}(G))$), and

(65.38) $$\nu = x^{\mathsf{T}}y = \sum_{i=1}^{n} \lambda_i y(C_i) \leq \sum_{i=1}^{n} \lambda_i = \nu.$$

Similarly, $x(S_j) = 1$ for $j = 1, \ldots, n$.

Consider, for some $i = 1, \ldots, n$,

(65.39) $$1 = y(C_i) = \sum_{j=1}^{n} \mu_j |C_i \cap S_j| \leq \sum_{j=1}^{n} \mu_j = \nu.$$

So the inequality is strict, and hence there is at least one j with $C_i \cap S_j = \emptyset$. Then

(65.40) $$1 = x(S_j) = \sum_{i'} \lambda_{i'} |C_{i'} \cap S_j| = \sum_{i' \neq i} \lambda_{i'} |C_{i'} \cap S_j| \leq \sum_{i' \neq i} \lambda_{i'} = \nu - \lambda_i.$$

Hence with (65.34),

(65.41) $$n \leq \sum_{i} (\nu - \lambda_i) = n\nu - \nu \leq n,$$

implying equality in (65.40) for each i. So if $C_i \cap S_j = \emptyset$, then $C_{i'} \cap S_j \neq \emptyset$ for each $i' \neq i$. Hence for each j, there is exactly one i with $C_i \cap S_j = \emptyset$, and conversely. We can assume that $C_i \cap S_j = \emptyset$ if and only if $i = j$.

Let M and N be the incidence matrices of $S_1, \ldots, S_n$ and of $C_1, \ldots, C_n$ respectively. So $MN^{\mathsf{T}} = J - I$. Hence $|\det M \det N| = |\det(J - I)| = n - 1$. Since $y(S_i) = 1$ for each i, we have $My = \mathbf{1}$. So $y' := |\det M| \cdot y$ is a positive integer vector. Similarly, $x' := |\det N| \cdot x$ is a positive integer vector. Then

(65.42) $$(x')^{\mathsf{T}} y' = |\det M \det N| x^{\mathsf{T}} y = |\det(J - I)| \nu = n.$$

The kernel of the argument now is that this implies that x' and y' are the all-one vectors, and therefore x and y each are scalar multiples of the all-one vector.

As $x \in A(P_{\text{stable set}}(G))$, $x(S) \leq 1$ for any stable set S, and hence $x = \alpha'^{-1} \cdot \mathbf{1}$ for some $\alpha' \geq \alpha(G)$. Similarly, $y = \omega'^{-1} \cdot \mathbf{1}$ for some $\omega' \geq \omega(G)$. As G is perfect, $\alpha'\omega' \geq \alpha(G)\omega(G) \geq n$. Hence $\nu = x^{\mathsf{T}} y = (\alpha'\omega')^{-1} n \leq 1$, a contradiction.

65.7b. Kernel solvability

The following generalization of the Gale-Shapley theorem on stable matchings was conjectured by Berge and Duchet [1986,1988a][9] and proved by Boros and Gurvich [1996], using a technique from game theory due to Scarf [1967]. With the strong perfect graph theorem it characterizes perfect graph by being kernel solvable.

Call a graph $G = (V, E)$ *kernel solvable* if the following holds: if for each clique C of G we have a total order $<_C$ of C, then there exists a stable set S such that for each $v \in V$ there is an $s \in S$ and a clique C such that $v, s \in C$ and $v \leq_C s$. Berge and Duchet conjectured that kernel solvable graphs are precisely the perfect graphs. With Theorem 65.14 below, this conjecture is implied by the strong perfect graph theorem.

Kernel solvability can be formulated equivalently in terms of kernels of digraphs. A *kernel* of a directed graph $D = (V, A)$ is a subset S of V such that S spans no arc of D and such that for each $v \in V \setminus S$ there is a $u \in S$ with $(v, u) \in A$.

For any graph $G = (V, E)$, a directed graph $D = (V, A)$ is called a *superorientation* of G if $E = \{\{u, v\} \mid (u, v) \in A\}$. (So $\{u, v\}$ is an edge of $G \iff$ at least

[9] Berge and Duchet [1986] refer to 'Séminaire du Lundi, MSH, Paris, Janvier 1983' (Monday Seminar, MSH, Paris, January 1983). See Jensen and Toft [1995] p. 140 for further references to the history of this conjecture.

one of (u, v) and (v, u) belongs to A.) Then a graph $G = (V, E)$ is kernel solvable if and only if any superorientation D of G has a kernel if each clique C of G induces a subgraph of D with a kernel.

Kernel solvability is closed under taking induced subgraphs: if $U \subseteq V$, and each clique C of $G[U]$ has a total order $<_C$, we can choose for each clique C of G a total order which coincides with $<_{C\cap U}$ on $C \cap U$ and which has $C \cap U$ as upper ideal.

Since neither C_k nor $\overline{C}_k$ is kernel solvable for odd $k \geq 5$, the strong perfect graph theorem implies that each kernel solvable graph is perfect.

Boros and Gurvich [1996] proved that a graph G is perfect if and only if each graph H arising from G by replicating vertices is kernel solvable. It implies that the strong perfect graph theorem is equivalent to: each Berge graph is kernel solvable (since the class of Berge graphs is closed under replicating vertices).

To show that each perfect graph is kernel solvable, we follow the proof method of Aharoni and Holzman [1998]. We first prove the following results of Scarf [1967].

Let M and N be disjoint finite nonempty sets, and for each $i \in M$ let $<_i$ be a total order of N. For any U, write $y <_i U$ if $y <_i u$ for each $u \in U$. Define $K := M \cup N$.

Call a subset L of K *light* if for each $j \in N$ there is an $i \in M\setminus L$ with $j \leq_i L\setminus M$. So any subset of a light set is light again. Let $m := |M|$ and define

(65.43) $$\mathcal{S} := \{M\} \cup \{L \mid L \text{ light}, |L| = m\}.$$

Note that M is not light.

Now Scarf first proved:

Lemma 65.13α. *Any light set L with $|L| = m - 1$ is contained in precisely two sets in $\mathcal{S}$.*

Proof. Extend each $<_i$ to a total order on K, with $i <_i j <_i i'$ for all $j \in N$ and all $i' \in M \setminus \{i\}$. Then

(65.44) any subset L of K is light if and only if for each $k \in K$ there is an $i \in M$ with $k \leq_i L$.

To see necessity in (65.44), let $L \subseteq K$ be light and let $k \in K$. If $k \in M$, then $k \leq_k L$. If $k \in N$, then there is an $i \in M \setminus L$ with $k \leq_i L \setminus M$. As $i \notin L$, we have also $k \leq_i L \cap M$ (since $k \leq_i M \setminus \{i\}$). So $k \leq_i L$.

To see sufficiency in (65.44), suppose $\forall k \in K \exists i \in M : k \leq_i L$. Let $j \in N$. Then $\exists i \in M : j \leq_i L$. Then $i \notin L$ (as otherwise $j \leq_i i$). Moreover, $j \leq_i L \setminus M$. This proves (65.44).

For any $i \in M$ and any nonempty $U \subseteq K$, let $\min_i U$ and $\max_i U$ denote the minimal and maximal element of U with respect to $<_i$.

First assume that $L \subseteq M$, say $L = M \setminus \{i\}$. Then L is contained in M, which belongs to $\mathcal{S}$. Moreover, $z := \max_i N$ is the unique element with $L \cup \{z\}$ light.[10] This proves the lemma.

So henceforth we can assume that $L \not\subseteq M$. Define $\pi : M \to L$ by $\pi(i) := \min_i L$. Then π is onto, since, as L is light, for each $r \in L$ there is an $i \in M$ with $r \leq_i L$. So $r = \min_i L = \pi(i)$.

[10] For let $x \in N$. Then $L \cup \{x\}$ is light $\iff$ $\forall j \in N \exists i \in M \setminus L : j \leq_i (L \cup \{x\}) \setminus M$ $\iff$ $\forall j \in N : j \leq_i x$ $\iff$ $x = \max_i N$.

Hence, as $|L| = |M| - 1$, there exist distinct $i_1, i_2 \in M$ with $\pi(i_1) = \pi(i_2)$, while all other values of π are mutually distinct and different from $\pi(i_1)$.

For $h = 1, 2$, define

(65.45) $$R_h := \{k \in K \mid k \not\leq_i L \text{ for all } i \neq i_h\}.$$

Then $R_h \neq \emptyset$, since $i_h \in R_h$, as there is an $r \in L \setminus M$ (as $L \not\subseteq M$), hence if $i \neq i_h$, then $i_h \not\leq_i r$. Also, $R_h \cap L = \emptyset$, since if $r \in L$, there is an $i \neq i_h$ with $\pi(i) = r$, so $\min_i L = r$, implying $r \leq_i L$, and hence $r \notin R_h$. Moreover, $R_1 \cap R_2 = \emptyset$, since otherwise there is a $k \in K$ with $k \not\leq_i L$ for all $i \in M$, contradicting the fact that L is light.

Define for $h = 1, 2$:

(65.46) $$r_h := \max_{i_h} R_h.$$

We first show that $L \cup \{r_1\}$ and $L \cup \{r_2\}$ are light. Suppose that (say) $L \cup \{r_1\}$ is not light. So there is a $k \in K$ with $k \not\leq_i L \cup \{r_1\}$ for each $i \in M$. Since $r_1 \not\leq_i L$ for each $i \neq i_1$ (by definition of R_1), it follows that $k \not\leq_i L$ for each $i \neq i_1$. Hence $k \in R_1$. However, $r_1 <_{i_1} L$, since $r_1 \in R_1$ and $r_1 \leq_i L$ for some $i \in M$. So $k \leq_{i_1} r_1 <_{i_1} L$, and therefore $k \leq_{i_1} L \cup \{r_1\}$, a contradiction. So $L \cup \{r_1\}$ and $L \cup \{r_2\}$ are light.

Finally we show that for any $s \in K \setminus L$, if $L \cup \{s\}$ is light, then $s = r_1$ or $s = r_2$. So let $L \cup \{s\}$ be light. Then the function $\pi' : M \to L \cup \{s\}$ defined by $\pi'(i) := \min_i(L \cup \{s\})$ is onto (as $L \cup \{s\}$ is light), implying that it is one-to-one (as $|M| = |L \cup \{s\}|$). Hence π' coincides with π on all but one element of M. Necessarily the exceptional element belongs to $\{i_1, i_2\}$. Say $\pi'(i) = \pi(i)$ for each $i \neq i_1$, while $\pi'(i_1) = s$. So $\min_i L = \pi(i) = \pi'(i) <_i s$ for each $i \neq i_1$; that is, $s \in R_1$. Suppose $s \neq r_1$. So $s <_{i_1} r_1$. Then $r_1 \not\leq_i L \cup \{s\}$ for each $i \in M$, contradicting the fact that $L \cup \{s\}$ is light. ∎

From this, Scarf derived:

Theorem 65.13 (Scarf's lemma). *Let A be a nonnegative $m \times n$ matrix and let $b \in \mathbb{R}^m_+$ be such that the polytope $P := \{x \in \mathbb{R}^n_+ \mid Ax \leq b\}$ is nonempty and bounded. For each $i = 1, \ldots, m$, let $<_i$ be a total order on $\{1, \ldots, n\}$. Then P has a vertex x such that*

(65.47) *for each $j \in \{1, \ldots, n\}$ there is an $i \in \{1, \ldots, m\}$ such that $a_i^{\mathsf{T}} x = b_i$ and such that $x_k = 0$ for each $k <_i j$.*

Proof. We can assume, by slightly perturbing b, that for each vertex x of P there are precisely n constraints among $x \geq \mathbf{0}$, $Ax \leq b$ satisfied with equality. Add n to each index i of $<_i$. (So $x <_{n+i} y$ in the new notation $\iff$ $x <_i y$ in the old notation.) Let $N := \{1, \ldots, n\}$, $M := \{n+1, \ldots, n+m\}$, and $K := N \cup M$. For each face f of P define

(65.48) $K_f := \{k \in K \mid$ the kth constraint in $x \geq \mathbf{0}$, $Ax \leq b$ is not tight at some point in $f\}$.

So $|K_v| = m$ for any vertex v and $|K_e| = m + 1$ for any edge e. Call an edge e of P *good* if $1 \in K_e$ and the set $K_e \setminus \{1\}$ belongs to $\mathcal{S}$ (cf. (65.43)).

Now $\mathbf{0}$ is incident with precisely one good edge. Hence there is a vertex $v \neq \mathbf{0}$ incident with an odd number of good edges. We show that $K_v \in \mathcal{S}$, and hence K_v is light (since $K_v \neq M$, as $v \neq \mathbf{0}$), implying that v satisfies (65.47).

Let e be a good edge incident with v. Then $K_e = K_v \cup \{k\}$ for some k. As e is good, we know that $1 \in K_e$ and $K_e \setminus \{1\} \in \mathcal{S}$.

If $1 \notin K_v$, then $k = 1$ and hence $K_v \in \mathcal{S}$. So we can assume that $1 \in K_v$. Applying Lemma 65.13α to the light set $K_v \setminus \{1\}$, there is precisely one $j \notin K_v \setminus \{1\}$ with $j \neq k$ and $K_v \setminus \{1\} \cup \{j\} \in \mathcal{S}$. If $j \neq 1$, then v is incident with precisely two good edges, a contradiction. So $j = 1$, and hence $K_v \in \mathcal{S}$. ∎

This implies the theorem of Boros and Gurvich [1996]:

Corollary 65.13a. *A perfect graph is kernel solvable.*

Proof. Let $G = (V, E)$ be a perfect graph, and for each clique C, let $<_C$ be a total order on C. We must prove that

(65.49) there exist a stable set S such that for each $v \in V$ there is a clique C and an element $s \in C \cap S$ with $v \in C$ and $v \leq_C s$.

Extend each $<_C$ to a total order on V with $w <_C v$ for each $w \in C$, $v \in V \setminus C$. Then by Theorem 65.13, the polytope in $\mathbb{R}^V$ determined by $x \geq \mathbf{0}$, $x(C) \leq 1$ (C clique), has a vertex x such that for each $v \in V$ there is a clique C with $x(C) = 1$ and such that $x_u = 0$ for each $u <_C v$. By Corollary 65.2e, x is the incidence vector of some stable set S. So for each $v \in V$ there is a clique C with $|C \cap S| = 1$ and with $u \notin S$ if $u <_C v$. Therefore, for the vertex s in $C \cap S$ we have $v \leq_C s$, and hence $v \in C$. This shows (65.49). ∎

It was conjectured by Berge and Duchet that conversely, each kernel solvable graph is perfect. This follows from the strong perfect graph theorem, since kernel solvability is closed under taking induced subgraphs and since odd circuits of length at least five and their complements are not kernel solvable.

It implies the following theorem found by Boros and Gurvich [1996], for which we give a direct proof. A graph H is called a *blow-up* of a graph G, if H arises from G by replicating vertices (replacing vertices by cliques).

Theorem 65.14. *A graph G is perfect if and only if each blow-up of G is kernel solvable.*

Proof. Since each blow-up of a perfect graph is perfect again (by the replication lemma (Corollary 65.2c)), necessity follows from Corollary 65.13a.

Sufficiency is shown by proving that each graph $G = (V, E)$ with $|V| \geq \alpha(G)\omega(G) + 1$ has a blow-up that is not kernel solvable. (This is sufficient by Theorem 65.2.)

Let $\mathcal{C}$ be the collection of cliques in G, and for each vertex v, let $\mathcal{C}_v$ be the collection of cliques containing v. Let $n := |V|$ and define

(65.50) $Y := \{y : \mathcal{C} \to \mathbb{Z}_+ \mid y(\mathcal{C}) \leq n|\mathcal{C}|\}.$

For each $y \in Y$, we choose a vertex v_y of G with

(65.51) $y(\mathcal{C}_{v_y}) \leq \omega(G)|\mathcal{C}|.$

This is possible since

(65.52) $$\sum_{v\in V} y(\mathcal{C}_v) = \sum_{C\in\mathcal{C}} |C| y_C \leq \omega(G) \sum_{C\in\mathcal{C}} y_C \leq \omega(G) n |\mathcal{C}|.$$

Let H be the graph with vertex set Y, two distinct vertices $y, z \in Y$ being adjacent if $v_y = v_z$ or v_y and v_z are adjacent in G. So H is a blow-up of G. We show that H is not kernel solvable.

For each clique $K \subseteq Y$ of H, the set $C := \{v_y \mid y \in K\}$ is a clique of G. Then choose a total order $<_K$ on K such that for all $y, z \in K$:

(65.53) if $y_C < z_C$, then $y <_K z$.

Assume that H is kernel solvable. Then H has a stable set $Z \subseteq Y$ such that for each $y \in Y$ there is a $z \in Z$ and a clique K of H with $y, z \in K$ and $y \leq_K z$. As Z is stable in H, the v_z for $z \in Z$ are distinct and form a stable set S in G. So for each clique C of G there is at most one $z \in Z$ with $v_z \in C$. Define $y : \mathcal{C} \to \mathbb{Z}_+$ by:

(65.54) $$y_C := \begin{cases} z_C + 1 & \text{if } v_z \in C, \text{ for } z \in Z, \\ 0 & \text{if } C \cap S = \emptyset. \end{cases}$$

Then y belongs to Y, since

(65.55) $$\begin{aligned} y(\mathcal{C}) &= \sum_{z\in Z} \sum_{C\in\mathcal{C}_{v_z}} (z_C + 1) = \sum_{z\in Z} (z(\mathcal{C}_{v_z}) + |\mathcal{C}_{v_z}|) \leq |Z|\omega(G)|\mathcal{C}| + |\mathcal{C}| \\ &\leq (\alpha(G)\omega(G) + 1)|\mathcal{C}| \leq n|\mathcal{C}|. \end{aligned}$$

(The first inequality follows from (65.51).) Hence there exist a $z \in Z$ and a clique K of H with $y, z \in K$ and $y \leq_K z$. So for $C := \{v_x \mid x \in K\}$ we have, by (65.53), $y_C \leq z_C$. Since $v_z \in C$ (as $z \in K$), this contradicts (65.54). ∎

Before the strong perfect graph conjecture was settled, and hence the conjecture of Berge and Duchet, partial and related results on the latter conjecture were obtained by Blidia [1986], Maffray [1986,1992], Duchet [1987], Berge and Duchet [1988b,1990], Champetier [1989], Blidia and Engel [1992], Blidia, Duchet, and Maffray [1993,1994], Chilakamarri and Hamburger [1993], and Galeana-Sánchez [1995, 1996,1997].

65.7c. The amalgam

A composition generalizing the 1-join, the *amalgam*, was shown to preserve perfection by Burlet and Fonlupt [1984]. Let $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ be perfect graphs such that $K := V_1 \cap V_2$ is a clique in both graphs. For $i = 1, 2$, let $v_i \in V_i \setminus K$ be such that each vertex in K is adjacent to v_i and to each neighbour of v_i. Let H be the graph on $(V_1 \setminus \{v_1\}) \cup (V_2 \setminus \{v_2\})$ obtained from the union of $G_1 - v_1$ and $G_2 - v_2$ by adding all edges between $N(v_1) \setminus K$ and $N(v_2) \setminus K$.

Theorem 65.15. *If G_1 and G_2 are perfect, then H is perfect.*

Proof. It suffices to show that $\omega(H) = \chi(H)$, since each induced subgraph of H arises by the same construction.

For $i = 1, 2$, let $p_i := \omega(G_i[N(v_i)])$ and let G_i' be the graph obtained from G_i by replicating v_i by a factor $\omega(H) - p_i$. So $\omega(G_i') = \omega(H)$. By the replication lemma, G_i' is perfect. Hence $\omega(H) = \chi(G_i')$.

Consider colourings of G_1' and G_2' with colours $1, \ldots, \omega(H)$. So $N(v_i)$ uses precisely p_i colours. As $p_1 + p_2 - |K| \leq \omega(H)$, we have $(\omega(H) - p_1) + (\omega(H) - p_2) \geq \omega(H) - |K|$. Hence we can assume that in G_1 and G_2 the colourings of K are the same, and that all colours are used by the replication vertices of v_1 and v_2 and by K. Then $N(v_1) \setminus K$ and $N(v_2) \setminus K$ have no colours in common. Hence we obtain an $\omega(H)$-colouring of H. ∎

Cornuéjols and Cunningham [1985] gave an $O(n^2m)$-time algorithm to decide if a graph is the amalgam of smaller graphs.

Perfection is trivially closed under 'clique sums', that is, identifying two cliques in two graphs. Whitesides [1981] gave an $O(nm)$ algorithm to find a clique cut in a graph, that is, a vertex-cut that is a clique. Tarjan [1985] gave an $O(nm)$-time algorithm to find for any graph a decomposition by clique cuts.

Fonlupt and Uhry [1982] gave conditions under which identification of two vertices in a graph maintains perfection. Ravindra and Parthasarathy [1977], Ravindra [1978], Mândrescu [1991], and Kwaśnik and Szelecka [1997] investigated the behaviour of perfection under taking (various) products of graphs.

More on the (de)composition of perfect graphs can be found in Hsu [1986,1987a], Conforti and Rao [1992a,1992b], Corneil and Fonlupt [1993], Burlet and Fonlupt [1994], and Conforti, Cornuéjols, Kapoor, and Vušković [1995].

65.7d. Diperfect graphs

Berge [1982a] introduced a directed variant of perfect graphs. In fact, there are two symmetric variants, as no complementary phenomenon holds in the directed case.

A *stable set* or *clique* in a directed graph is a stable set of clique in the underlying undirected graph. A directed graph $D = (V, A)$ is called *α-diperfect* if for every induced subgraph $D' = (V', A')$ of D and for each maximum-size stable set S in D' there is a partition of V' into directed paths each intersecting S in exactly one vertex.

Then:

(65.56) if the underlying undirected graph G of D is perfect, then D is α-diperfect.

Indeed, if G is perfect, there is a maximum-size stable set S and a partition of V into cliques each intersecting S. Each clique C gives a tournament on C in D, and hence, by Rédei's theorem (Corollary 14.14a), it contains a directed path spanning C.

Another class of α-diperfect digraphs is formed by the *symmetric* digraphs: directed graphs $D = (V, A)$ such that if $(u, v) \in A$, then $(v, u) \in A$:

(65.57) each symmetric digraph is α-diperfect.

To see this, let S be a maximum-size stable set in D, and let D' arise from D by deleting all arcs entering S. By the Gallai-Milgram theorem (Theorem 14.14), V can be partitioned into $|S|$ directed paths in D'. These paths are as required.

Berge offered the following conjecture characterizing α-diperfect digraphs:

(65.58) (?) A directed graph $D = (V, A)$ is α-diperfect if and only if D has no induced subgraph C whose underlying undirected graph is a chordless odd circuit of length ≥ 5, say with vertices $v_1, \ldots, v_{2k+1}$ (in order) such that each of $v_1, v_2, v_3, v_4, v_6, v_8, \ldots, v_{2k}$ is a source or a sink. (?)

The odd circuit described is not α-diperfect, since $\{v_1, v_4, v_6, v_8, \ldots, v_{2k}\}$ is a maximum-size stable set, but there are no directed paths as required.

A 'dual' concept is that of a χ-*diperfect* graph, which is a digraph $D = (V, A)$ such that for each induced subgraph $D' = (V', A')$ of D and for each minimum vertex-colouring (in the underlying undirected graph of D') there exists a directed path intersecting each colour exactly once.

Again one has:

(65.59) if the underlying undirected graph G of D is perfect, then D is χ-diperfect.

Indeed, any maximum-size clique C intersects each colour in each minimum vertex-colouring, and, again by Rédei's theorem (Corollary 14.14a), there is a path spanning C.

Also:

(65.60) any symmetric digraph is χ-diperfect.

To see this, let $S_1, \ldots, S_k$ be an optimum vertex-colouring. Let D' be the graph obtained from D by deleting all arcs from S_j to S_i for all $j > i$. By the theorem of Gallai and Roy (see (64.52)), D' has a directed path of length k. Necessarily, it intersects each S_i exactly once.

One may show that the odd undirected circuit described in (65.58) is not χ-diperfect. So conjecture (65.58) would imply that each χ-diperfect digraph is α-diperfect.

In fact, any odd undirected circuit that contains three consecutive vertices v_1, v_2, v_3 that are sources or sinks, is not χ-diperfect (since there is an optimum 3-vertex-colouring where $\{v_2\}$ is one of the colours — hence v_2 should belong to a directed path with 3 vertices). In particular, the undirected circuit with vertices $v_1, \ldots, v_7$ and arcs

(65.61) $(v_1, v_2), (v_3, v_2), (v_3, v_4), (v_4, v_5), (v_5, v_6), (v_6, v_7), (v_1, v_7)$

is α-diperfect but not χ-diperfect (cf. Figure 65.2).

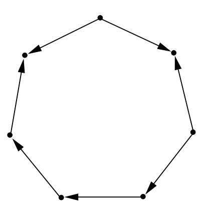

Figure 65.2

65.7e. Further notes

Cameron, Edmonds, and Lovász [1986] showed that if the edges of a complete graph are coloured with three colours such that no triangle gets three different colours, and two of these colours form perfect graphs, then so does the third. (This generalizes the perfect graph theorem.) A generalization and a related characterization of perfection in terms of decomposition was given by Cameron and Edmonds [1997].

Markosyan and Karapetyan [1976] characterize perfection with the help of *critical edges* (edges e with $\alpha(G-e) > \alpha(G)$) and *essential edges* (edges e with $\chi(G-e) > \chi(G)$). More on such edges can be found in Markosyan [1975], Karapetyan [1976], Sebő [1996a], and Markossian, Gasparian, Karapetian, and Markosian [1998]. Edge-minimal perfect graphs are studied by Wagler [1999], colouring perfect 'degenerate' graphs by Aït Haddadène and Maffray [1997], 'Gallai graphs' and 'anti-Gallai graphs' by Le [1993a,1996b], and 'edge perfect graphs' by Müller [1996].

An alternative polyhedral characterization of perfection of graphs was given by Zaremba and Perz [1982]. Related is the work of Zaremba [1991] and Hujter [1999].

Chandrasekaran and Tamir [1984] and Cook, Fonlupt, and Schrijver [1986] showed that, for any perfect graph $G = (V, E)$ and any weight $w : V \to \mathbb{Z}_+$, the weighted colouring number is attained by a weighted colouring using at most $|V|$ different stable sets.

Von Rimscha [1983] showed that if $G = (V, E)$ and $H = (V, F)$ are graphs with $G - v$ isomorphic to $H - v$ for each $v \in V$, then G is perfect if and only if H is perfect.

Bienstock [1991] showed that it is NP-complete to decide if a given graph has an odd hole containing a prescribed vertex. More on the complexity of finding odd holes can be found in Reed [1990]. A survey on forbidding holes and antiholes was given by Hayward and Reed [2001].

Le [1996a] showed that if a graph G is imperfect and has no odd hole, then the intersection graph of the edge sets of chordless circuits in G has an odd hole. Akiyama and Chvátal [1990] characterized for which graphs $G = (V, E)$ the intersection graph of the triples spanning at least two edges, is perfect. Olaru and Mândrescu [1992] considered perfection of products of graphs, and de Werra and Hertz [1999] perfection of sums of graphs. Hertz [1998] characterized the graphs for which all graphs obtained by 'switching' are perfect.

Variants of the notion of perfect graph were studied by Kőrner [1973], Duchet [1980], Galeana-Sánchez [1982,1986,1988], Duchet and Meyniel [1983], Galeana-Sánchez and Neumann-Lara [1986,1991a,1991b,1994,1996,1998], Lehel and Tuza [1986], Conforti, Corneil, and Mahjoub [1987], Cameron [1989], Brown, Corneil, and Mahjoub [1990], Markosyan and Gasparyan [1990], Reed [1990], Scheinerman and Trenk [1990,1993], Berge [1992b,1992a,1995], Kőrner, Simonyi, and Tuza [1992], Lehel [1994], Trenk [1995], Cai and Corneil [1996], Markossian, Gasparian, and Reed [1996], Tamura [1997,2000], Gutin and Zverovich [1998], De Simone and Kőrner [1999], Huang and Guo [1999], Fachini and Kőrner [2000], and de Figueiredo and Vušković [2000].

Introductions to and surveys of perfect graphs are given by Berge [1973b,1975, 1986], Golumbic [1980], Lovász [1983b], Berge and Chvátal [1984] (a collection of papers on perfect graphs), Chvátal [1985b,1987b], Jensen and Toft [1995], Toft [1995], Ravindra [1997], Brandstädt, Le, and Spinrad [1999], and Ramírez Alfonsín and Reed [2001] (a collection of survey papers on perfect graphs). The latter reference includes a bibliography on perfect graphs by Chvátal [2001]. Applications of perfect graphs to graph entropy were surveyed by Simonyi [2001] (cf. Simonyi [1995]). Algorithmic aspects are discussed in Golumbic [1984].

We refer for historical remarks on perfect graphs to Section 67.4g.

Chapter 66

Classes of perfect graphs

In this chapter we consider classes of perfect graphs. The phenomenon observed by Berge that clique number and colouring number are equal for bipartite graphs, their line graphs, comparability graphs, and chordal graphs, and for their complements, formed the motivation for him to raise the conjecture that the complement of a perfect graph is perfect again ($\equiv$ perfect graph theorem).
The perfection of the graphs considered in this chapter follows directly from the strong perfect graph theorem. However, since its proof is highly complicated, we will give direct proofs of the perfection of several of these graphs.

66.1. Bipartite graphs and their line graphs

The perfect graph theorem can be used to prove several min-max relations on bipartite graphs: Kőnig's matching theorem, the Kőnig-Rado edge cover theorem, and Kőnig's edge colouring theorem.

We start from the trivial observation that:

Theorem 66.1. $\omega(G) = \chi(G)$ *for each bipartite graph* G.

Proof. Trivial. ∎

Since the class of bipartite graphs is closed under taking induced subgraphs, this gives:

Corollary 66.1a. *Each bipartite graph is perfect.*

Proof. See above. ∎

Hence, by the perfect graph theorem, also the complements of bipartite graphs are perfect. This amounts to the Kőnig-Rado edge cover theorem (Theorem 19.4):

Corollary 66.1b (Kőnig-Rado edge cover theorem)**.** *For any bipartite graph* G, $\alpha(G) = \overline{\chi}(G)$. *Equivalently, the stable set number of any bipartite graph (without isolated vertices) is equal to its edge cover number.*

Proof. Directly from the perfect graph theorem, since by Theorem 66.1, any bipartite graph is perfect. Note that if G is a bipartite graph, then its cliques have size at most 2; hence $\overline{\chi}(G)$ is equal to the edge cover number of G if G has no isolated vertices. ∎

We saw in Section 16.2 that by Gallai's theorem (Theorem 19.1), the Kőnig-Rado edge cover theorem implies Kőnig's matching theorem (Theorem 16.2), saying that the matching number of a bipartite graph G is equal to its vertex cover number. That is, the stable set number of the line graph $L(G)$ of G is equal to the minimum number of cliques of $L(G)$ that cover all vertices of $L(G)$; in notation:

(66.1) $$\alpha(L(G)) = \overline{\chi}(L(G)).$$

As this is true for any induced subgraph of $L(G)$ we know that the complement $\overline{L(G)}$ of the line graph $L(G)$ of any bipartite graph G is perfect.

Hence with the perfect graph theorem we know:

Corollary 66.1c. *The line graph of any bipartite graph is perfect.*

Proof. See above. ∎

This amounts to Kőnig's edge-colouring theorem (Theorem 20.1):

Corollary 66.1d (Kőnig's edge-colouring theorem)**.** *If G is the line graph of a bipartite graph, then $\omega(G) = \chi(G)$. Equivalently, the edge-colouring number of any bipartite graph is equal to its maximum degree.*

Proof. Again directly from Kőnig's matching theorem and the perfect graph theorem. ∎

Complexity. In Part II on bipartite matching and covering, we saw that the optimization problems corresponding to the perfect graph parameters are solvable in polynomial time, and their weighted versions are solvable in strongly polynomial time, mainly by utilizing network flow techniques. We review the results.

The maximum-weight clique and the minimum colouring problem for bipartite graphs are trivially solvable in strongly polynomial time. Also the weighted colouring problem for bipartite graphs is easily solvable in strongly polynomial time.

A maximum-size stable set and a minimum clique cover in a bipartite graph can be found in polynomial time (cf. Corollary 19.3a). Note that in bipartite graphs, the minimum clique cover problem amounts to the minimum-size edge cover problem. Also the weighted versions are solvable in strongly polynomial time by max-flow techniques (cf. Corollary 21.25a). In bipartite graphs, the minimum weighted clique cover problem amounts to the minimum-size b-edge cover problem.

A bipartite graph is easily recognized, by checking if there is no odd circuit.

In *line graphs of bipartite graphs*, finding a maximum-weight clique is trivial (by checking all stars of the graph). In Sections 20.1 and 20.2 we saw that a minimum weighted colouring can be found in strongly polynomial time.

Finding a maximum clique and a minimum colouring in the complement of the line graph of a bipartite graph G amounts to finding a maximum-size matching and a minimum-size vertex cover in G, which can be found in polynomial time (cf. Theorem 16.3 and Corollary 16.6a). Their weighted versions can be found in strongly polynomial time with the methods for the assignment and the minimum-cost flow problems (cf. Theorems 17.4 and 17.6).

Van Rooij and Wilf [1965] showed that line graphs of bipartite graphs can be recognized in polynomial time, and that the corresponding bipartite graph can be reconstructed in polynomial time.

66.2. Comparability graphs

Also Dilworth's decomposition theorem (Theorem 14.2) can be derived from the perfect graph theorem. Let $(V, \leq)$ be a partially ordered set. Let $G = (V, E)$ be the graph with:

(66.2) $uv \in E$ if and only if $u < v$ or $v < u$.

Any graph G obtained in this way is called a *comparability graph*.

In Theorem 14.1 we saw the following easy 'dual' form of Dilworth's decomposition theorem:

Theorem 66.2. *In any partially ordered set $(V, \leq)$, the maximum size of a chain is equal to the minimum number of antichains needed to cover V.*

Proof. For any $v \in V$ define the *height* of v as the maximum size of a chain in V with maximum element v. Let k be the maximum height of the elements of V. For $i = 1, \ldots, k$, let A_i be the set of elements of height i. Then $A_1, \ldots, A_k$ are antichains covering V, and moreover, there is a chain of size k, since there is an element of height k. ∎

Equivalently, we have $\omega(G) = \chi(G)$ for any comparability graph. As the class of comparability graphs is closed under taking induced subgraphs we have:

Corollary 66.2a. *Each comparability graph is perfect.*

Proof. Directly from Theorem 66.2. ∎

Hence, by the perfect graph theorem, also the complement of a comparability graph is perfect. This implies:

Corollary 66.2b (Dilworth's decomposition theorem)**.** *In any partially ordered set $(V, \leq)$, the maximum size of an antichain is equal to the minimum number of chains needed to cover V.*

Proof. Directly from Corollary 66.2a. ∎

Complexity. The optimization problems corresponding to the perfect graph parameters for comparability graphs can be solved in strongly polynomial time by path and flow techniques, as we saw in Chapter 14. With a greedy method, one can find a maximum-weight clique in a comparability graph $G = (V, E)$ with weight function $w : V \to \mathbb{Q}_+$ (if the underlying partial order $\leq$ is given): if all weights are 0, the problem is trivial; if there exist vertices of positive weights, find the set S of minimal elements of positive weight, let $\alpha := \min_{v \in S} w(v)$, reset $w(v) := w(v) - \alpha$ for $v \in S$, and find recursively a maximum-weight clique C for the new weights. Then we can assume that $C \cap S \neq \emptyset$. Hence C is also a maximum-weight clique for the original weight function.

This method also solves the weighted colouring problem in strongly polynomial time. An $O(n^2)$ algorithm for the weighted colouring problem for comparability graphs was given by Hoàng [1994]. The weighted stable set and clique cover problems can be solved in strongly polynomial time with flow techniques (see Chapter 14).

Trivially, recognizing comparability graphs belongs to NP (by giving the underlying partial order), and membership of co-NP follows from the characterizations of Ghouila-Houri [1962a,1964] and Gilmore and Hoffman [1964]. A method of Gallai [1967] implies that the problem in fact is polynomial-time solvable (cf. Pnueli, Lempel, and Even [1971], Golumbic [1977], Spinrad [1985], Muller and Spinrad [1989], and McConnell and Spinrad [1994,1997,1999] (the latter paper gives a linear-time recognition algorithm)).

Golumbic, Rotem, and Urrutia [1983] and Lovász [1983b] characterized complements of comparability graphs as those graphs that are the intersection graph of a family of continuous functions $f : (0, 1) \to \mathbb{R}$. (Here f and g *intersect* if $f(x) = g(x)$ for some $x \in (0, 1)$.)

Permutation graphs. A *permutation graph* is a graph on $\{1, \ldots, n\}$ for which there exists a permutation π of $\{1, \ldots, n\}$ such that $i, j \in \{1, \ldots, n\}$ are adjacent if and only if $(i-j)(\pi(i)-\pi(j)) > 0$. A graph G is (isomorphic to) a permutation graph if and only if both G and $\overline{G}$ are comparability graphs (Dushnik and Miller [1941] (also Even, Pnueli, and Lempel [1972])). McConnell and Spinrad [1997] showed that permutation graphs can be recognized in linear time (improving McConnell and Spinrad [1994]). Another characterization was given by Baker, Fishburn, and Roberts [1972].

The books by Even [1973] and Golumbic [1980] devote chapters to comparability graphs and to permutation graphs.

66.3. Chordal graphs

We next consider a further class of perfect graphs, the 'chordal graphs' (or 'rigid circuit graphs' or 'triangulated graphs'). A graph G is called *chordal* if each circuit in G of length at least 4 has a chord. (A *chord* is an edge connecting two vertices of the circuit that are nonadjacent in the circuit.) Equivalently, a graph is chordal if it has no hole.

For any set U of vertices, let $N(U)$ denote the set of vertices not in U that are adjacent to at least one vertex in U. Call a vertex v *simplicial* if $N(\{v\})$ is a clique in G.

Dirac [1961] showed the following basic property of chordal graphs:

Theorem 66.3. *Each chordal graph G contains a simplicial vertex.*

Proof. We may assume that G has at least two nonadjacent vertices a, b. Let U be a maximal nonempty subset of V with $G[U]$ connected and with $U \cup N(U) \neq V$. Such a subset U exists as $U := \{a\}$ induces a connected subgraph of G and as $\{a\} \cup N(\{a\}) \neq V$.

Let $W := V \setminus (U \cup N(U))$. Then each vertex v in $N(U)$ is adjacent to each vertex in W, since otherwise we could increase U by v. Moreover, $N(U)$ is a clique, for suppose that $u, w \in N(U)$ are nonadjacent. Choose $v \in W$. Let P be a shortest path in $U \cup N(U)$ connecting u and w. Then $P \cup \{u, v, w\}$ would form a chordless circuit of length at least 4, a contradiction.

Now inductively we know that $G[W]$ contains a vertex v that is simplicial in $G[W]$. Since $N(U)$ is a clique and since each vertex in W is adjacent to each vertex in $N(U)$, v is also simplicial in G. ∎

(The proof of Theorem 66.3 implies that, in a chordal graph, each vertex v that is nonadjacent to at least one vertex $w \neq v$, is nonadjacent to at least one simplicial vertex $w \neq v$. Hence each noncomplete chordal graph contains at least two nonadjacent simplicial vertices.)

As was observed by Fulkerson [1972a], Theorem 66.3 implies a result of Berge [1963a] (the result was announced (with partial proof) in Berge [1960a]):

Theorem 66.4. *Any chordal graph G satisfies $\omega(G) = \chi(G)$.*

Proof. By Theorem 66.3, G has a simplicial vertex v. By induction we have $\omega(G - v) = \chi(G - v)$. In particular, $G - v$ has an $\omega(G)$-vertex-colouring. As $|N(v)| \leq \omega(G) - 1$ (since $\{v\} \cup N(v)$ is a clique), we can extend this to an $\omega(G)$-vertex-colouring of G. ∎

As the class of chordal graphs is closed under taking induced subgraphs, this implies:

Corollary 66.4a. *Each chordal graph is perfect.*

Proof. Directly from Theorem 66.4. ∎

With the perfect graph theorem, this implies the following result of Hajnal and Surányi [1958] (which also can be derived directly from Theorem 66.3):

Corollary 66.4b. *For any chordal graph G, $\alpha(G) = \overline{\chi}(G)$.*

Proof. Directly from Corollary 66.4a and the perfect graph theorem (Corollary 65.2a). ∎

Complexity. Dirac's theorem (Theorem 66.3) can be used to obtain strongly polynomial-time algorithms for the basic optimization problems for chordal graphs. The proof of Theorem 66.4 yields such an algorithm to find an optimum colouring and clique, also for the weighted versions. Similarly, the strong polynomial-time solvability of the weighted stable set and clique cover problems can be derived (Gavril [1972], Frank [1976b]). $O(n^2)$ algorithms for minimum weighted colouring for chordal graphs were given by Balas and Xue [1991] and Hoàng [1994].

Dirac's theorem also directly gives a polynomial-time recognition algorithm for chordal graphs: iteratively find and delete a simplicial vertex until the graph is empty. Linear-time algorithms were given by Lueker [1974], Rose and Tarjan [1975], Rose, Tarjan, and Lueker [1976], and Tarjan and Yannakakis [1984]. (Gavril [1974b] gave another polynomial-time algorithm.)

Dirac's theorem also implies the following other characterizations of chordal graphs (Dirac [1961] (stated explicitly by Fulkerson and Gross [1965] and Rose [1970])):

(66.3) A graph $G = (V, E)$ is chordal $\iff$ each induced subgraph has a simplicial vertex $\iff$ G has an acyclic orientation $D = (V, A)$ such that if (u, v), $(u, w) \in A$, then $\{v, w\} \in E$.

Dirac [1961] moreover showed that a graph is chordal if and only if each inclusionwise minimal vertex-cut is a clique.

Interval graphs. An *interval graph* is the intersection graph G of a family $\mathcal{C}$ of nonempty intervals on the real line[11]. Trivially, such a graph is the complement of a comparability graph: define $I < J \iff i < j$ for all $i \in I$, $j \in J$. This gives a partial order, and the corresponding comparability graph is equal to $\overline{G}$.

Perfection of the complements of interval graphs was observed by T. Gallai (see Hajnal and Surányi [1958]) — that is, the maximum number of disjoint intervals in $\mathcal{C}$ is equal to the minimum number of points intersecting all intervals in $\mathcal{C}$. This is not hard to prove, and can be proved similarly to the easy dual of Dilworth's decomposition theorem (Theorem 14.1). In fact, a graph is an interval graph if and only if it is chordal and its complement is a comparability graph.

The clique, stable set, colouring, and clique cover problem and their weighted versions can be solved in strongly polynomial time with the methods for comparability graphs described above. If the intervals are given in the order of their maximal elements, and we consecutively assign to each interval the smallest available colour (numbering the colours $1, 2, \ldots$), we obtain an optimum colouring. (Kierstead [1988] showed that if we get the intervals in an *arbitrary* order and we assign to any given interval the smallest possible colour ('on-line'), then we need at most $40\chi(G)$ colours.)

In fact, for any clique C in G there is a point x such that all intervals in C contain x (by Helly's theorem: a family of pairwise intersecting intervals has a nonempty intersection). So finding a maximum-weight clique is trivial. A maximum-size stable

[11] The *intersection graph* of a family $\mathcal{C}$ is the graph with vertex set $\mathcal{C}$, two sets in $\mathcal{C}$ being adjacent if and only if they intersect.

set can be found by a greedy method: first find an interval $I \in \mathcal{C}$ with $\sup I$ minimal. Next find recursively a maximum-size stable set S among the intervals in $\mathcal{C}$ disjoint from I. Then $S \cup \{I\}$ is a maximum-size stable set in G.

In reply to questions of Hajós [1957] and Benzer [1959], interval graphs have been characterized by Lekkerkerker and Boland [1962] (cf. Halin [1982]), Gilmore and Hoffman [1964], and Fulkerson and Gross [1965]. The latter paper gives a polynomial-time recognition algorithm. A linear-time recognition algorithm was given by Booth and Lueker [1975,1976]. This was simplified by Korte and Möhring [1987], Corneil, Olariu, and Stewart [1998], Hsu and Ma [1999], and Hsu [2002].

More on interval graphs can be found in the books by Golumbic [1980], Skrien [1982], Fishburn [1985], and Brandstädt, Le, and Spinrad [1999], and in the survey article by Golumbic [1985].

Split graphs. A *split graph* is a graph $G = (V, E)$ where V can be partitioned into a clique C and a stable set S. Trivially, a split graph is perfect, since C is contained in a maximum-size clique; hence we can assume that C is a maximum-size clique; so for each $s \in S$ there is a $c \in C$ nonadjacent to s; this yields a $|C|$-vertex-colouring of G.

A graph G is a split graph if and only if both G and $\overline{G}$ are chordal graphs (Foldes and Hammer [1977], Hammer and Simeone [1981]). The book by Golumbic [1980] devotes a chapter to split graphs.

Trivially perfect graphs. Golumbic [1978] calls a graph *trivially perfect* if for each induced subgraph, the stability number is equal to the number of inclusion-wise maximal cliques. Trivially, each trivially perfect graph is perfect. Choudom, Parthasarathy, and Ravindra [1975] and Golumbic [1978] showed that a graph is trivially perfect if and only if it has no induced subgraph equal to the path P_4 or the circuit C_4 (each with 4 vertices). This implies (by a theorem of Wolk [1962] (proof simplified in Wolk [1965])) that a graph is trivially perfect if and only if it is the comparability graph coming from a branching. Another characterization of trivially perfect graphs was given by Alexe and Olaru [1997].

Threshold graphs. A *threshold graph* is a graph on vertex set V given by a function $w : V \to \mathbb{R}$, such that two distinct vertices u, v are adjacent if and only if $w(u)+w(v) > 0$. Chvátal and Hammer [1977] showed that a graph G is a threshold graph if and only if neither G nor $\overline{G}$ has an induced subgraph equal to the path P_4 or the circuit C_4 (each with 4 vertices) — that is, both G and $\overline{G}$ are trivially perfect.

Each threshold graph is a split graph (trivially) and a permutation graph (order the vertices as $v_1, \ldots, v_n$ such that $w(v_1) \leq w(v_2) \leq \cdots \leq w(v_n)$, and let π be the permutation given by ordering $|w(v_1)|, |w(v_2)|, \ldots, |w(v_n)|$). However, the path P_4 with 4 vertices is both a split graph and a permutation graph, but no threshold graph.

The book by Mahadev and Peled [1995] focuses on threshold graphs, and the book by Golumbic [1980] devotes a chapter to threshold graphs. A related class of graphs was described by Wang [1995,1996].

'Strongly chordal' graphs have been studied by Farber [1983,1984] and Kaplan and Shamir [1994], and an analogue of chordal graphs for bipartite graphs by Golumbic and Goss [1978].

66.3a. Chordal graphs as intersection graphs of subtrees of a tree

Chordal graphs can be characterized as intersection graphs of subtrees of a tree, as was shown by L. Surányi (see Gyárfás and Lehel [1970]) and also by Walter [1972, 1978], Buneman [1974], and Gavril [1974c].

Let $\mathcal{S}$ be a collection of nonempty subtrees of a tree T. The *intersection graph* of $\mathcal{S}$ is the graph with vertex set $\mathcal{S}$, where two vertices S, S' are adjacent if and only if S and S' have at least one vertex in common.

The class of graphs obtained in this way coincides with the class of chordal graphs. To see this, we first show the following elementary lemma:

Lemma 66.5α. *Let $\mathcal{S}$ be a collection of pairwise intersecting subtrees of a tree T. Then there is a vertex of T contained in all subtrees in $\mathcal{S}$.*

Proof. By induction on $|VT|$. If $|VT| = 1$ the lemma is trivial, so assume $|VT| \geq 2$. Let t be an end vertex of T. If there exists a subtree in $\mathcal{S}$ consisting only of t, the lemma is trivial. Hence we may assume that each subtree in $\mathcal{S}$ containing t also contains the neighbour of t. So deleting t from T and from all subtrees in $\mathcal{S}$ gives the lemma by induction. ∎

Then we have the subtree characterization of chordal graphs:

Theorem 66.5. *A graph is chordal if and only if it is isomorphic to the intersection graph of a collection of subtrees of some tree.*

Proof. *Necessity.* Let $G = (V, E)$ be chordal. By Theorem 66.3, G contains a simplicial vertex v. By induction, the graph $G - v$ is the intersection graph of a collection $\mathcal{S}$ of subtrees of some tree T. Let $\mathcal{S}'$ be the subcollection of $\mathcal{S}$ corresponding to the set N of neighbours of v in G. As N is a clique, $\mathcal{S}'$ consists of pairwise intersecting subtrees. Hence, by Lemma 66.5α, these subtrees have a vertex t of T in common. Now we extend T and all subtrees in $\mathcal{S}'$ with a new vertex s and a new edge st. Moreover, we introduce a new subtree $\{s\}$ representing v. In this way we obtain a subtree representation for G.

Sufficiency. Let G be the intersection graph of some collection $\mathcal{S}$ of subtrees of some tree T. By (66.3) it suffices to show that G has a simplicial vertex. Let s be an end vertex of T. If $\mathcal{S}$ contains a subtree only consisting of s, it gives a simplicial vertex in G. If $\mathcal{S}$ contains no such subtree, then each subtree in $\mathcal{S}$ containing s also contains the neighbour t (say) of s. So deleting s from T and from all subtrees in $\mathcal{S}$, does not modify the graph G. Hence we are done by induction. ∎

This theorem enables us to interpret the perfection of chordal graphs in terms of trees:

Corollary 66.5a. *Let $\mathcal{S}$ be a collection of nonempty subtrees of a tree T. Then the maximum number of pairwise vertex-disjoint trees in $\mathcal{S}$ is equal to the minimum number of vertices of T intersecting each tree in $\mathcal{S}$.*

Proof. Directly from Corollary 66.4b and Theorem 66.5, using Lemma 66.5α. ∎

(This result was also stated by Cockayne, Hedetniemi, and Slater [1979].)

Similarly we have:

Corollary 66.5b. *Let $\mathcal{S}$ be a collection of subtrees of a tree T. Let k be the maximum number of times that any vertex of T is covered by trees in $\mathcal{S}$. Then $\mathcal{S}$ can be partitioned into subcollections $\mathcal{S}_1, \ldots, \mathcal{S}_k$ such that each $\mathcal{S}_i$ consists of pairwise vertex-disjoint trees.*

Proof. Directly from Theorems 66.4 and 66.5, again using Lemma 66.5α. ∎

Variations of the problem of packing and covering a tree by subtrees were studied by Bárány, Edmonds, and Wolsey [1986]. More characterizations of chordal graphs were offered by Benzaken, Crama, Duchet, Hammer, and Maffray [1990]. More on chordal graphs can be found in the book of Golumbic [1980] and in Skrien [1982], Leung [1984], Seymour and Weaver [1984] (a generalization of chordal graphs), Lubiw [1987], Wallis and Wu [1995], and Nakamura and Tamura [2000] (a generalization to bidirected graphs).

66.4. Meyniel graphs

Markosyan and Karapetyan [1976] and Meyniel [1976] showed the perfection of graphs in which each odd circuit of length at least five has at least two chords (*Meyniel graphs*). This was conjectured by Olaru [1969,1972].

It implies the perfection of *Gallai graphs* — graphs in which each odd circuit of length at least five has two *noncrossing* chords (Gallai [1962], cf. Surányi [1968] for a shorter proof [12]), *parity graphs* — graphs in which each odd circuit of length at least five has two crossing chords (Olaru [1969,1972, 1977], cf. Sachs [1970]), and graphs that have no path P_4 as induced subgraph (Seinsche [1974]).

We follow the proof given by Lovász [1983b] (which is a simplification of Meyniel's original proof).

Theorem 66.6. *Each Meyniel graph is perfect.*

Proof. I. We first show that in a Meyniel graph $G = (V, E)$:

(66.4) for each odd circuit C and each vertex v on C, C has a chord disjoint from v or each vertex of $C - v$ is adjacent to v.

[12] Gallai [1962] published a proof that $\alpha(G) = \overline{\chi}(G)$ for graphs in which each odd circuit of length 5 has two noncrossing chords. Berge [1997] wrote that Gallai informed him in a letter that he knew that also $\omega(G) = \chi(G)$ holds for these graphs.

Let C have no chord disjoint from v. Then the subgraph of G induced by VC is outerplanar, with C as boundary. As each odd circuit of size at least five has a chord we know that each odd bounded face is a triangle. (A face is *odd* (*even*) if its is incident with an odd (even) number of edges.)

Moreover, as C is odd, there is at least one odd bounded face. So if v is not adjacent to all vertices of $C - v$, there is an even bounded face, neighbouring an odd bounded face. But then the union of these two faces forms an odd circuit with only one chord, contradicting the condition.

II. We now prove the theorem. It suffices to show that $\chi(G) = \omega(G)$ for any Meyniel graph $G = (V, E)$, as the class of Meyniel graphs is closed under taking induced subgraphs. We may assume that $V = \{1, \ldots, n\}$. Let $k := \chi(G)$.

For each colouring $\phi : V \to \{1, \ldots, k\}$, let the (ordered) clique $K_\phi = (v_1, \ldots, v_t)$ be obtained recursively as follows. If $v_1, \ldots, v_i$ have been determined (for $i \geq 0$), then v_{i+1} is the largest vertex of colour $i+1$ that is adjacent to each of $v_1, \ldots, v_i$. If no such vertex exists, we stop, setting $t := i$.

Let ϕ be a k-colouring with $K_\phi = (v_1, \ldots, v_t)$ lexicographically minimal. If $t = k$ we are done, so assume $t < k$. Consider the subgraph of G induced by the vertices coloured t and $t + 1$, and let H be its component containing v_t. Let ψ be the colouring obtained from ϕ by interchanging colours t and $t+1$ in H. We show that K_ψ is lexicographically less than K_ϕ, contradicting our assumption.

Trivially, $v_1, \ldots, v_{t-1}$ belong to K_ψ (since we did not change any of the colours $1, \ldots, t-1$). If no other vertex is in K_ψ we are done, so we can assume that K_ψ contains a vertex w with $\psi(w) = t$.

Then $w \neq v_t$, since $\psi(v_t) = t + 1$. If $w < v_t$ we are done, so we can assume that $w > v_t$. If $\phi(w) = t$, this contradicts the choice of $v_t \in K_\phi$. So $\phi(w) = t + 1$, and H contains a shortest path P from v_t to w. Necessarily, this path is odd, and has no chords.

Let u be the second vertex on P. So $\phi(u) = t + 1$. Since v_t is the last vertex in K_ϕ we know that there is an $i \in \{1, \ldots, t-1\}$ with v_i not adjacent to u. Let C be the circuit made by P, $v_i v_t$, and $v_i w$. As P has no chords, by (66.4) v_i is adjacent to u, a contradiction. ∎

Ravindra [1982] showed that each Meyniel graph is strongly perfect (see Section 66.5a below). This was extended by Hoàng [1987b], who showed that Meyniel graphs are precisely those graphs with the property that for each induced subgraph H and each vertex v of H, there exists a stable set in H containing v and intersecting all inclusionwise maximal cliques of H. (This was conjectured by Meyniel.)

Complexity. Burlet and Fonlupt [1984] showed that the class of Meyniel graphs is closed under amalgamation (see Section 65.7c) and that each Meyniel graph arises by amalgamation from chordal graphs and bipartite graphs added with one vertex connected to all vertices of the bipartite graph. They showed that it yields a polynomial-time recognition algorithm (speeded up by Roussel and Rusu [1999b]).

Hoàng [1987b] gave an $O(n^8)$-time algorithm to find a minimum colouring and a maximum clique. An $O(n^3)$ algorithm was given by Hertz [1990a].

(Conforti, Cornuéjols, Kapoor, and Vušković [1999] consider an extension by decomposing *cap-free* graphs (where a *cap* is a circuit with exactly one chord, connecting two vertices at distance two in the circuit) — a (not necessarily perfect) generalization of Meyniel graphs.)

Gallai graphs. As mentioned, these are graphs in which each odd circuit of length ≥ 5 has two noncrossing chords. Polynomial-time recognition algorithms were given by Burlet and Fonlupt [1984], Whitesides [1984], and Cicerone and Di Stefano [1999b] (linear-time). The latter paper also gives a linear-time maximum-weight clique algorithm. A linear-time colouring algorithm was found by Roussel and Rusu [1999a].

Parity graphs. As mentioned, these are graphs in which each odd circuit of length ≥ 5 has two crossing chords. Parity graphs can be characterized alternatively as those graphs such that for each pair u, v of vertices, all chordless $u - v$ paths have the same parity.

Combinatorial strongly polynomial-time algorithms to solve the weighted clique, stable set, colouring, and clique cover problems in parity graphs were given by Burlet and Uhry [1982], who also gave a polynomial-time recognition algorithm (by decomposition of the graph into smaller parity graphs).

The parity graphs include the *line-perfect graphs*, which are graphs whose line graph is perfect. They were characterized by Trotter [1977] — see the claw-free graphs in Section 65.6d. More on parity graphs can be found in Adhar and Peng [1990], Bandelt and Mulder [1991], Przytycka and Corneil [1991], Rusu [1995b], Jansen [1998], and Cicerone and Di Stefano [1999a].

66.5. Further results and notes

66.5a. Strongly perfect graphs

Following Berge and Duchet [1984], a graph $G = (V, E)$ is *strongly perfect* if each induced subgraph H has a stable set intersecting all inclusionwise maximal cliques of H. Each strongly perfect graph is perfect (by (65.2)). Berge and Duchet showed that comparability graphs, chordal graphs, and complements of chordal graphs are strongly perfect. Ravindra [1982] showed that Meyniel graphs are strongly perfect, and Chvátal [1984d] that perfectly orderable graphs are strongly perfect.

Berge and Duchet also showed that the recognition problem for strongly perfect graphs belongs to co-NP. No combinatorial polynomial-time algorithms are known for the optimization problems for strongly perfect graphs.

Olaru [1996] showed that the graphs that are both minimally strongly imperfect and imperfect are precisely the odd circuits of length at least five and their complements. Hence to prove the strong perfect graph theorem it suffices to show that each minimally imperfect graph is also minimally strongly imperfect.

More on strongly perfect graphs can be found in Ravindra [1981,1999], Berge [1983], Basavayya and Ravindra [1985,1987], Preissmann [1985], Preissmann and de Werra [1985], Olaru and Mîndrescu [1986a,1986b], Olaru [1987,1993], Ravindra and Basavayya [1988,1992,1994,1995], Olariu [1989a], Włoch [1995], Blidia, Duchet, and Maffray [1996], Szelecka and Włoch [1996], and Alexe and Olaru [1997].

66.5b. Perfectly orderable graphs

A graph $G = (V, E)$ is a *perfectly orderable graph* if it has an acyclic orientation $D = (V, A)$ such that if four vertices v_1, v_2, v_3, v_4 induce a chordless path in G with edges v_1v_2, v_2v_3, v_3v_4, then $(v_1, v_2) \in A$ or $(v_4, v_3) \in A$. Chvátal [1984d] showed that perfectly orderable graphs are perfect — in fact, strongly perfect:

Theorem 66.7. *Each perfectly orderable graph is strongly perfect.*

Proof. We can assume that $V = \{1, \ldots, n\}$ and that if $(i, j) \in A$, then $i < j$. Let S be the stable set with $\sum(2^{-i} \mid i \in S)$ maximal. Then each $v \notin S$ has a neighbour $u \in S$ with $u < v$, since otherwise $(S \setminus N(v)) \cup \{v\}$ is better than S.

We show that each inclusionwise maximal clique K intersects S. Suppose $K \cap S = \emptyset$. For $s \in S$, let K_s be the set of neighbours $v \in K$ with $s < v$. Choose $s \in S$ with $\sum(2^i \mid i \in K_s)$ maximal. As K is a maximal clique, s is nonadjacent to some $v \in K$. Let $u \in S$ be a neighbour of v with $u < v$. So $v \in K_u \setminus K_s$. By the choice of s, there is a vertex $i \in K_s \setminus K_u$ with $i > v$. So $u < v < i$, and hence u and i are nonadjacent (otherwise $i \in K_u$). As u and s are nonadjacent (since $u, s \in S$) and v and i are adjacent (since $v, i \in K$), u, v, i, s induce a P_4 subgraph with $(u, v), (v, i), (s, i) \in A$, a contradiction. ∎

(Another proof, and a generalization, of this was given by Duchet and Olariu [1991].)

Note that the set S in this proof can be found by a greedy method. So we can find an optimum colouring in polynomial time. Given an orientation as above, also a maximum-size clique can be found in a greedy way — see Chvátal [1984d]. Hoàng [1994] gave $O(nm)$-time algorithms, also for the weighted versions. Middendorf and Pfeiffer [1990a] showed that it is NP-complete to decide if a graph is perfectly orderable.

Comparability graphs, chordal graphs, and complements of chordal graphs are perfectly orderable.

More on perfectly orderable graphs can be found in Cochand and de Werra [1986], Preissmann, de Werra, and Mahadev [1986], Chvátal, Hoàng, Mahadev, and de Werra [1987], Lehel [1987], Hertz [1988,1990b], Hoàng and Khouzam [1988], Olariu [1988a,1993], Bielak [1989], Hoàng and Mahadev [1989], Hoàng and Reed [1989a,1989b], Jamison and Olariu [1989a], Chvátal [1990,1993], Hoàng, Maffray, and Preissmann [1991], Croitoru and Radu [1992a], Hoàng, Maffray, Olariu, and Preissmann [1992], Gavril, Toledano Laredo, and de Werra [1994], Arikati and Peled [1996], Giakoumakis [1996], Hoàng [1996a,1996b,2001], Rusu [1996], Hayward [1997a], Hoàng, Maffray, and Noy [1999], and Hoàng and Tu [2000].

More classes of graphs based on orienting or colouring edges are given by Hoàng [1987a].

66.5c. Unimodular graphs

A graph $G = (V, E)$ is *unimodular* if the following matrix M is totally unimodular: the columns are indexed by V and the rows are the incidence vectors of all inclusionwise maximal cliques of G. Any induced subgraph of a unimodular graph is unimodular again, since for each $v \in V$ and for each maximal clique C of $G - v$, either C or $C \cup \{v\}$ is a maximal clique of G.

Unimodular graphs include bipartite graphs, line graphs of bipartite graphs, and interval graphs.

Perfection of unimodular graphs and their complements was shown by Berge [1963a]. Perfection of the complements of unimodular graphs follows from the Hoffman-Kruskal theorem (Hoffman and Kruskal [1956]), since

(66.5) $$\alpha(G) = \max\{\mathbf{1}^{\mathsf{T}}x \mid x \geq \mathbf{0}, Mx \leq \mathbf{1}\} = \min\{y^{\mathsf{T}}\mathbf{1} \mid y \geq \mathbf{0}, y^{\mathsf{T}}M \geq \mathbf{1}\} = \chi(\overline{G}),$$

as the LP-optima are attained by integer vectors x and y.

The perfection of a unimodular graph $G = (V, E)$ can also be derived from the Hoffman-Kruskal theorem, with an idea which Berge [1963a] attributed to M.H. McAndrew. It suffices to find a stable set that intersects all maximum-size cliques. Let M' be the submatrix of M corresponding to the maximum-size cliques. The system $\mathbf{0} \leq x \leq \mathbf{1}$, $Mx \leq \mathbf{1}$, $M'x \geq \mathbf{1}$ has a solution (namely $x = \omega(G)^{-1}\mathbf{1}$). Hence, as M is total unimodular, it has an integer solution x. This is the incidence vector of a stable set as required.

By a result of Heller [1957] (cf. Theorem 21.4 in Schrijver [1986b]), a unimodular graph has at most $|V|(|V|+1)$ inclusionwise maximal cliques. As W.H. Cunningham (cf. Grötschel, Lovász, and Schrijver [1988]) observed, this gives a polynomial-time method to enumerate all maximal cliques: Choose $v \in V$. Enumerate the maximal cliques $C_1, \ldots, C_t$ of $G - v$ (recursively). Then the maximal cliques of G are among the cliques C_i ($i = 1, \ldots, t$), and $(C_i \cap N(v)) \cup \{v\}$ ($i = 1, \ldots, t$). We can select the maximal cliques among these cliques in polynomial time. Since $t \leq |V|(|V| + 1)$, this gives a polynomial-time method.

This directly gives a strongly polynomial-time method to find a maximum-weight clique. It also implies that the weighted versions of the stable set, colouring, and clique cover problems can be solved in strongly polynomial time, by solving an explicit linear programming problem (using Tardos [1986]). The colouring problem can be solved recursively by first finding (with LP-techniques) a $0, 1$ vector x satisfying $x(C) \leq 1$ for each maximal clique C and $x(C) = 1$ for each maximum-size clique C, and next colouring $G - S$ recursively (where $x = \chi^S$). The weighted version can be solved similarly.

Since by a theorem of Seymour [1980a], totally unimodular matrices can be recognized in polynomial time, this also yields a polynomial-time method to recognize a unimodular matrix.

Ghouila-Houri [1962b] showed that a graph $G = (V, E)$ is unimodular if and only if each nonempty subset U of V contains two disjoint sets U_1 and U_2 such that $U_1 \cup U_2 \neq \emptyset$ and such that each maximal clique C of G with $|C \cap U|$ even, satisfies $|C \cap U_1| = |C \cap U_2|$.

66.5d. Further classes of perfect graphs

Weakly chordal graphs. A graph $G = (V, E)$ is called *weakly chordal* (or *weakly triangulated*) if neither G nor its complement contains a chordless circuit of length at least 5. Hayward [1985] showed that weakly chordal graphs are perfect. Polynomial-time algorithms for the optimization problems related to weakly chordal graphs were given by Hayward, Hoàng, and Maffray [1989], Spinrad and Sritharan [1995], and Hayward, Spinrad, and Sritharan [2000], and polynomial-time recognition algorithms by Spinrad and Sritharan [1995] and Hayward, Spinrad, and Sritharan [2000]. The class of weakly chordal graphs contains both the chordal graphs and their complements.

More on weakly chordal graphs is given in Hoàng, Maffray, Olariu, and Preissmann [1992], Hayward [1996,1997a,1997b], and McMorris, Wang, and Zhang [1998]. Weakly chordal comparability graphs were studied by Eschen, Hayward, Spinrad, and Sritharan [1999].

Quasi-parity graphs. A graph $G = (V, E)$ is a *quasi-parity graph* if each induced subgraph H that is not a clique has two vertices that are not connected by a chordless path of odd length. Meyniel [1987] showed that these graphs are perfect, and that they include the Meyniel graphs and the perfectly orderable graphs. (A short proof of this last is given by Hertz and de Werra [1988].)

Berge [1986] showed that the class of quasi-parity graphs can be enlarged to those graphs in which for each induced subgraph H with at least two vertices, there exist two vertices such that in H or $\overline{H}$ there is no chordless odd-length path connecting them.

Edmonds-Giles graphs. Let $D = (V, A)$ be a directed graph and let $\mathcal{C}$ be a crossing collection of subsets of V with $\delta^{\text{out}}(U) = \emptyset$ for each $U \in \mathcal{C}$. Make an undirected graph G with vertex set A, two arcs a, a' being adjacent if and only if there is a $U \in \mathcal{C}$ such that both a and a' enter U. In Schrijver [1983a] such a graph is called an *Edmonds-Giles graph*. Each such graph is perfect, as can be seen as follows.

A special case of the Edmonds-Giles theorem (Theorem 60.1) is that the system (in $x \in \mathbb{R}^A$)

$$\text{(66.6)} \qquad \begin{array}{lll} \text{(i)} & 0 \leq x(a) \leq 1 & \text{for } a \in A, \\ \text{(ii)} & x(\delta^{\text{in}}(U)) \leq 1 & \text{for } U \in \mathcal{C}, \end{array}$$

is totally dual integral. Hence it determines an integer polytope. Now the integer vectors x satisfying (66.6) are exactly the incidence vectors of the stable sets of G. Each inequality (66.6)(ii) is a clique inequality. The stable set polytope of G therefore is determined by the clique inequalities, and hence G is perfect (Corollary 65.2e). It in particular implies that each clique of G is contained in $\delta^{\text{in}}(U)$ for some $U \in \mathcal{C}$.

A special case of Edmonds-Giles graphs was given by Kahn [1984], where $D = (V, A)$ is a directed graph and $\mathcal{C}$ is the collection of nonempty proper subsets U of V with $\delta^{\text{out}}(U) = \emptyset$ and $|\delta^{\text{in}}(U)|$ minimal. With the perfect graph theorem this implies that the arcs of a digraph can be coloured in such a way that each minimum-size directed cut contains each colour exactly once.

p-comparability graphs. Cameron and Edmonds [1992] showed perfection of the following graphs. Let $D = (V, A)$ be a directed graph and let $U \subseteq V$ be such that each directed circuit of D has precisely one vertex in U. Let G be the undirected graph on $V \setminus U$ with any two $u, v \in V \setminus U$ adjacent if and only if there is a directed circuit containing u and v. Cameron and Edmonds [1992] call such graphs *p-comparability graphs*. Any comparability graph is a p-comparability graph, but not conversely.

Each such graph G is perfect. The proof is by reduction to minimum-cost flow, using the facts that each clique of G is contained in some directed circuit of D and that by Theorem 65.11 it suffices to show that $\overline{\chi}^*(G) = \overline{\chi}(G)$. (The class of p-comparability graphs is closed under taking induced subgraphs, since adding all arcs (u, v) for which there is a directed $u-v$ path avoiding U, maintains the above property of D.)

Now a minimum fractional clique cover of G corresponds to a minimum fractional covering of $V \setminus U$ by directed circuits. By the integer flow theorem, this last is attained by an integer covering of $V \setminus U$ by directed circuits. Hence, the minimum fractional clique cover in G is attained by an integer clique cover. This amounts to $\overline{\chi}^*(G) = \overline{\chi}(G)$.

Polyominoes. A *polyomino* is a union of unit squares in the plane. (A unit square is a square with integer coordinates and area 1.)

Given a polyomino P, make a graph G with vertices all unit squares contained in P, two of them being adjacent if and only if P contains a rectangle (with horizontal and vertical sides) containing both squares. Győri [1984] showed that if P is horizontally convex, then $\alpha(G) = \overline{\chi}(G)$ (see Section 60.3d). (P is *horizontally convex* if each horizontal line has a convex intersection with P.) This extends a result of Chaiken, Kleitman, Saks, and Shearer [1981], who proved $\alpha(G) = \overline{\chi}(G)$ if P is orthogonally convex. (P is *orthogonally convex* if each horizontal or vertical line has a convex intersection with P.) The latter paper also mentions that E. Szemerédi gave an example that one cannot delete orthogonal convexity, and it gives an example of F.R.K. Chung (1979) showing that one cannot relax it to simple connectivity.

Saks [1982] showed that if P is orthogonally convex, then the subgraph of G induced by the boundary squares is perfect. (A *boundary square* of P is a unit square having a neighbouring square not in P.) (This was proved for the subset of corner squares by Chaiken, Kleitman, Saks, and Shearer [1981]. (A *corner square* of P is a unit square having at least two neighbouring squares not in P.))

Shearer [1982] showed that also the following graph G arising from a *simply connected* polyomino P is perfect: the vertices of G are the rectangles contained in P, where two of them are adjacent if and only if they have a unit square in common.

Motwani, Raghunathan, and Saran [1989] showed that the visibility graph of a horizontally convex polyomino is perfect; in fact, a permutation graph. More on this and related problems can be found in Berge, Chen, Chvátal, and Seow [1981], Győri [1985], Motwani, Raghunathan, and Saran [1988,1990], and Maire [1994a].

66.5e. Further notes

Hayward [1990] showed that graphs containing neither C_5 nor P_6 nor $\overline{P_6}$ as induced subgraphs, are perfect. Other classes of perfect graphs were studied by Ravindra

[1976], Payan [1983], Golumbic, Monma, and Trotter [1984], Hammer and Mahadev [1985], Monma, Reed, and Trotter [1988], Hertz [1989a,1989b,1989c], Hoàng and Maffray [1989,1992], Bertschi [1990], Lubiw [1991b], Sun [1991], Croitoru and Radu [1993], Gurvich, Temkin, Udalov, and Shapovalov [1993], Thomas [1993], Maire [1994b,1996], Rusu [1995b,1999c,1999a], Cheah and Corneil [1996], Gyárfás, Kratsch, Lehel, and Maffray [1996] Giakoumakis [1997], Giakoumakis and Rusu [1997], and Maffray and Preissmann [1999]. Le [2000] gave conjectures on the perfection of certain classes of graphs. A survey of several classes of perfect graphs and their recognition and interrelations, is given in the book by Brandstädt, Le, and Spinrad [1999]. The book of Simon [1992] studies efficient algorithms for classes some of perfect graphs.

Conforti, Cornuéjols, Kapoor, and Vušković [1997] investigated 'universally signable' graphs, a generalization of chordal graphs.

Hammer and Maffray [1993] introduced 'preperfect' graphs, and showed that each preperfect graph is perfect, and that preperfect graphs include the Gallai and the parity graphs (cf. Section 66.4).

Corneil and Stewart [1990] studied the complexity of finding minimum-size dominating sets in several classes of perfect graphs. (A *dominating set* is a set U of vertices with $U \cup N(U) = V$.)

Berge and Las Vergnas [1970] showed that a graph G is perfect if for each odd circuit C and each maximal clique K, the intersection of C and K does not consist of two vertices that form an edge of C.

Vertex cuts in perfect and minimally imperfect graphs were surveyed by Rusu [2001]. A characterization of perfect total graphs was given by Rao and Ravindra [1977].

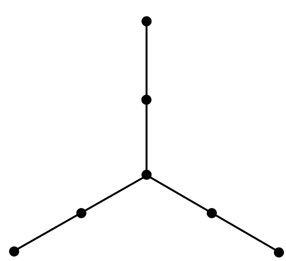

Figure 66.1

Lovász [1983b] calls a graph *k-perfect* if for each induced subgraph $G = (V, E)$ one has:

(66.7) $$\omega_k(G) = \min_{U \subseteq V} (k\chi(G - U) + |U|)$$

where $\omega_k(G)$ is the maximum size of a union of k cliques. By the results of Greene and Kleitman (Corollaries 14.8a and 14.10a), comparability graphs and their complements are k-perfect for each k. Also, complements of line graphs of bipartite graphs are k-perfect, by Corollary 21.4b. On the other hand, the line graph of the bipartite graph in Figure 66.1 is not 2-perfect (Greene [1976]). Related results were given by Berge [1989b,1992a,1992b] and Cameron [1989].

A.J. Hoffman and E.L. Johnson (cf. Golumbic [1980]) proposed the following sharpening of perfection. Let $G = (V, E)$ be a graph and let $w : V \to \mathbb{Z}_+$. A k-*interval colouring* is an assignment to each vertex v of an open subinterval of $[0, k]$ of length $w(v)$ such that adjacent vertices obtain disjoint intervals. Let $\chi_{\text{int}}(G, w)$ denote the minimum value of k for which G has a k-interval colouring. If $w(v) = 1$ for each vertex v, then $\chi_{\text{int}}(G, w) = \chi(G)$. Call G *superperfect* if $\chi_{\text{int}}(G, w)$ is equal to the maximum of $w(K)$ over all cliques K in G. As Hoffman observed, each comparability graph is superperfect (this can be derived from Dilworth's decomposition theorem), but none of the other known interesting classes of perfect graphs have this property.

A survey on subclasses of 'classical' perfect graphs (comparability graphs and chordal graphs) was given by Duchet [1984]. More examples and applications of perfect graphs were given by Shannon [1956], Berge [1967], and Tucker [1973a].

Chapter 67

Perfect graphs: polynomial-time solvability

In this chapter we show that a maximum-weight stable set and a minimum weighted clique cover in a perfect graph can be found in strongly polynomial time. This was shown by Grötschel, Lovász, and Schrijver [1981,1988] with the help of the ellipsoid method and of the function $\vartheta(G)$, introduced by Lovász [1979d] as upper bound on the Shannon capacity of a graph G. No combinatorial polynomial-time algorithms for these problems are known.

We should stress that the naive approach of applying the ellipsoid method to the stable set polytope of a perfect graph using the clique inequalities does not work: it reduces the problem of finding a maximum-weight stable set to deciding for any $x \in \mathbb{R}_+^V$ if there is a clique C satisfying $x(C) > 1$. This is equivalent to finding a maximum-weight clique, which is equivalent to finding a maximum-weight stable set in the complementary graph, which is perfect again. So this would give nothing but a reduction to itself.

In this chapter, all graphs can be assumed to be simple.

67.1. Optimum clique and colouring in perfect graphs algorithmically

Lovász [1979d] introduced the following real number $\vartheta(G)$ for any graph $G = (V, E)$. Let $\mathcal{M}_G$ be the collection of symmetric $V \times V$ matrices satisfying $M_{u,v} = 0$ for any two distinct adjacent vertices u and v and satisfying $\mathrm{Tr}M = 1$. Here $\mathrm{Tr}M$ is the trace of M (sum of diagonal elements). Define

(67.1) $$\vartheta(G) := \max\{\mathbf{1}^{\mathsf{T}} M \mathbf{1} \mid M \in \mathcal{M}_G \text{ positive semidefinite}\}.$$

Here $\mathbf{1}$ denotes the all-one vector in $\mathbb{R}^V$.

$\vartheta(G)$ has two important properties: it can be calculated (at least, approximated) in polynomial time, and it gives an, often close, upper bound on the stable set number $\alpha(G)$ (Lovász [1979d]).

First we show (where $\overline{\chi}^*(G)$ denotes the fractional clique cover number — cf. Section 64.8):

Theorem 67.1. *For any graph $G = (V, E)$:*

$$\alpha(G) \leq \vartheta(G) \leq \overline{\chi}^*(G). \tag{67.2}$$

Proof. To see $\alpha(G) \leq \vartheta(G)$, let S be a maximum-size stable set and let M be the matrix given by:

$$M := \frac{1}{|S|}\chi^S(\chi^S)^\mathsf{T}. \tag{67.3}$$

Here χ^S is the incidence vector of S in $\mathbb{R}^V$. Then M belongs to $\mathcal{M}_G$ and is positive semidefinite. Hence $\alpha(G) = |S| = \mathbf{1}^\mathsf{T}M\mathbf{1} \leq \vartheta(G)$.

To see $\vartheta(G) \leq \overline{\chi}^*(G)$, let M attain the maximum in (67.1). Consider cliques $C_1, \ldots, C_k$ and $\lambda_1, \ldots, \lambda_k \geq 0$ with

$$\sum_{i=1}^k \lambda_i \chi^{C_i} = \mathbf{1} \text{ and } \sum_{i=1}^k \lambda_i = \overline{\chi}^*(G). \tag{67.4}$$

Then, setting $\gamma := \overline{\chi}^*(G)$:

$$\begin{aligned} 0 &\leq \sum_{i=1}^k \lambda_i(\gamma\cdot\chi^{C_i} - \mathbf{1})^\mathsf{T}M(\gamma\cdot\chi^{C_i} - \mathbf{1}) \\ &= \gamma^2\sum_{i=1}^k \lambda_i(\chi^{C_i})^\mathsf{T}M\chi^{C_i} - 2\gamma\sum_{i=1}^k \lambda_i(\chi^{C_1})^\mathsf{T}M\mathbf{1} + \gamma\mathbf{1}^\mathsf{T}M\mathbf{1} \\ &= \gamma^2\mathrm{Tr}M - 2\gamma\mathbf{1}^\mathsf{T}M\mathbf{1} + \gamma\mathbf{1}^\mathsf{T}M\mathbf{1} = \gamma^2 - \gamma\vartheta(G), \end{aligned} \tag{67.5}$$

since $\mathrm{Tr}M = 1$, $\mathbf{1}^\mathsf{T}M\mathbf{1} = \vartheta(G)$, and $M_{u,v} = 0$ if $u \neq v$ and $u, v \in C_i$ for some i.

(67.5) implies that $\vartheta(G) \leq \gamma = \overline{\chi}^*(G)$. ∎

Moreover, $\vartheta(G)$ can be approximated in polynomial time (Grötschel, Lovász, and Schrijver [1981]):

Theorem 67.2. *There is an algorithm that for any given graph $G = (V, E)$ and any $\varepsilon > 0$, returns a rational closer than ε to $\vartheta(G)$, in time bounded by a polynomial in $|V|$ and $\log(1/\varepsilon)$.*

Proof. This is a consequence of Corollary (4.3.12) in Grötschel, Lovász, and Schrijver [1988], stating that we can solve a convex optimization problem approximatively in polynomial time, if we know a ball contained in the feasible region and a ball containing the feasible region, and if we can test membership of the feasible region in polynomial time. These conditions are satisfied, if we restrict ourselves to the affine space $\mathcal{M}_G$. The convex body of all positive semidefinite matrices in $\mathcal{M}_G$ contains the ball with center $(1/|V|)\cdot I$ and radius $1/|V|^2$, and is contained in the ball with center the all-zero matrix and radius $|V|^2$. Membership can be tested in polynomial time, since we can test positive semidefiniteness in polynomial time. ∎

The two theorems above imply:

Corollary 67.2a. *For any graph G satisfying $\alpha(G) = \overline{\chi}(G)$, the stable set number can be found in polynomial time.*

Proof. Theorem 67.1 implies $\alpha(G) = \vartheta(G) = \overline{\chi}(G)$, and by Theorem 67.2 we can find a number closer than $\frac{1}{2}$ to $\vartheta(G)$ in time polynomial in $|V|$. Rounding to the closest integer yields $\alpha(G)$. ∎

To obtain an explicit maximum-size stable set, we need perfection of the graph:

Corollary 67.2b. *A maximum-size stable set in a perfect graph can be found in polynomial time.*

Proof. Let $G = (V, E)$ be a perfect graph. Iteratively, for each $v \in V$, replace G by $G - v$ if $\alpha(G - v) = \alpha(G)$. By the perfection of G, we can calculate these values in polynomial time, by Corollary 67.2a.

We end up with a graph that forms a maximum-size stable set in the original graph. ∎

As perfection is closed under taking complements, also a maximum-size clique in a perfect graph can be found in polynomial time.

The method described in the proof of Corollary 67.2b applies to all graphs G for which $\alpha(H) = \vartheta(H)$ holds for each induced subgraph H of G; but, as we shall see in Corollary 67.14a, these are precisely the perfect graphs.

From Corollary 67.2b one can derive that a minimum colouring of a perfect graph can also be found in polynomial time (we follow the method given in Grötschel, Lovász, and Schrijver [1988]):

Corollary 67.2c. *A minimum colouring in a perfect graph can be found in polynomial time.*

Proof. Let $G = (V, E)$ be a perfect graph. It suffices to find a stable set S intersecting each maximum-size clique in G; applying recursion to $G - S$ does the rest.

Starting with $t = 0$, we iteratively extend a list of maximum-size cliques $K_1, \ldots, K_t$ as follows. First, find a stable set S intersecting each of $K_1, \ldots, K_t$. This can be done by considering

(67.6) $$c := \chi^{K_1} + \cdots + \chi^{K_t},$$

and finding a stable set S maximizing $c(S)$. This can be found by replacing each vertex v by $c(v)$ nonadjacent vertices (adjacent to the new vertices that replace vertices adjacent to v), and finding a maximum-size stable set in the new graph. This gives a stable set S in the original graph maximizing $c(S)$.

Necessarily, $c(S) = t$, since G has a stable set intersecting each maximum-size clique (as G is perfect). So S intersects each K_i.

If $\omega(G-S) < \omega(G)$, then S intersects each maximum-size clique in G, and we are done. If $\omega(G-S) = \omega(G)$, we find a maximum-size clique K_{t+1} in $G-S$, add it to our list, and iterate.

The number of iterations is bounded by $|V|$, since in each iteration the dimension of the space L_t of vectors $x \in \mathbb{R}^V$ with $x(K_i) = 1$ for each i drops, as for the S found we have $\chi^S \in L_t$ and $\chi^S \notin L_{t+1}$. ∎

67.2. Weighted clique and colouring algorithmically

In a straightforward way, the results of the previous section can be extended to the weighted case. Let $G = (V, E)$ be a graph and let $w : V \to \mathbb{Z}_+$ be a weight function. Let G_w be the graph obtained from G by replacing each vertex v by a stable set S_v of size $w(v)$, where vertices in distinct S_u and S_v are adjacent if and only if u and v are adjacent in G. So the maximum *weight* of a stable set in G is equal to the maximum *size* of a stable set in G_w. Define:

(67.7) $$\alpha_w(G) := \alpha(G_w),\ \vartheta_w(G) := \vartheta(G_w),\ \overline{\chi}_w(G) := \overline{\chi}(G_w),$$ $$\overline{\chi}^*_w(G) := \overline{\chi}^*(G_w).$$

So $\alpha_w(G)$ is equal to the maximum weight of a stable set in G. The definitions of $\overline{\chi}_w(G)$ and $\overline{\chi}^*_w(G)$ agree with those in Section 64.8.

Theorem 67.1 gives the following inequalities:

Theorem 67.3. *For any graph $G = (V, E)$ and $w : V \to \mathbb{R}_+$:*

(67.8) $$\alpha_w(G) \leq \vartheta_w(G) \leq \overline{\chi}^*_w(G).$$

Proof. Directly from Theorem 67.1 and (67.7). ∎

In order to calculate $\vartheta_w(G)$, we need not construct G_w and calculate $\vartheta(G_w)$. This would not be a polynomial-time method. We can calculate $\vartheta_w(G)$ more concisely as follows.

Define $\sqrt{w} : V \to \mathbb{R}_+$ by:

(67.9) $$\sqrt{w}(v) := \sqrt{w(v)}$$

for $v \in V$. Then:

Theorem 67.4. *For any graph G and $w : VG \to \mathbb{Z}_+$:*

(67.10) $$\vartheta_w(G) = \max\{\sqrt{w}^{\mathsf{T}} M \sqrt{w} \mid M \in \mathcal{M}_G \text{ positive semidefinite}\}.$$

Proof. We may assume that $w > \mathbf{0}$. Let D be the $VG_w \times VG$ matrix defined by

(67.11) $$D_{u,v} := \begin{cases} w(v)^{-\frac{1}{2}} & \text{if } u \in S_v, \\ 0 & \text{if } u \notin S_v, \end{cases}$$

for $u \in VG_w$ and $v \in VG$.

First let M attain the maximum in (67.10). Then $M' := DMD^{\mathsf{T}}$ is positive semidefinite, and, moreover, belongs to $\mathcal{M}_{G_w}$. Indeed, for adjacent vertices u, u' of G_w, say $u \in S_v$ and $u' \in S_{v'}$, with v and v' adjacent vertices of G, we have $M_{v,v'} = 0$, and hence

(67.12) $$M'_{u,u'} = (DMD^{\mathsf{T}})_{u,u'} = \sum_{t,t' \in VG} D_{u,t} M_{t,t'} D_{u',t'} = w(v)^{-\frac{1}{2}} w(v')^{-\frac{1}{2}} M_{v,v'} = 0.$$

Also (setting $v_u := v$ if $u \in S_v$):

(67.13) $$\mathrm{Tr} M' = \mathrm{Tr}(DMD^{\mathsf{T}}) = \sum_{u \in VG_w} \sum_{v,v' \in VG} D_{u,v} D_{u,v'} M_{v,v'} = \sum_{u \in VG_w} w(v_u)^{-1} M_{v_u,v_u} = \sum_{v \in VG} w(v)^{-1} w(v) M_{v,v} = \mathrm{Tr} M = 1.$$

So $M' \in \mathcal{M}_{G_w}$. Hence

(67.14) $$\vartheta_w(G) = \vartheta(G_w) \geq \mathbf{1}^{\mathsf{T}} M' \mathbf{1} = \mathbf{1}^{\mathsf{T}} (DMD^{\mathsf{T}}) \mathbf{1} = \sqrt{w}^{\mathsf{T}} M \sqrt{w}.$$

This shows $\geq$ in (67.10).

To see the reverse inequality, let M' be a positive semidefinite matrix in $\mathcal{M}_{G_w}$ with $\mathbf{1}^{\mathsf{T}} M' \mathbf{1} = \vartheta(G_w)$. Then $M := D^{\mathsf{T}} M' D$ is positive semidefinite, and, moreover, belongs to $\mathcal{M}_G$. Indeed, for adjacent $v, v' \in VG$ we have

(67.15) $$M_{v,v'} = (D^{\mathsf{T}} M D)_{v,v'} = \sum_{u,u' \in VG_w} D_{u,v} D_{u',v'} M'_{u,u'} = \sum_{u \in S_v} \sum_{u' \in S_{v'}} w(v)^{-\frac{1}{2}} w(v')^{-\frac{1}{2}} M'_{u,u'} = 0.$$

Also:

(67.16) $$\mathrm{Tr} M = \sum_{v \in VG} \sum_{u,u' \in VG_w} D_{u,v} D_{u',v} M'_{u,u'} = \sum_{v \in VG} \sum_{u \in S_v} \sum_{u' \in S_v} w(v)^{-1} M'_{u,u'} \leq \sum_{v \in VG} \sum_{u \in S_v} M'_{u,u} = \mathrm{Tr} M' = 1.$$

The inequality holds as for any positive semidefinite matrix A one has: $\mathbf{1}^{\mathsf{T}} A \mathbf{1} \leq \mathbf{1}^{\mathsf{T}} \mathbf{1} \cdot \mathrm{Tr} A$, since the largest eigenvalue of A is at most $\mathrm{Tr} A$. This is applied to the $S_v \times S_v$ submatrix of M, for each $v \in V$.

Hence the matrix $\widetilde{M} := (\mathrm{Tr} M)^{-1} \cdot M$ belongs to $\mathcal{M}_G$, and so the maximum in (67.10) is at least $\sqrt{w}^{\mathsf{T}} \widetilde{M} \sqrt{w}$, and hence at least

(67.17) $$\sqrt{w}^{\mathsf{T}} M \sqrt{w} = \sqrt{w}^{\mathsf{T}} D^{\mathsf{T}} M' D \sqrt{w} = \mathbf{1}^{\mathsf{T}} M' \mathbf{1} = \vartheta_w(G).$$ ∎

This implies that $\vartheta_w(G)$ can be approximated in polynomial time:

Theorem 67.5. *There is an algorithm that for any given graph $G = (V, E)$, any $w : V \to \mathbb{Z}_+$, and any $\varepsilon > 0$, returns a rational closer than ε to $\vartheta_w(G)$, in time bounded by a polynomial in $|V|$, $\log \|w\|_\infty$, and $\log(1/\varepsilon)$.*

Proof. Similar to the proof of Theorem 67.2. ∎

The two theorems above imply:

Corollary 67.5a. *For any graph G and weight function $w : V \to \mathbb{Z}_+$ satisfying $\alpha_w(G) = \overline{\chi}_w(G)$, the weighted stable set number can be found in polynomial time.*

Proof. Theorem 67.3 implies $\alpha_w(G) = \vartheta_w(G) = \overline{\chi}_w(G)$, and by Theorem 67.5 we can find a number closer than $\frac{1}{2}$ to $\vartheta_w(G)$ in time polynomial in $|V|$. Rounding to the closest integer yields $\alpha_w(G)$. ∎

To obtain a maximum-weight stable set explicitly, we again need perfection of the graph:

Corollary 67.5b. *A maximum-weight stable set in a perfect graph can be found in polynomial time.*

Proof. Let $G = (V, E)$ be a perfect graph and $w : V \to \mathbb{Z}_+$. Iteratively, for each $v \in V$, replace G by $G - v$ if $\alpha_w(G - v) = \alpha_w(G)$. By the perfection of G, we can calculate these values in polynomial time, by Corollary 67.5a.

We end up with a graph that forms a maximum-weight stable set in the original graph. ∎

As perfection is closed under taking complements, also a maximum-weight clique in a perfect graph can be found in polynomial time. So for any $w : V \to \mathbb{Z}_+$, we can determine

(67.18) $\quad \omega_w(G) :=$maximum of $w(C)$ over cliques C of G

in polynomial time.

Moreover, a minimum weighted colouring of a perfect graph can be found in polynomial time (again, we follow the method given in Grötschel, Lovász, and Schrijver [1988]):

Corollary 67.5c. *Given a perfect graph $G = (V, E)$ and a weight function $w : V \to \mathbb{Z}_+$, a minimum weighted colouring can be found in polynomial time.*

Proof. Let $G = (V, E)$ be a perfect graph and let $w : V \to \mathbb{Z}_+$. As in the proof of Corollary 67.2c, we can find a stable set S intersecting each maximum-weight clique in G, as follows. Starting with $t = 0$, we iteratively extend a list of maximum-weight cliques $K_1, \ldots, K_t$. First find a stable set S intersecting each of $K_1, \ldots, K_t$. This can be done by considering

$$(67.19) \qquad c := \chi^{K_1} + \cdots + \chi^{K_t},$$

and finding a stable set S maximizing $c(S)$. This can be found by replacing each vertex v by $c(v)$ nonadjacent vertices (adjacent to the new vertices that replace vertices adjacent to v), and finding a maximum-size stable set in the new graph. This gives a stable set S maximizing $c(S)$.

Necessarily, $c(S) = t$, since G has a stable set intersecting each maximum-weight clique (as G_w is perfect). So S intersects each K_i.

If $\omega_w(G - S) < \omega_w(G)$, then S intersects each maximum-weight clique in G, and we have the required S. If $\omega_w(G - S) = \omega_w(G)$, we find a maximum-weight clique K_{t+1} in $G - S$, add it to our list, and iterate.

The number of iterations is bounded by $|V|$, since in each iteration the dimension of the space L_t of vector $x \in \mathbb{R}^V$ with $x(K_i) = 1$ for each i drops, since for the S found we have $\chi^S \in L_t$ and $\chi^S \notin L_{t+1}$.

This describes the method to find a stable set intersecting all maximum-weight cliques. To find a minimum weighted colouring, we iteratively find stable sets $S_1, \ldots, S_i$, $\lambda_1, \ldots, \lambda_i \in \mathbb{Z}_+$, and a weight function w_i as follows. Set $w_1 := w$. Next iteratively for $i = 1, 2, \ldots$, as long as $w_i \neq \mathbf{0}$, find a stable set S_i intersecting all cliques C maximizing $w_i(C)$, calculate

$$(67.20) \qquad \lambda_i := \omega_{w_i}(G) - \omega_{w_i}(G - S_i),$$

and set $w_{i+1} := w_i - \lambda_i \chi^{S_i}$.

Then the λ_i, S_i form a minimum weighted colouring, since

$$(67.21) \qquad \sum_i \lambda_i \chi^{S_i} = w \text{ and } \sum_i \lambda_i = \omega_w(G) = \chi_w(G).$$

To prove this, we first show:

$$(67.22) \qquad \omega_{w_{i+1}}(G) = \omega_{w_{i+1}}(G - S_i) = \omega_{w_i}(G - S_i) = \omega_{w_i}(G) - \lambda_i.$$

Here the second equality is trivial (since w_i and w_{i+1} coincide outside S_i). The third inequality follows from definition (67.20) of λ_i. For the first equality, $\geq$ is trivial. To see $\leq$, consider a clique C intersecting S_i. Then $w_{i+1}(C) = w_i(C) - \lambda_i |C \cap S_i| \leq \omega_{w_i}(G) - \lambda_i$. This proves (67.22), which implies the second equality in (67.21).

Moreover, the number of iterations is at most $|V|$, since in each iteration the face of the clique polytope spanned by the cliques C maximizing $w_i(C)$, increases in dimension: each clique C in G maximizing $w_i(C)$ also maximizes $w_{i+1}(C)$ (since $w_{i+1}(C) \geq w_i(C) - \lambda_i = \omega_{w_i}(G) - \lambda_i = \omega_{w_{i+1}}(G)$, by (67.22)), and there is a clique C maximizing $w_{i+1}(C)$ but not $w_i(C)$ (namely any clique C of $G - S_i$ maximizing $w_i(C)$, since $w_{i+1}(C) = w_i(C) = \omega_{w_i}(G - S_i) = \omega_{w_{i+1}}(G)$). ∎

67.3. Strong polynomial-time solvability

In the previous section we showed the polynomial-time solvability of the weighted versions of the stable set and colouring problems in perfect graphs. By Theorem 5.11 of Frank and Tardos [1985,1987], this can be strengthened to *strong* polynomial-time solvability.

Theorem 67.6. *A maximum-weight clique and a minimum weighted colouring in a perfect graph can be found in strongly polynomial time.*

Proof. A maximum-weight clique can be found in strongly polynomial time by Theorem 5.11, since the class of clique polytopes of perfect graphs is polynomial-time solvable by Corollary 67.5b.

Next, a minimum weighted colouring can be found with the method described in the proof of Corollary 67.5c: it is strongly polynomial-time because we can find (by the above) a maximum-weight clique in strongly polynomial time. ∎

This implies:

Corollary 67.6a. *A maximum-weight stable set and a minimum-weight vertex cover in a perfect graph can be found in strongly polynomial time.*

Proof. Directly from Theorem 67.6, since stable sets in a perfect graph are precisely the cliques in the complementary graph, which is again perfect. Moreover, the vertex covers are precisely the complements of stable sets. ∎

67.4. Further results and notes

67.4a. Further on $\vartheta(G)$

In this section we give some further results on the function $\vartheta(G)$, and we consider the related convex body $\mathrm{TH}(G)$. We use the following notation, for vector $a, b \in \mathbb{R}_+^V$:

(67.23) b/a is the vector in $\mathbb{R}^V$ with vth entry $b(v)/a(v)$,
$\sqrt{b} = b^{\frac{1}{2}}$ is the vector in $\mathbb{R}^V$ with vth entry $b(v)^{\frac{1}{2}}$,
$b^{-\frac{1}{2}}$ is the vector in $\mathbb{R}^V$ with vth entry $b(v)^{-\frac{1}{2}}$,
Δ_b is the $V \times V$ diagonal matrix with diagonal b.

We set $(b/a)_v := 0$ if $a_v = 0$ and $(b^{-\frac{1}{2}})_v := 0$ if $b_v = 0$. (This will turn out not to harm the consistency.)

Moreover, we define, for any graph $G = (V, E)$ and any symmetric matrix M:

(67.24) $\mathcal{L}_G :=$ the set of symmetric $V \times V$ matrices A with $A_{u,v} = 0$ if $u = v$ or u and v are nonadjacent;
$\Lambda(M) :=$ the largest eigenvalue of M,
$\mathrm{PSD} :=$ the set of symmetric positive semidefinite matrices.

We usually restrict PSD to appropriate dimensions, like $V \times V$. We define for any two matrices X, Y (of equal dimensions) the 'inner product' $X \bullet Y$ by

(67.25) $$X \bullet Y := \mathrm{Tr}(XY^{\mathsf{T}}).$$

So if $X \in \mathcal{M}_G$ and $Y \in \mathcal{L}_G$, then $X \bullet Y = 0$.

A min-max relation for $\vartheta_w(G)$

$\vartheta_w(G)$ is defined as a maximum. Applying convex duality, we can describe $\vartheta_w(G)$ alternatively as a minimum (Lovász [1979d]):

Theorem 67.7. *For each* $w \in \mathbb{R}_+^V$*:*

(67.26) $$\vartheta_w(G) = \min\{\Lambda(W + A) \mid A \in \mathcal{L}_G\},$$

where $W := \sqrt{w}\sqrt{w}^{\mathsf{T}}$.

Proof. Let M maximize $\sqrt{w}^{\mathsf{T}} M \sqrt{w}$ over $\mathrm{PSD} \cap \mathcal{M}_G$. So $\vartheta_w(G) = \sqrt{w}^{\mathsf{T}} M \sqrt{w}$.

To prove $\leq$ in (67.26), let $A \in \mathcal{L}_G$ attain the minimum in (67.26) and let $\lambda := \Lambda(W + A)$. Then $Y := \lambda I - W - A$ is positive semidefinite, and hence

(67.27) $$0 \leq Y \bullet M = (\lambda I - W - A) \bullet M = \lambda \mathrm{Tr} M - W \bullet M = \lambda - \sqrt{w}^{\mathsf{T}} M \sqrt{w} = \Lambda(W + A) - \vartheta_w(G).$$

To prove $\geq$ in (67.26), we use convexity theory. Since M maximizes $W \bullet M$ over the intersection of the convex sets PSD and $\mathcal{M}_G$, there exist supporting hyperplanes $\{X \mid C \bullet X = \gamma\}$ of PSD and $\{X \mid D \bullet X = \delta\}$ of $\mathcal{M}_G$ such that

(67.28) $$\mathrm{PSD} \subseteq \{X \mid C \bullet X \geq \gamma\},\ \mathcal{M}_G \subseteq \{X \mid D \bullet X \geq \delta\},\ C \bullet M = \gamma,\ D \bullet M = \delta, \text{ and } W = C + D.$$

Since PSD and $\mathcal{M}_G$ consist of symmetric matrices only, we can assume that C and D are symmetric (we can replace them by $\frac{1}{2}(C + C^{\mathsf{T}})$ and $\frac{1}{2}(D + D^{\mathsf{T}})$).

Since PSD is a convex cone, we have $\gamma = 0$. Then $C \in \mathrm{PSD}$, as $xx^{\mathsf{T}} \in \mathrm{PSD}$ for each $x \in \mathbb{R}^V$, hence $x^{\mathsf{T}} C x = C \bullet (xx^{\mathsf{T}}) \geq 0$.

Since $\mathcal{M}_G$ is an affine space and since $D \bullet M = \delta$, we have $\mathcal{M}_G \subseteq \{X \mid D \bullet X = \delta\}$. This implies that $D = \delta \cdot I - A$ for some $A \in \mathcal{L}_G$ (since each symmetric $0,1$ matrix containing precisely one 1 belongs to $\mathcal{M}_G$; the matrix remains to belong to $\mathcal{M}_G$ after putting a nonzero entry in any nonadjacent position and its transpose). So

(67.29) $$\delta = D \bullet M = (W - C) \bullet M = W \bullet M.$$

As C is positive semidefinite, $\delta \cdot I - W - A$ is positive semidefinite. Hence

(67.30) $$\Lambda(W + A) \leq \delta = W \bullet M = \vartheta_w(G).$$ ∎

The product $\vartheta(G)\vartheta(\overline{G})$ is at least $|V|$

For perfect graphs $G = (V, E)$, we have $\alpha(G)\omega(G) \geq |V|$, and hence $\vartheta(G)\vartheta(\overline{G}) \geq |V|$. The latter inequality holds for any graph G. To prove it, we use the following fact from matrix theory:

(67.31) If X and Y are symmetric positive semidefinite $n \times n$ matrices, then also $X * Y$ is positive definite,

where $X * Y$ is the $n \times n$ matrix given by: $(X * Y)_{i,j} = X_{i,j} Y_{i,j}$. (67.31) follows from the fact that there exist vectors $u_1, \ldots, u_n$ and $v_1, \ldots, v_n$ with $X_{i,j} = u_i^{\mathsf{T}} u_j$ and $Y_{i,j} = v_i^{\mathsf{T}} v_j$ for all i, j. Hence $(X * Y)_{i,j} = (u_i \circ v_i)^{\mathsf{T}} (u_j \circ v_j)$ for all i, j, where $\circ$ denotes tensor product[13]. So $X * Y$ is positive semidefinite.

Theorem 67.8. *$\vartheta(G)\vartheta(\overline{G}) \geq |V|$ for each graph $G = (V, E)$.*

Proof. By (67.26), there exist $A \in \mathcal{L}_G$ and $B \in \mathcal{L}_{\overline{G}}$ with

(67.32) $$\vartheta(G) = \Lambda(J + A) \text{ and } \vartheta(\overline{G}) = \Lambda(J + B).$$

So $C := \vartheta(G) \cdot I - J - A$ and $D := \vartheta(\overline{G}) \cdot I - J - B$ are positive semidefinite. Now

(67.33) $$\begin{aligned} C * D + C * J + J * D &= (C + J) * (D + J) - J * J \\ &= (\vartheta(G) \cdot I - A) * (\vartheta(\overline{G}) \cdot I - B) - J = \vartheta(G)\vartheta(\overline{G}) \cdot I - J \end{aligned}$$

(as $A * I = I * B = A * B$ is the all-zero matrix). By (67.31), the first matrix in (67.33) is positive semidefinite, hence also the last. So

(67.34) $$0 \leq \mathbf{1}^{\mathsf{T}} (\vartheta(G)\vartheta(\overline{G}) \cdot I - J)\mathbf{1} = \vartheta(G)\vartheta(\overline{G})|V| - |V|^2,$$

implying the theorem. ∎

The convex body TH(G)

The function $\vartheta_w(G)$ is related to a convex body TH(G) defined in Grötschel, Lovász, and Schrijver [1986]. The following equivalent representation of TH(G) was given by Lovász and Schrijver [1991].

For any symmetric matrix A, define the matrix $R(A)$ by:

(67.35) $$R(A) := \begin{pmatrix} 1 & a^{\mathsf{T}} \\ a & A \end{pmatrix},$$

where $a := \text{diag}A$ (the diagonal vector of A; that is, $a_i = A_{i,i}$ for each coordinate i).

Given a graph $G = (V, E)$, consider the collection $\mathcal{R}_G$ of symmetric $V \times V$ matrices A with $R(A)$ positive semidefinite and with $A_{u,v} = 0$ for distinct adjacent u, v. Then define:

(67.36) $$\text{TH}(G) = \{\text{diag}A \mid A \in \mathcal{R}_G\}.$$

Theorem 67.9. TH(G) *is convex and down-monotone in* $\mathbb{R}_+^V$.

Proof. TH(G) is convex, as it is a projection of the convex set $\mathcal{R}_G$. Moreover, if $a \in \text{TH}(G)$ and $\mathbf{0} \leq b \leq a$, then $b \in \text{TH}(G)$. Indeed, since $a \in \text{TH}(G)$, there exists a matrix $A \in \mathcal{R}_G$ with $a = \text{diag}A$. Then the matrix

(67.37) $$\begin{pmatrix} 1 & 0 \\ 0 & \Delta_{b/a} \end{pmatrix} \begin{pmatrix} 1 & a^{\mathsf{T}} \\ a & A \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & \Delta_{b/a} \end{pmatrix} = \begin{pmatrix} 1 & b^{\mathsf{T}} \\ b & \Delta_{b/a} A \Delta_{b/a} \end{pmatrix}$$

[13] The *tensor product* of vectors $x \in \mathbb{R}^U$ and $y \in \mathbb{R}^V$ is the vector $x \circ y$ in $\mathbb{R}^{U \times V}$ defined by: $(x \circ y)_{(u,v)} := x_u y_v$ for $u \in U$ and $v \in V$.

is positive semidefinite. As the vth entry on the diagonal of $\Delta_{b/a} A \Delta_{b/a}$ is equal to $b(v)^2/a(v)$ (or 0 if $a(v) = 0$), which is at most $b(v)$, we have that

(67.38) $$\Delta_{b/a} A \Delta_{b/a} + (\Delta_{b-b^2/a})$$

belongs to $\mathcal{R}_G$ and has diagonal equal to b. This proves that $b \in \mathrm{TH}(G)$, and hence $\mathrm{TH}(G)$ is down-monotone. ∎

To obtain a relation of $\mathrm{TH}(G)$ with the function $\vartheta_w(G)$, we first show the following, where for $x, y \in \mathbb{R}^V$, $x * y$ is the vector in $\mathbb{R}^V$ defined by:

(67.39) $$(x * y)_v := x_v y_v \text{ for } v \in V.$$

Theorem 67.10. *Let M maximize $\sqrt{w}^{\mathsf{T}} M \sqrt{w}$ over $\mathrm{PSD} \cap \mathcal{M}_G$. Then*

(67.40) $$M\sqrt{w} = \vartheta_w(G) \cdot b * w^{-\frac{1}{2}},$$

where $b := \mathrm{diag} M$.

Proof. The maximum of

(67.41) $$\sqrt{w}^{\mathsf{T}} \Delta_x M \Delta_x \sqrt{w}$$

over $x \in \mathbb{R}^V$ satisfying $x^{\mathsf{T}} \Delta_b x = 1$, is attained by $x = \mathbf{1}$. (Otherwise we can replace M by $\Delta_x M \Delta_x$ to increase $\sqrt{w}^{\mathsf{T}} M \sqrt{w}$.) Now (67.41) is equal to

(67.42) $$x^{\mathsf{T}} \Delta_{\sqrt{w}} M \Delta_{\sqrt{w}} x.$$

So the maximum of (67.42) over $x \in \mathbb{R}^V$ satisfying $x^{\mathsf{T}} \Delta_b x = 1$, is attained by $x = \mathbf{1}$. Hence, by Lagrange's theorem, there exists a $\mu \in \mathbb{R}$ with

(67.43) $$\Delta_{\sqrt{w}} M \Delta_{\sqrt{w}} \mathbf{1} = \mu \cdot \Delta_b \mathbf{1} = \mu \cdot b.$$

Then

(67.44) $$\vartheta_w(G) = \sqrt{w}^{\mathsf{T}} M \sqrt{w} = \mathbf{1}^{\mathsf{T}} \Delta_{\sqrt{w}} M \Delta_{\sqrt{w}} \mathbf{1} = \mu \mathbf{1}^{\mathsf{T}} b = \mu \mathrm{Tr} M = \mu.$$

(67.43) and (67.44) give

(67.45) $$M\sqrt{w} = M \Delta_{\sqrt{w}} \mathbf{1} = \mu \cdot w^{-\frac{1}{2}} * b = \vartheta_w(G) \cdot b * w^{-\frac{1}{2}},$$

which is (67.40). ∎

Now the relation of $\mathrm{TH}(G)$ with $\vartheta_w(G)$ is:

Theorem 67.11. *For each $w \in \mathbb{R}^V_+$:*

(67.46) $$\vartheta_w(G) = \max\{w^{\mathsf{T}} x \mid x \in \mathrm{TH}(G)\}.$$

Proof. I. We first show $\leq$ in (67.46). Let M be a matrix maximizing $\sqrt{w}^{\mathsf{T}} M \sqrt{w}$ over the positive semidefinite matrices $M \in \mathcal{M}_G$. It suffices to show that the matrix

(67.47) $$A := \vartheta_w(G) \cdot \Delta_{w^{-\frac{1}{2}}} M \Delta_{w^{-\frac{1}{2}}}$$

belongs to $\mathcal{R}_G$, since $w^{\mathsf{T}} \mathrm{diag} A = \vartheta_w(G) \mathrm{Tr} M = \vartheta_w(G)$.

Trivially, $A_{u,v} = 0$ for distinct adjacent u, v (since $M_{u,v} = 0$ for distinct adjacent u, v). To see that $R(A)$ is positive semidefinite, write $a := \mathrm{diag} A$, $b := \mathrm{diag} M$, and $\vartheta := \vartheta_w(G)$. By (67.40) we have $M\sqrt{w} = \vartheta \cdot b * w^{-\frac{1}{2}}$. So $\Delta_{w^{-\frac{1}{2}}} M \sqrt{w} = \vartheta \cdot \Delta_{w^{-\frac{1}{2}}} (b * w^{-\frac{1}{2}}) = \vartheta \cdot (b/w)$. Hence

(67.48) $$R(A) = \begin{pmatrix} 1 & a^{\mathsf{T}} \\ a & A \end{pmatrix} = \begin{pmatrix} 1 & \vartheta \cdot (b/w)^{\mathsf{T}} \\ \vartheta \cdot (b/w) & \vartheta \cdot \Delta_{w^{-\frac{1}{2}}} M \Delta_{w^{-\frac{1}{2}}} \end{pmatrix}$$
$$= \begin{pmatrix} \vartheta^{-1}\sqrt{w}^{\mathsf{T}} M \sqrt{w} & \sqrt{w}^{\mathsf{T}} M \Delta_{w^{-\frac{1}{2}}} \\ \Delta_{w^{-\frac{1}{2}}} M \sqrt{w} & \vartheta \cdot \Delta_{w^{-\frac{1}{2}}} M \Delta_{w^{-\frac{1}{2}}} \end{pmatrix} = \vartheta^{-1} \cdot U^{\mathsf{T}} M U,$$

where U is the matrix given by

(67.49) $$U := (\sqrt{w} \quad \vartheta \cdot \Delta_{w^{-\frac{1}{2}}}).$$

So $R(A)$ is positive semidefinite.

II. To see $\geq$ in (67.46), let $A \in \mathcal{R}_G$ maximize $w^{\mathsf{T}}\mathrm{diag}A$. Define $a := \mathrm{diag}A$, $\eta := w^{\mathsf{T}}a$, and

(67.50) $$M := \eta^{-1} \cdot \Delta_{w^{\frac{1}{2}}} A \Delta_{w^{\frac{1}{2}}}.$$

Trivially, M is positive semidefinite and belongs to $\mathcal{M}_G$. Also

(67.51) $$0 \leq (\eta, -w^{\mathsf{T}}) \begin{pmatrix} 1 & a^{\mathsf{T}} \\ a & A \end{pmatrix} \begin{pmatrix} \eta \\ -w \end{pmatrix} = \eta^2 - 2\eta \cdot w^{\mathsf{T}} a + w^{\mathsf{T}} A w$$
$$= \eta \sqrt{w}^{\mathsf{T}} M \sqrt{w} - \eta^2.$$

Therefore $\sqrt{w}^{\mathsf{T}} M \sqrt{w} \geq \eta$, which proves $\geq$ in (67.46). ∎

(67.46) implies that $\vartheta_w(G)$ is a convex function of w and that

(67.52) $$\mathrm{TH}(G) = \{x \in \mathbb{R}^V_+ \mid w^{\mathsf{T}} x \leq \vartheta_w(G) \text{ for each } w \in \mathbb{R}^V_+\}.$$

By (67.8),

(67.53) $$\alpha_w(G) \leq \vartheta_w(G) \leq \overline{\chi}^*_w(G).$$

This gives:

Corollary 67.11a. *For each graph $G = (V, E)$:*

(67.54) $$P_{\text{stable set}}(G) \subseteq \mathrm{TH}(G) \subseteq A(P_{\text{clique}}(G)).$$

Proof. This follows directly from Theorem 67.11 with the inequalities (67.53), since for each $w \in \mathbb{R}^V_+$:

(67.55) $$\alpha_w(G) = \max\{w^{\mathsf{T}} x \mid x \in P_{\text{stable set}}(G)\},$$
$$\vartheta_w(G) = \max\{w^{\mathsf{T}} x \mid x \in \mathrm{TH}(G)\},$$
$$\overline{\chi}^*_w(G) = \max\{w^{\mathsf{T}} x \mid x \in A(P_{\text{clique}}(G))\}.$$ ∎

The antiblocking body of TH(G)

It turns out that taking the antiblocking body $A(\mathrm{TH}(G))$ of $\mathrm{TH}(G)$ corresponds to replacing G by its complement (Grötschel, Lovász, and Schrijver [1986]). We first observe that

(67.56) $$A(\mathrm{TH}(G)) = \{w \in \mathbb{R}^V_+ \mid \vartheta_w(G) \leq 1\},$$

since for each $w : V \to \mathbb{R}_+$: $w \in A(\mathrm{TH}(G)) \iff \max\{w^\top x \mid x \in \mathrm{TH}(G)\} \le 1$ $\iff \vartheta_w(G) \le 1$.

Theorem 67.12. *$A(\mathrm{TH}(G)) = \mathrm{TH}(\overline{G})$.*

Proof. I. We first show $A(\mathrm{TH}(G)) \subseteq \mathrm{TH}(\overline{G})$. Let $w \in A(\mathrm{TH}(G))$; that is (by (67.56)), $\vartheta_w(G) \le 1$. To show that w belongs to $\mathrm{TH}(\overline{G})$ we should show by (67.52) that

$$w^\top a \le \vartheta_a(\overline{G}) \tag{67.57}$$

for each $a \in \mathbb{R}^V_+$.

By (67.26), there exist $A \in \mathcal{L}_G$ and $B \in \mathcal{L}_{\overline{G}}$ such that

$$\vartheta_w(G) = \Lambda(\sqrt{w}\sqrt{w}^\top + A) \text{ and } \vartheta_a(\overline{G}) = \Lambda(\sqrt{a}\sqrt{a}^\top + B). \tag{67.58}$$

So $C := \vartheta_w(G) \cdot I - \sqrt{w}\sqrt{w}^\top - A$ and $D := \vartheta_a(\overline{G}) \cdot I - \sqrt{a}\sqrt{a}^\top - B$ are positive semidefinite. Therefore, the matrix

$$\vartheta_w(G)\vartheta_a(\overline{G})\cdot I - \sqrt{w*a}\sqrt{w*a}^\top = C*D + C*(\sqrt{a}\sqrt{a}^\top) + (\sqrt{w}\sqrt{w}^\top)*D \tag{67.59}$$

is positive semidefinite by (67.31) (note that $A*I = I*B = A*B$ is the all-zero matrix). Hence

$$\begin{aligned} 0 &\le \sqrt{w*a}^\top(\vartheta_w(G)\vartheta_a(\overline{G})\cdot I - \sqrt{w*a}\sqrt{w*a}^\top)\sqrt{w*a} \\ &= \vartheta_w(G)\vartheta_a(\overline{G})\sqrt{w*a}^\top\sqrt{w*a} - \sqrt{w*a}^\top\sqrt{w*a}\sqrt{w*a}^\top\sqrt{w*a} \\ &= \vartheta_w(G)\vartheta_a(\overline{G})w^\top a - (w^\top a)^2, \end{aligned} \tag{67.60}$$

implying (67.57).

II. To prove $\mathrm{TH}(\overline{G}) \subseteq A(\mathrm{TH}(G))$, let $w \in \mathrm{TH}(\overline{G})$. By (67.56) we should prove $\vartheta_w(G) \le 1$.

Let B maximize $\sqrt{w}^\top B\sqrt{w}$ over $\mathrm{PSD} \cap \mathcal{M}_G$. Let $b := \mathrm{diag}B$ and define

$$C := \Delta_{\sqrt{w/b}} B \Delta_{\sqrt{w/b}}. \tag{67.61}$$

Then, with (67.40),

$$C\sqrt{b} = \Delta_{\sqrt{w/b}} B\sqrt{w} = \mu \cdot \Delta_{\sqrt{w/b}} b * w^{-\frac{1}{2}} = \mu \cdot \sqrt{b}, \tag{67.62}$$

where $\mu := \vartheta_w(G)$. So C has $\sqrt{b}$ as eigenvector, with eigenvalue μ. Since C is positive semidefinite, also the matrix

$$C - \mu(\sqrt{b}\sqrt{b}^\top) \tag{67.63}$$

is positive semidefinite. Hence the matrix

$$\Delta_{w^{-\frac{1}{2}}}(C - \mu\cdot\sqrt{b}\sqrt{b}^\top)\Delta_{w^{-\frac{1}{2}}} = \Delta_{b^{-\frac{1}{2}}} B \Delta_{b^{-\frac{1}{2}}} - \mu\cdot\sqrt{b/w}\sqrt{b/w}^\top \tag{67.64}$$

is positive semidefinite.

Define $A := I - \Delta_{b^{-\frac{1}{2}}} B \Delta_{b^{-\frac{1}{2}}}$ and $z := b/w$. So $A \in \mathcal{L}_{\overline{G}}$ and $\mu\cdot\sqrt{z}\sqrt{z}^\top + A$ has largest eigenvalue at most 1. Hence $\vartheta_z(\overline{G}) \le \mu^{-1}$, and so

$$\vartheta_w(G)\vartheta_z(\overline{G}) = \mu\vartheta_z(\overline{G}) \le 1 = \mathrm{Tr}B = b^\top\mathbf{1} = w^\top z \le \vartheta_z(\overline{G}), \tag{67.65}$$

where the last inequality holds as $w \in \mathrm{TH}(\overline{G})$. Hence $\vartheta_w(G) \le 1$. ∎

Facets of TH(G)

A subset F of TH(G) is called a *facet* of TH(G) if there is an inequality $c^\mathsf{T}x \leq \gamma$ (with $c \neq \mathbf{0}$) which is valid for TH(G), such that F is the set of vectors in TH(G) having equality and such that F has dimension $|V|-1$. Then (Grötschel, Lovász, and Schrijver [1986]):

Theorem 67.13. *For each graph $G=(V,E)$, each facet F of* TH(G) *is determined by an inequality $x_v \geq 0$ for some $v \in V$ or by $x(C) \leq 1$ for some clique C of G.*

Proof. Let F be determined by the inequality $c^\mathsf{T}x \leq \gamma$. If there is a $v \in V$ with $x_v = 0$ for each $x \in F$, then F is determined by the inequality $x_v \geq 0$. So we can assume that $x > 0$ for some $x \in F$. Since $\mathrm{TH}(G) = A(\mathrm{TH}(\overline{G}))$, there is a $w \in \mathbb{R}_+^V$ with $\vartheta_w(\overline{G}) = 1$ and F is determined by $w^\mathsf{T}x \leq 1$. So $w \in \mathrm{TH}(\overline{G})$, and therefore there is a matrix $A \in \mathcal{R}_{\overline{G}}$ with diag$A = w$. As $A \in \mathcal{R}_{\overline{G}}$, the matrix $R(A)$ is positive semidefinite. Hence there exist linearly independent vectors $\begin{pmatrix}\alpha_i\\ a_i\end{pmatrix}$ $(i=1,\ldots,k)$ such that

(67.66) $$\begin{pmatrix}1 & w^\mathsf{T}\\ w & A\end{pmatrix} = R(A) = \sum_{i=1}^{k}\begin{pmatrix}\alpha_i\\ a_i\end{pmatrix}(\alpha_i, a_i^\mathsf{T}).$$

We can assume that $\alpha_i \geq 0$ for each $i=1,\ldots,k$. Now

(67.67) $a_i^\mathsf{T}x = \alpha_i$ for each $x \in F$ and each $i=1,\ldots,k$.

To see this, choose $x \in F$. As $x \in \mathrm{TH}(G)$, there is a matrix $B \in \mathcal{R}_G$ with diag$B = x$. Since $R(B)$ is positive semidefinite, also the matrix

(67.68) $$B' := \begin{pmatrix}1 & -x^\mathsf{T}\\ -x & B\end{pmatrix}$$

is positive semidefinite. We therefore have (where again $X \bullet Y := \mathrm{Tr}(XY^\mathsf{T})$):

(67.69) $$\sum_{i=1}^{k}(\alpha_i, a_i^\mathsf{T})B'\begin{pmatrix}\alpha_i\\ a_i\end{pmatrix} = R(A)\bullet B' = 1-2w^\mathsf{T}x+A\bullet B = 1-2w^\mathsf{T}x+w^\mathsf{T}x = 0.$$

(Here $A \bullet B = w^\mathsf{T}x$ follows from the fact that $A \in \mathcal{R}_G$, $B \in \mathcal{R}_{\overline{G}}$, diag$A = w$, and diag$B = x$.)

Since B' is positive semidefinite, (67.69) implies that, for each $i=1,\ldots,k$:

(67.70) $$(\alpha_i, a_i^\mathsf{T})B'\begin{pmatrix}\alpha_i\\ a_i\end{pmatrix} = 0,$$

and therefore

(67.71) $$B'\begin{pmatrix}\alpha_i\\ a_i\end{pmatrix} = \mathbf{0}.$$

In particular,

(67.72) $$(1, -x^\mathsf{T})\begin{pmatrix}\alpha_i\\ a_i\end{pmatrix} = 0,$$

that is, $a_i^{\mathsf{T}} x = \alpha_i$, proving (67.67).

Since F is a facet, and since the $\begin{pmatrix} \alpha_i \\ a_i \end{pmatrix}$ are linearly independent, we know $k = 1$. So

$$(67.73) \qquad \begin{pmatrix} 1 & w^{\mathsf{T}} \\ w & A \end{pmatrix} = \begin{pmatrix} \alpha_1 \\ a_1 \end{pmatrix} (\alpha_1, a_1^{\mathsf{T}}).$$

Since $\alpha_1 \geq 0$, this implies $\alpha_1 = 1$ and $a_1 = w$. Since diag$A = w$, we know $w(v)^2 = w(v)$ for each $v \in V$, and so $w \in \{0,1\}^V$. Hence $A = \chi^C (\chi^C)^{\mathsf{T}}$ for some $C \subseteq V$. As $A_{u,v} = 0$ for distinct nonadjacent u, v, we know that C is a clique. ∎

This gives as consequence:

Corollary 67.13a. TH(G) *is a polytope if and only if G is perfect.*

Proof. If G is perfect, we have

$$(67.74) \qquad P_{\text{stable set}}(G) \subseteq \text{TH}(G) \subseteq A(P_{\text{clique}}(G)) = P_{\text{stable set}}(G),$$

implying that TH$(G) = P_{\text{stable set}}(G)$, and therefore is a polytope.

To see the reverse implication, if TH(G) is a polytope, by (67.54) and Theorem 67.13, TH(G) is fully determined by the nonnegativity and clique inequalities; that is,

$$(67.75) \qquad \text{TH}(G) = A(P_{\text{clique}}(G)).$$

Since also $A(\text{TH}(G)) = \text{TH}(\overline{G})$ is a polytope, we know similarly that $\text{TH}(\overline{G}) = A(P_{\text{clique}}(\overline{G}))$. Hence

$$(67.76) \qquad \text{TH}(G) = A(\text{TH}(\overline{G})) = P_{\text{clique}}(\overline{G}) = P_{\text{stable set}}(G).$$

(67.75) and (67.76) imply that $P_{\text{stable set}}(G) = A(P_{\text{clique}}(G))$, and therefore G is perfect by Corollary 65.2e. ∎

Characterizing perfection by $\vartheta(G)$

Lovász [1983b] showed that perfection can be characterized by the function $\vartheta(G)$. To this end, Lovász first proved:

Theorem 67.14. *If G is a partitionable graph, then*

$$(67.77) \qquad \alpha(G) < \vartheta(G) < \overline{\chi}^*(G).$$

Proof. Let M be the incidence matrix of the maximum-size stable sets in G and let N be the incidence matrix of the maximum-size cliques of G. Define $n := |VG|$, $\alpha := \alpha(G)$, and $\omega := \omega(G)$. We first show the second inequality.

Let λ be the smallest eigenvalue of $N^{\mathsf{T}}N$. Since N is nonsingular (Theorem 65.9), we know $\lambda > 0$, and since $\text{Tr}(N^{\mathsf{T}}N) = n\omega$ and $N^{\mathsf{T}}N\mathbf{1} = \omega^2 \cdot \mathbf{1}$, we know $\lambda < \omega$ (otherwise $\text{Tr}(N^{\mathsf{T}}N) \geq \omega^2 + (n-1)\omega > n\omega$). So

$$(67.78) \qquad N^{\mathsf{T}}N - \lambda I - \frac{\omega^2 - \lambda}{n} J$$

is positive semidefinite, and therefore

$$(67.79)\qquad \frac{n(\omega-\lambda)}{\omega^2-\lambda}I - J + \frac{n}{\omega^2-\lambda}(N^{\mathsf{T}}N-\omega I)$$

is positive semidefinite. So (using (67.26) and (65.24))

$$(67.80)\qquad \vartheta(G) \le \Lambda(J - \frac{n}{\omega^2-\lambda}(N^{\mathsf{T}}N-\omega I)) \le \frac{n(\omega-\lambda)}{\omega^2-\lambda} < \frac{n}{\omega} = \chi^*(\overline{G}).$$

So we have the second inequality in (67.77), which implies the first, since:

$$(67.81)\qquad \vartheta(G) \ge \frac{n}{\vartheta(\overline{G})} > \frac{n}{\chi^*(G)} = \alpha,$$

by (65.24) and Theorem 67.8. ∎

This implies a characterization of perfect graphs:

Corollary 67.14a. *For any graph G, the following are equivalent:*

(67.82)
(i) *G is perfect,*
(ii) *$\alpha(H) = \vartheta(H)$ for each induced subgraph H of G,*
(iii) *$\vartheta(H) = \overline{\chi}^*(H)$ for each induced subgraph H of G,*
(iv) *$\vartheta(H)$ is an integer for each induced subgraph H of G.*

Proof. Directly from Theorem 67.14, using (65.24). ∎

67.4b. The Shannon capacity $\Theta(G)$

Shannon [1956] introduced the following parameter $\Theta(G)$, now called the Shannon capacity of a graph G.

The *strong product* $G \cdot H$ of graphs G and H is the graph with vertex set $VG \times VH$, with two distinct vertices (u, v) and (u', v') adjacent if and only if u and u' are equal or adjacent in G and v and v' are equal or adjacent in H.

The strong product of k copies of G is denoted by G^k. Then the *Shannon capacity* $\Theta(G)$ of G is defined by:

$$(67.83)\qquad \Theta(G) = \sup_k \sqrt[k]{\alpha(G^k)}.$$

(The interpretation is that if V is an alphabet, and adjacency means 'confusable', then $\alpha(G^k)$ is the maximum number of k-letter words any two of which have unequal and inconfusable letters in at least one position. Then $\Theta(G)$ is the maximum possible 'information rate'.)

Since $\alpha(G^{k+l}) \ge \alpha(G^k)\alpha(G^l)$, we know by Fekete's lemma (Corollary 2.2a) that

$$(67.84)\qquad \Theta(G) = \lim_{k\to\infty} \sqrt[k]{\alpha(G^k)}.$$

Guo and Watanabe [1990] showed that there exist graphs G for which $\Theta(G)$ is not achieved by a finite product (that is, $\sqrt[k]{\alpha(G^k)} < \Theta(G)$ for each k).

Since $\alpha(G^k) \ge \alpha(G)^k$, we have

$$(67.85)\qquad \alpha(G) \le \Theta(G),$$

while strict inequality may hold: the 5-circuit C_5 has $\alpha(C_5) = 2$ and $\alpha(C_5^2) = 5$. (If C_5 has vertices $1, \ldots, 5$ and edges 12, 23, 34, 45, and 51, then $(1,1)$, $(2,3)$, $(3,5)$, $(4,2)$, $(5,4)$ is a stable set in C_5^2.) So $\Theta(C_5) \geq \sqrt{5}$, and Shannon [1956] raised the question if equality holds here. Shannon proved $\Theta(C_5) \leq \frac{5}{2}$; more generally, he proved, for any graph G:

(67.86) $$\Theta(G) \leq \overline{\chi}^*(G),$$

where $\overline{\chi}^*(G)$ is the fractional clique cover number. This bound can be proved by showing that

(67.87) $$\overline{\chi}^*(G \cdot H) \leq \overline{\chi}^*(G)\overline{\chi}^*(H).$$

This follows from the fact that if C and D are cliques of G and H respectively, then $C \times D$ is a clique of $G \cdot H$; hence if $\lambda : \mathcal{C} \to \mathbb{R}_+$ and $\mu : \mathcal{D} \to \mathbb{R}_+$ are minimum fractional clique covers for G and H respectively, where $\mathcal{C}$ and $\mathcal{D}$ denote the collections of cliques of G and H respectively, then (where $\circ$ denotes tensor product — see footnote on page 1161, and $\mathbf{1}_U$ denotes the all-one vector in $\mathbb{R}^U$, for any set U)

(67.88) $$\sum_{C\in\mathcal{C}}\sum_{D\in\mathcal{D}} \lambda_C\mu_D\chi^{C\times D} = \sum_{C\in\mathcal{C}}\sum_{D\in\mathcal{D}} \lambda_C\mu_D(\chi^C \circ \chi^D)$$
$$= \Big(\sum_{C\in\mathcal{C}} \lambda_C\chi^C\Big) \circ \Big(\sum_{D\in\mathcal{D}} \mu_D\chi^D\Big) = \mathbf{1}_{VG} \circ \mathbf{1}_{VH} = \mathbf{1}_{VG\times VH}$$

and hence

(67.89) $$\overline{\chi}^*(G \cdot H) \leq \sum_{C\in\mathcal{C}}\sum_{D\in\mathcal{D}} \lambda_C\mu_D = \Big(\sum_{C\in\mathcal{C}} \lambda_C\Big)\Big(\sum_{D\in\mathcal{D}} \mu_D\Big) = \overline{\chi}^*(G)\overline{\chi}^*(H).$$

This proves (67.87) (in (67.112) we show equality).

(67.87) implies (67.86), since

(67.90) $$\sqrt[k]{\alpha(G^k)} \leq \sqrt[k]{\overline{\chi}^*(G^k)} \leq \sqrt[k]{\overline{\chi}^*(G)^k} = \overline{\chi}^*(G).$$

This bound was improved by Lovász [1979d] as follows (which will imply that $\Theta(C_5) = \sqrt{5}$):

Theorem 67.15. *$\Theta(G) \leq \vartheta(G)$ for each graph G.*

Proof. Since $\alpha(G) \leq \vartheta(G)$, it suffices to show that for each k: $\alpha(G^k) \leq \vartheta(G)^k$. For this it suffices to show that

(67.91) $$\vartheta(G \cdot H) \leq \vartheta(G)\vartheta(H)$$

for any graphs G and H.

By (67.26), there exist matrices $A \in \mathcal{L}_G$ and $B \in \mathcal{L}_H$ such that

(67.92) $$\vartheta(G) = \Lambda(J_{VG} + A) \text{ and } \vartheta(H) = \Lambda(J_{VH} + B),$$

where J_U denotes the $U \times U$ all-one matrix, for any set U. Hence the matrices

(67.93) $$C := \vartheta(G) \cdot I_{VG} - J_{VG} - A \text{ and } D := \vartheta(H) \cdot I_{VH} - J_{VH} - B$$

are positive semidefinite, where I_U denotes the $U \times U$ identity matrix, for any set U.

Therefore, also the following matrix[14] is positive semidefinite:

[14] The *tensor product* of a $W \times X$ matrix M and a $Y \times Z$ matrix N (where W, X, Y, Z are sets), is the $(W \times Y) \times (X \times Z)$ matrix $M \circ N$ defined by

(67.94) $$C \circ D + C \circ J_{VH} + J_{VG} \circ D = (C + J_{VG}) \circ (D + J_{VH}) - J_{VG} \circ J_{VH} \\ = (\vartheta(G) \cdot I_{VG} - A) \circ (\vartheta(H) \cdot I_{VH} - B) - J_{VG \times VH} \\ = \vartheta(G)\vartheta(H) \cdot I_{VG \times VH} - J_{VG \times VH} - M,$$

where $M := \vartheta(G) \cdot I_{VG} \circ B + \vartheta(H) A \circ I_{VH} - A \circ B$. Since $I_{VG} \circ B$, $A \circ I_{VH}$, and $A \circ B$ belong to $\mathcal{L}_{G \cdot H}$,[15] also M belongs to $\mathcal{L}_{G \cdot H}$. Therefore,

(67.95) $$\vartheta(G \cdot H) \leq \Lambda(J_{VG \times VH} + M) \leq \vartheta(G)\vartheta(H),$$

giving (67.91). ∎

This proof consists of showing the inequality (67.91) for any two graphs G and H. In fact, equality holds (Lovász [1979d]):

(67.96) $$\vartheta(G \cdot H) = \vartheta(G)\vartheta(H).$$

Indeed, let M and N attain the maximum in definition (67.1) for $\vartheta(G)$ and $\vartheta(H)$ respectively. Then $M \circ N \in \mathcal{M}_{G \cdot H}$, and hence

(67.97) $$\vartheta(G \cdot H) \geq \mathbf{1}_{VG \times VH}^{\mathsf{T}} (M \circ N) \mathbf{1}_{VG \times VH} = (\mathbf{1}_{VG}^{\mathsf{T}} M \mathbf{1}_{VG})(\mathbf{1}_{VH}^{\mathsf{T}} N \mathbf{1}_{VH}) \\ = \vartheta(G)\vartheta(H).$$

Theorem 67.15 implies that $\Theta(C_5) = \sqrt{5}$. One may give an explicit construction to prove this, but it also follows from the following general result (Lovász [1979d]):[16]

Theorem 67.16. *For each graph $G = (V, E)$: $\vartheta(G)\vartheta(\overline{G}) \geq |V|$, with equality if G is vertex-transitive.*

Proof. The inequality is Theorem 67.8. If G is vertex-transitive, then $\mathbf{1}^{\mathsf{T}} x$ is maximized over $\mathrm{TH}(G)$ at a vector $x = \mu \cdot \mathbf{1}$ for some $\mu \in \mathbb{R}$, since if it is maximized at x we can replace it by

(67.98) $$\frac{1}{|\Gamma|} \sum_{P \in \Gamma} Px,$$

where Γ is the group of permutation matrices representing automorphisms of G. (This follows from the fact that $Px \in \mathrm{TH}(G)$ and $\mathbf{1}^{\mathsf{T}} Px = \mathbf{1}^{\mathsf{T}} x$.)

As the maximum value is equal to $\vartheta := \vartheta(G)$, we know $\mathbf{1}^{\mathsf{T}} x = \vartheta$, and so $\mu = \vartheta/n$, where $n := |V|$. Since $x \in \mathrm{TH}(G) = A(\mathrm{TH}(\overline{G}))$ (by Theorem 67.12), we have $\vartheta_x(\overline{G}) \leq 1$; hence (as $x = \mu \cdot \mathbf{1}$) $\vartheta(\overline{G}) \leq \mu^{-1} = n/\vartheta$. This shows $\vartheta(G)\vartheta(\overline{G}) \leq n$. ∎

$$(M \circ N)_{(w,y),(x,z)} := M_{w,x} N_{y,z}$$

for $w \in W$, $x \in X$, $y \in Y$, $z \in Z$. If M and N are symmetric positive semidefinite matrices, then $M \circ N$ is symmetric and positive semidefinite again, since if $M = U^{\mathsf{T}} U$ and $N = V^{\mathsf{T}} V$, then $M \circ N = (U \circ V)^{\mathsf{T}} (U \circ V)$.

[15] To see this, let (u, v) and (u', v') be equal or nonadjacent. Then (by definition of $G \cdot H$) $u = u'$ and $v = v'$, or $u \neq u'$ and u and u' are nonadjacent, or $v \neq v'$ and v and v' are nonadjacent. Hence $(I_{VG})_{u,u'} = 0$ or $B_{v,v'} = 0$, and $A_{u,u'} = 0$ or $(I_{VH})_{v,v'} = 0$, and $A_{u,u'} = 0$ or $B_{v,v'} = 0$.

[16] An *automorphism* of a graph $G = (V, E)$ is a permutation $\pi : V \to V$ with $E = \{\{\pi(u), \pi(v)\} \mid \{u, v\} \in E\}$. The graph G is *vertex-transitive* if for all $u, v \in V$ there exists an automorphism π with $\pi(u) = v$.

Since $\overline{C}_5$ is isomorphic to C_5, Theorem 67.16 gives $\vartheta(C_5) = \sqrt{5}$. So $\Theta(G) \leq \sqrt{5}$. As $\Theta(G) \geq \sqrt{\alpha(C_5^2)} = \sqrt{5}$, one has $\Theta(G) = \sqrt{5}$.

Another consequence of Theorem 67.16 is that for any vertex-transitive graph G: $\Theta(G \cdot \overline{G}) = |VG|$, since the pairs (v, v) for $v \in VG$ form a stable set in $G \cdot \overline{G}$ (so $\Theta(G \cdot \overline{G}) \geq |VG|$), and since $\Theta(G \cdot \overline{G}) \leq \vartheta(G \cdot \overline{G}) = \vartheta(G)\vartheta(\overline{G}) = |VG|$. If moreover G is self-complementary (like C_5), then $\Theta(G) = \sqrt{|VG|}$.

For graphs that are not vertex-transitive, $\vartheta(G)\vartheta(\overline{G}) > |VG|$ may hold, even $\alpha(G)\alpha(\overline{G}) > |VG|$, for instance for $G = K_{1,2}$.

Lovász [1979d] also gave the value of $\vartheta(C_n)$ for any odd circuit C_n:

(67.99) $$\vartheta(C_n) = \frac{n \cos(\pi/n)}{1 + \cos(\pi/n)} \text{ for odd } n.$$

For odd $n \geq 7$, it is unknown if this is the value of $\Theta(C_n)$. Since each C_n is vertex-transitive, by Theorem 67.16 we can derive from (67.99) the value of $\vartheta(\overline{C}_n)$ for odd n.

Lovász asked the question if $\Theta(G) = \vartheta(G)$ for each graph G. This was answered in the negative by Haemers [1979], by giving the following alternative upper bound on the Shannon capacity of a graph $G = (V, E)$. Let $\eta(G)$ be the minimum rank of a $V \times V$ matrix M (over any field) such that $M_{v,v} = 1$ for each $v \in V$ and $M_{u,v} = 0$ for distinct nonadjacent u and v. Then

(67.100) $$\Theta(G) \leq \eta(G).$$

This follows from the facts that $\alpha(G) \leq \eta(G)$ (since any stable set S in G gives an $S \times S$ identity submatrix of M), and that $\eta(G \cdot H) \leq \eta(G)\eta(H)$ (since $\text{rank}(M \circ N) = \text{rank}(M)\text{rank}(N)$ for any two matrices (over the same field)). Moreover, one has $\eta(G) \leq \overline{\chi}(G)$ (by considering, for any clique cover of G, the $\{0, 1\}$ matrix M with $M_{u,v} = 1$ if and only if u and v belong to some clique in the clique cover).

Haemers gave a graph G on 27 vertices (the complement of the 'Schläfli graph') with $\eta(G) \leq 7$ and $\vartheta(G) = 9$, implying $\Theta(G) \leq 7 < \vartheta(G)$. Since $\vartheta(\overline{G}) = 3$, this also gives an example of a graph G satisfying $\Theta(G)\Theta(\overline{G}) < |VG|$ and (hence) $\Theta(G)\Theta(\overline{G}) < \Theta(G \cdot \overline{G})$. (This disproves the conjecture of Shannon [1956] that $\Theta(G)\Theta(H) = \Theta(G \cdot H)$ for all graphs G, H, and answering to the negative the question of Lovász [1979d] whether $\Theta(G)\Theta(\overline{G}) \geq |VG|$ for all graphs G.)

It is unknown if Haemers' bound $\eta(G)$ can be computed in polynomial time. (Peeters [1996] reports results on this. More work on Haemers' bound in Haemers [1981].)

The following bound follows with a method of Rosenfeld [1967]:

(67.101) $$\alpha(G \cdot H) \leq \overline{\chi}^*(G)\alpha(H).$$

To see this, let $C_1, \ldots, C_k$ be cliques in G and $\lambda_1, \ldots, \lambda_k \geq 0$ be such that

(67.102) $$\lambda_1 \chi^{C_1} + \cdots + \lambda_k \chi^{C_k} = \mathbf{1}_{VG} \text{ and } \lambda_1 + \cdots + \lambda_k = \overline{\chi}^*(G).$$

Let $S \subseteq VG \times VH$ be a stable set in $G \cdot H$ of size $\alpha(G \cdot H)$. For each $u \in VG$, let $S_u := \{v \in VH \mid (u, v) \in S\}$. Then S_u is a stable set of H, and if u and u' are adjacent vertices of G, then $S_u \cap S_{u'} = \emptyset$. For each $i = 1, \ldots, k$, let

(67.103) $$T_i := \{v \in VH \mid \exists u \in C_i : (u, v) \in S\} = \bigcup_{u \in C_i} S_u.$$

Since C_i is a clique in G, T_i is a stable set in H, and $|T_i| = \sum_{u \in C_i} |S_u|$. Hence

(67.104) $$|S| = \sum_{u \in VG} |S_u| = \sum_{i=1}^{k} \lambda_i \sum_{u \in C_i} |S_u| = \sum_{i=1}^{k} \lambda_i |T_i| \le \sum_{i=1}^{k} \lambda_i \alpha(H) = \overline{\chi}^*(G)\alpha(H).$$

This shows (67.101).

Rosenfeld [1967] showed that for each graph G:

(67.105) $\alpha(G \cdot H) = \alpha(G)\alpha(H)$ for each graph $H \iff \alpha(G) = \overline{\chi}^*(G)$.

Here $\Longleftarrow$ follows from (67.101). To see $\Longrightarrow$, let $x \in \mathbb{Q}_+^{VG}$ be a vector satisfying $x(C) \le 1$ for each clique C, and $\mathbf{1}^\mathsf{T} x = \overline{\chi}^*(G)$. Let K be a positive integer such that $w := K \cdot x$ is integer. Let G^w be the graph obtained from G by replacing each vertex u by a clique C_u of size $w(u)$ (where vertices in distinct $C_u, C_{u'}$ are adjacent if and only if u and u' are adjacent). Then $\omega(G^w) \le K$. Hence for $H := \overline{G^w}$ we have $\alpha(H) \le K$.

Now let

(67.106) $S := \{(u, v) \mid u \in VG, v \in C_u\}$.

Then S is a stable set in $G \cdot H$, since if (u, v) and (u', v') are distinct elements in S, then, if $u = u'$, v and v' belong to C_u and hence are nonadjacent in H, and, if $u \ne u'$, u and u' are nonadjacent in G or v and v' are nonadjacent in H.

So $|S| \le \alpha(G \cdot H) = \alpha(G)\alpha(H)$. Hence

(67.107) $$\overline{\chi}^*(G) = \mathbf{1}^\mathsf{T} x = \frac{1}{K}\mathbf{1}^\mathsf{T} w = \frac{1}{K}|S| \le \frac{1}{K}\alpha(G)\alpha(H) \le \alpha(G).$$

Hence $\overline{\chi}^*(G) = \alpha(G)$.

More results on the stable set number of products of graphs are given by Vizing [1963], Barnes and Mackey [1978], and Jha and Slutzki [1994].

The stable set number of products of circuits

The following equality was given by Baumert, McEliece, Rodemich, Rumsey, Stanley, and Taylor [1971] and Markosyan [1971]:

(67.108) $\alpha(C_{2k+1}^2) = k^2 + \lfloor \frac{1}{2}k \rfloor$.

$\le$ directly follows from (67.101), since $\alpha(C_{2k+1}) = k$ and $\overline{\chi}^*(C_{2k+1}) = k + \frac{1}{2}$. To see $\ge$, we may assume that the vertices of C_{2k+1} are $0, 1, \ldots, 2k$, in order. Then the pairs $(2i, \lfloor 2i/k \rfloor)$, for $i = 1, \ldots, k^2 + \lfloor \frac{1}{2}k \rfloor$, where we take integers mod $2k+1$, form a stable set of size $k^2 + \lfloor \frac{1}{2}k \rfloor$ in C_{2k+1}^2.

Baumert, McEliece, Rodemich, Rumsey, Stanley, and Taylor [1971] showed moreover the following inequalities (next to several other estimates for $\alpha(C_n^k)$):

(67.109) $$\alpha(C_{n+2}^k) \ge 1 + \frac{(n+2)^k - 2^k}{n^k}\alpha(C_n^k),$$
$$\alpha(C_n^k) \le \frac{n^k - n^{k-1}}{2^k},$$
$$\alpha(C_5^3) = 10,\ \alpha(C_5^4) = 25,\ \alpha(C_7^3) = 33.$$

Hales [1973] extended (67.108) to:

(67.110) $\alpha(C_{2k+1} \cdot C_{2l+1}) = kl + \lfloor \frac{1}{2}\min\{k, l\} \rfloor$.

Related results on the stable set number of products of circuits are given by Sonnemann and Krafft [1974], Stein [1977], Hell and Roberts [1982], Mead and Narkiewicz [1982], Vesel [1998], and Vesel and Žerovnik [1998].

67.4c. Clique cover numbers of products of graphs

As for the analogue of the Shannon capacity for clique cover numbers, McEliece and Posner [1971] showed that it gives no new parameter. We follow the proof of Lovász [1975c].

Theorem 67.17. *For any graph G:*

$$(67.111)\qquad \inf_k \sqrt[k]{\overline{\chi}(G^k)} = \lim_{k\to\infty} \sqrt[k]{\overline{\chi}(G^k)} = \overline{\chi}^*(G).$$

Proof. We first show that for any two graphs G, H:

$$(67.112)\qquad \overline{\chi}^*(G\cdot H) = \overline{\chi}^*(G)\overline{\chi}^*(H).$$

Here $\leq$ follows from (67.87). To see $\geq$, choose vectors $x : VG \to \mathbb{R}_+$ with $x(C) \leq 1$ for each clique, and with $x(VG) = \overline{\chi}^*(G)$, and $z : VH \to \mathbb{R}_+$ with $z(C) \leq 1$ for each clique, and with $z(VH) = \overline{\chi}^*(H)$. Define $y : VG \times VH \to \mathbb{R}_+$ by

$$(67.113)\qquad y(u, v) := x(u)z(v)$$

for $(u, v) \in VG \times VH$. Then $y(C) \leq 1$ for each clique C of $G \cdot H$, since there are cliques C' and C'' of G and H, respectively, such that $C \subseteq C' \times C''$; then $y(C) \leq y(C' \times C'') = x(C')z(C'') \leq 1$.

Hence

$$(67.114)\qquad \overline{\chi}^*(G\cdot H) \geq y(VG \times VH) = x(VG)z(VH) = \overline{\chi}^*(G)\overline{\chi}^*(H).$$

This proves (67.112).

To prove (67.111), the first equality follows from Fekete's lemma (Corollary 2.2a), since $\overline{\chi}(G^{k+l}) = \overline{\chi}(G^k)\cdot\overline{\chi}(G^l)$. Also we have by (67.112):

$$(67.115)\qquad \inf_k \sqrt[k]{\overline{\chi}(G^k)} \geq \inf_k \sqrt[k]{\overline{\chi}^*(G^k)} = \overline{\chi}^*(G),$$

So it suffices to prove the reverse inequality in (67.115). Since $\omega(G^k) = \omega(G)^k$ and since $\overline{\chi}^*(G^k) = \overline{\chi}^*(G)^k$, we have by Theorem 64.13 (applied to $\overline{G^k}$):

$$(67.116)\qquad \inf_k \sqrt[k]{\overline{\chi}(G^k)} \leq \inf_k \sqrt[k]{(1+\ln\omega(G^k))\overline{\chi}^*(G^k)}$$
$$= \inf_k \sqrt[k]{(1+k\ln\omega(G))}\overline{\chi}^*(G) = \overline{\chi}^*(G),$$

as required. ∎

An alternative proof was given by Hell and Roberts [1982]. A related information-theoretic characterization of perfect graphs was given by Csiszár, Kőrner, Lovász, Marton, and Simonyi [1990] (proving a conjecture of Kőrner and Marton [1988]). More on the colouring number of products of graphs can be found in Borowiecki [1972], Greenwell and Lovász [1974], Vesztergombi [1980,1981], Turzík [1983], Duffus, Sands, and Woodrow [1985], El-Zahar and Sauer [1985], Puš [1988], Soukop [1988], Linial and Vazirani [1989], and Klavžar [1996] (survey).

Hales [1973] showed that for all graphs G, H:

$$(67.117)\qquad \overline{\chi}(G\cdot H) \geq \overline{\chi}^*(G)\overline{\chi}(H),$$

and

$$(67.118)\qquad \overline{\chi}(C_{2k+1}\cdot C_{2l+1}) = (k+1)(l+1) - \lceil \tfrac{1}{2}\min\{k, l\}\rceil.$$

McEliece and Taylor [1973] showed that $\overline{\chi}(C_{n,t}^2) = \lceil n/t\lceil n/t\rceil\rceil$, where $C_{n,t}$ is the graph obtained from the circuit C_n by adding all chords connecting vertices at distance less than t in C_n.

67.4d. A sharper upper bound $\vartheta'(G)$ on $\alpha(G)$

McEliece, Rodemich, and Rumsey [1978] and Schrijver [1979a] gave the following sharper bound $\vartheta'(G)$ on the stable set number $\alpha(G)$, generally sharper than $\vartheta(G)$. Again, let $\mathcal{M}_G$ be the collection of symmetric $V \times V$ matrices satisfying $M_{u,v} = 0$ for any two distinct adjacent vertices u and v, and $\mathrm{Tr}M = 1$. (Here $\mathrm{Tr}M$ is the trace of M (sum of diagonal elements).) Then define

(67.119) $\vartheta'(G) := \max\{\mathbf{1}^{\mathsf{T}} M \mathbf{1} \mid M \in \mathcal{M}_G$ nonnegative and positive semidefinite$\}$.

Here $\mathbf{1}$ denotes the all-one vector in $\mathbb{R}^V$. Similarly to $\vartheta(G)$, the value of $\vartheta'(G)$ can be calculated in polynomial time. Moreover

(67.120) $\alpha(G) \leq \vartheta'(G) \leq \vartheta(G)$

for each graph G. The first inequality is proved similarly to the proof of the first inequality in Theorem 67.1, while the second inequality follows from the fact that the range of the maximization problem for $\vartheta'(G)$ is contained in that for $\vartheta(G)$.

$\vartheta'(G)$ indeed can be a sharper upper bound on the stable set number than $\vartheta(G)$, as M.R. Best (cf. Schrijver [1979a]) found the following example of a graph G with $\vartheta'(G) < \vartheta(G)$. The vertex set is $\{0,1\}^6$, two vectors being adjacent if and only if their Hamming distance[17] is at most 3. Then $\vartheta'(G) = 4$ whereas $\vartheta(G) = 16/3$.

Schrijver [1979a] gave relations of $\vartheta'(G)$ with the linear programming bound for codes of Delsarte [1973]. Related work can be found in Schrijver [1981a] and Miklós [1996]. (The polynomial-time computable upper bound for $\alpha(G)$ given by Luz [1995] is at least $\vartheta'(G)$ for all graphs G.)

67.4e. An operator strengthening convex bodies

The matrix method describing $\mathrm{TH}(G)$ given in Section 67.4a can be seen as a special case of a method of improving approximations of the stable set polytope — in fact, of any polytope with $\{0,1\}$ vertices (Lovász and Schrijver [1989,1991]).

Let K be a convex set, let $R(A)$ be defined as in (67.35), and define

(67.121) $\mathcal{N}_K :=$ the collection of symmetric $n \times n$ matrices A with $R(A)$ positive semidefinite, and with $A_i \in A_{i,i} \cdot K$ and $\mathrm{diag}A - A_i \in (1 - A_{i,i}) \cdot K$ for each $i = 1, \ldots, n$,

where A_i denotes the ith column of A.

Define the following new convex set $N_+(K)$:

(67.122) $N_+(K) := \{\mathrm{diag}A \mid A \in \mathcal{N}_K\}$.

Then $N_+(K) \subseteq [0,1]^n$, since $R(A)$ is positive semidefinite. The ellipsoid method gives, for any collection $\mathcal{K}$ of convex sets:

(67.123) if the optimization problem over K is polynomial-time solvable for each $K \in \mathcal{K}$, then also the optimization problem over $N_+(K)$ is polynomial-time solvable for each $K \in \mathcal{K}$.

[17] The *Hamming distance* of two vectors of equal dimension is equal to the number of coordinates in which they differ.

Indeed, if the optimization problem over K is polynomial-time solvable, then the membership problem over K is polynomial-time solvable. Hence the membership problem over $\mathcal{N}_K$ is polynomial-time solvable, implying that the optimization problem over $\mathcal{N}_K$ is polynomial-time solvable. Therefore, the optimization problem over $N_+(K)$ is polynomial-time solvable. (Cf. Chapter 4 of Grötschel, Lovász, and Schrijver [1988].)

Before proving further properties of the operator N_+, we note that it commutes with the following reflection. Define $r : \mathbb{R}^n \to \mathbb{R}^n$ by $r(x)_1 := 1 - x_1$ and $r(x)_i := x_i$ for $i = 2, \ldots, n$, for $x \in \mathbb{R}^n$: Then

(67.124) $$N_+(r(K)) = r(N_+(K)).$$

To see this, let, for any $n \times n$ matrix A, the matrix A' be defined by:

(67.125) $$A'_{1,1} := 1 - A_{1,1};\ A'_{1,i} := A'_{i,1} := A_{i,i} - A_{i,1} \text{ for } i = 2, \ldots, n;$$
$$A'_{i,j} := A_{i,j} \text{ for } i, j = 2, \ldots, n.$$

Then $R(A)$ is positive semidefinite if and only if $R(A')$ is positive semidefinite, since

(67.126) $$R(A') = \begin{pmatrix} 1 & 0 & 0 \\ 1 & -1 & 0 \\ 0 & 0 & I \end{pmatrix} R(A) \begin{pmatrix} 1 & 1 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & I \end{pmatrix}.$$

Moreover, $A \in \mathcal{N}_K \iff A' \in \mathcal{N}_{r(K)}$ and $\text{diag}A' = r(\text{diag}A)$. This gives (67.124).

From this one can derive, if K is compact and convex and intersects $[0,1]^n$:

(67.127) $$N_+(K) \subseteq K.$$

For let $A \in \mathcal{N}_K$ and define $a := \text{diag}A$. If $a \notin K$, there exists a $w \in \mathbb{R}^n$ and $\beta \in \mathbb{R}$ with $w^\mathsf{T} x \leq \beta$ for each $x \in K$ and $w^\mathsf{T} a > \beta$. Since by (67.124) we can flip signs if necessary, we can assume $w \geq \mathbf{0}$. Then, since for each i the vector A_i belongs to $A_{i,i} \cdot K$,

(67.128) $$w^\mathsf{T} A w = \sum_i w_i \big(\sum_j w_j A_{i,j}\big) = \sum_i w_i (w^\mathsf{T} A_i) \leq \sum_i w_i A_{i,i} \beta = \beta w^\mathsf{T} a.$$

Hence

(67.129) $$0 \leq (w^\mathsf{T} a, -w^\mathsf{T}) \begin{pmatrix} 1 & a^\mathsf{T} \\ a & A \end{pmatrix} \begin{pmatrix} w^\mathsf{T} a \\ -w \end{pmatrix} = (w^\mathsf{T} a)^2 - 2(w^\mathsf{T} a)^2 + w^\mathsf{T} A w$$
$$\leq -(w^\mathsf{T} a)^2 + \beta \cdot w^\mathsf{T} a = (\beta - w^\mathsf{T} a) w^\mathsf{T} a < 0,$$

since $\beta - w^\mathsf{T} a < 0$ and $w^\mathsf{T} a > \beta \geq 0$ (since $\beta \geq w^\mathsf{T} x \geq 0$ for any $x \in K \cap [0,1]^n$). This is a contradiction, showing (67.127).

Moreover, if $K \subseteq [0,1]^n$, then $N_+(K)$ remains to contain the integer hull of K:

(67.130) $$(N_+(K))_\mathrm{I} = K_\mathrm{I}.$$

To see this, it suffices to show that $x \in N_+(K)$ for each 0,1 vector x in K. Obviously, $A := xx^\mathsf{T}$ belongs to $\mathcal{N}_K$. Hence $x = \text{diag}A$ belongs to $N_+(K)$. This proves (67.130).

Finally, if $K \subseteq [0,1]^n$, then repeated application of the N_+ operator gives the integer hull K_I of K. In fact, one has:

(67.131) $$N_+^n(K) = K_\mathrm{I}.$$

This follows from the fact that for each $j = 1, \ldots, n$:

(67.132) $\quad N_+(K) \subseteq \text{conv.hull}\{x \in K \mid x_j \in \{0,1\}\}$.

To see this, we may assume that $j = n$. Let $a \in N_+(K)$, with $a = \text{diag}A$ and $A \in \mathcal{N}_K$. Then $A_n \in a_n \cdot K$ and $(a - A_n) \in (1 - a_n) \cdot K$. If $a_n \in \{0,1\}$, then a belongs to the right-hand side of (67.132). So we can assume that $0 < a_n < 1$. Set

(67.133) $\quad a' := \frac{1}{a_n} A_n$ and $a'' := \frac{1}{1-a_n}(a - A_n)$.

Then a' and a'' belong to K, and $a'_n = 1$, $a''_n = 0$. As $a = a_n \cdot a' + (1 - a_n) \cdot a''$, we have that a belongs to the right-hand side of (67.132). This proves (67.132).

(67.131) implies that, when starting with $K := \text{TH}(G)$, we can obtain better and better approximations of $P_{\text{stable set}}(G)$ by applying the N_+ operator. After any fixed number of iterations, we can optimize over the convex body in polynomial time, by (67.123).

Stephen and Tunçel [1999] showed that for the line graph $G = L(K_{2n+1})$ of the complete graph K_{2n+1}, when starting with the polytope determined by the nonnegativity and edge constraints ((64.10) in Section 64.5), the number of iterations is precisely n. Related results were given by Cook and Dash [2001].

Leaving out the positive semidefiniteness condition in $\mathcal{N}_K$ yields a weaker operator $N(K)$, which however still satisfies a number of the above properties, including (67.131). The operator $N(K)$ is a special case of a more general operator introduced by Sherali and Adams [1990].

Results relating a related operator to perfection of graphs were given by Aguilera, Escalante, and Nasini [2002].

67.4f. Further notes

Juhász [1982] showed that for a random graph G on n vertices, $\vartheta(G)$ is of the order $\sqrt{n}$, while $\Theta(G)$ is 'likely' to be of the order $\log n$. Knuth [1994] asked if there is a constant c such that $\vartheta(G) \leq c\sqrt{n}\alpha(G)$ for each graph G. This was answered negatively by Feige [1995,1997], who showed that there is a constant $c > 0$ such that

(67.134) $\quad \vartheta(G) > \alpha(G)n/2^{c\sqrt{\log n}}$

for infinitely many graphs G (where $n := |VG|$).

The results of Kashin and Konyagin [1981] and Konyagin [1981] imply that if $\alpha(G) \leq 2$, then $\vartheta(G) \leq 2^{\frac{2}{3}} n^{\frac{1}{3}}$ and (in the worst case) $\vartheta(G) = \Omega(n^{\frac{1}{3}}/\sqrt{\log n})$.

Karger, Motwani, and Sudan [1994,1998] showed the existence of a constant $c > 0$ such that

(67.135) $\quad \overline{\chi}(G) \leq n^{1 - \frac{c}{\vartheta(G)}}$

for each graph G (where $n := |VG|$). More on approximating $\alpha(G)$ or $\overline{\chi}(G)$ by $\vartheta(G)$ can be found in Szegedy [1994] and Charikar [2002].

Kleinberg and Goemans [1998] observed that for any graph G:

(67.136) $\quad \tau(G) \leq 2(|V| - \vartheta(G)) \leq 2\tau(G)$

(where $\tau(G)$ is the vertex cover number of G), and they showed that the factor 2 cannot be improved. Thus the factor 2 as relative error of $\nu(G)$ for approximating $\tau(G)$ is not improved by $2(|V| - \vartheta(G))$.

Fast practical algorithms to compute $\vartheta(G)$, based on interior-point methods, were developed by Alizadeh [1991,1995]. The latter paper also gives a survey on applying semidefinite programming to combinatorial optimization.

A colouring algorithm for perfect graphs based on decomposition was described by Hsu [1986]. An on-line colouring algorithm for perfect graphs (not necessarily yielding an optimum colouring) was given by Kierstead and Kolossa [1996]. An algorithm for colouring some perfect graphs was given by Aït Haddadène, Gravier, and Maffray [1998]. Kratochvil and Sebő [1997] studied the complexity of colouring a perfect graph if some vertices are pre-coloured. Brandstädt [1987] showed the NP-completeness of several optimization problems for special classes of perfect graphs, like finding a minimum feedback vertex set or a minimum dominating set.

Introductory surveys were given by Knuth [1994] and Goemans [1997] on $\vartheta(G)$, by Grötschel, Lovász, and Schrijver [1984c] on polynomial-time algorithms for clique and colouring problems in perfect graphs, and by Reed [2001a] on semi-definite programming in relation to perfect graphs. Another characterization of perfection in terms of $\mathrm{TH}(G)$ was given by Shepherd [2001].

A generalization of $\vartheta(G)$ was given by Narasimhan and Manber [1990]. A generalization of the Shannon capacity to directed graphs was studied by Bidamon and Meyniel [1985]. An analogue of the Shannon capacity based on the 'independent domination number' of a graph, was investigated by Farber [1986]. The Shannon capacity of probabilistic graphs was investigated by Marton [1993].

Further investigations of eigenvalue methods to bound the Shannon capacity are reported by Haemers [1995] and Fiol [1999]. Further convex programming duality phenomena for perfect graphs were found by Wei [1988].

67.4g. Historical notes on perfect graphs

Shannon

As Berge [1997] mentioned, the perfect graph conjectures root in work of Shannon [1956] concerning the 'zero error capacity of a noisy channel'. It amounts to a study of what we now call the Shannon capacity of a graph. Shannon gave the example of C_5 where $\alpha(C_5) = 2$ and $\alpha(C_5^2) = 5$, implying $\Theta(C_5) \geq \sqrt{5} > \alpha(C_5)$. Denoting the logarithm of the Shannon capacity by C_0, Shannon remarked:

> No method has been found for determining C_0 for the general discrete channel, and this we propose as an interesting problem in coding theory.

Shannon proved the following lower and upper bounds on the Shannon capacity $\Theta(G)$ of a graph $G = (V, E)$. First:

$$\text{(67.137)} \qquad \max_p \left(\sum (p_u p_v \mid u, v \in V, u = v \text{ or } uv \in E)\right)^{-1} \leq \Theta(G),$$

where p ranges over all $p \in \mathbb{R}_+^V$ with $\sum_{v \in V} p(v) = 1$. It was observed by Korn [1968] that this lower bound (and also the lower bound given by Gallager [1965]) is equal to the stable set number $\alpha(G)$: if $p_u > 0$ and $p_v > 0$ for two adjacent vertices u and v, either resetting $p_u := p_u + p_v$ and $p_v := 0$, or resetting $p_v := p_u + p_v$ and $p_u := 0$, would increase the value in (67.137), a contradiction. So the set $S := \{v \mid p_v > 0\}$ is a stable set. Then the value in (67.137) is maximized by taking $p_v := 1/|S|$ for $v \in S$. (As we saw in Section 64.9c, this also follows from a theorem of Motzkin and Straus [1965].)

The upper bound given by Shannon [1956] amounts to:

(67.138) $\Theta(G) \leq \overline{\chi}^*(G)$.

Shannon formulated and proved this upper bound in terms of information theory as follows. Let V be an alphabet, let Σ be a set of 'signals', and for $v \in V$ and $\sigma \in \Sigma$, let $p_{v,\sigma}$ be the probability that when transmitting symbol v, signal σ is received. So $\sum_{\sigma \in \Sigma} p_{v,\sigma} = 1$ for each $v \in V$. Let G be the graph on V where two elements $u, v \in V$ are adjacent if and only if there is a signal σ with $p_{u,\sigma} > 0$ and $p_{v,\sigma} > 0$. For each $\sigma \in \Sigma$, define the clique $K_\sigma := \{v \in V \mid p_{v,\sigma} > 0\}$ and the real number $\lambda_\sigma := \max\{p_{v,\sigma} \mid v \in V\}$. So

(67.139) $$\sum_{\sigma \in \Sigma} \lambda_\sigma \chi^{K_\sigma} \geq \mathbf{1}.$$

Hence, by definition of $\overline{\chi}^*(G)$,

(67.140) $$\overline{\chi}^*(G) \leq \sum_{\sigma \in \Sigma} \lambda_\sigma.$$

Moreover, for any fixed G, the minimum of the right-hand side in (67.140) is equal to the left-hand side.

For any $v = (v_1, \ldots, v_k) \in V^k$ and $s = (s_1, \ldots, s_k) \in \Sigma^k$ define

(67.141) $$p_{v,s} := \prod_{i=1}^{k} p_{v_i,s_i} \text{ and } \lambda_s := \prod_{i=1}^{k} \lambda_{s_i}.$$

So $p_{v,s}$ is the probability that transmitted word v is received as word s.

Now consider any nonempty 'code' $C \subseteq V^k$. The 'error probability' of C is equal to

(67.142) $$q(C) := \min_{\phi} \frac{1}{|C|} \sum_{v \in C} \sum (p_{v,s} \mid s \in \Sigma^k, \phi(s) \neq v),$$

where ϕ ranges over all functions $\phi : \Sigma^k \to C$. So it is the minimum error probability taken over all possible 'decoding schemes' ϕ. Trivially, this minimum is attained by the function ϕ with $\phi(s)$ equal to any $v \in C$ maximizing $p_{v,s}$ over $v \in C$. So

(67.143) $$1 - q(C) = \frac{1}{|C|} \sum_{s \in \Sigma^k} \max_{v \in C} p_{v,s} \leq \frac{1}{|C|} \sum_{s \in \Sigma^k} \lambda_s = \frac{1}{|C|} \Big(\sum_{\sigma \in \Sigma} \lambda_\sigma \Big)^k.$$

Therefore,

(67.144) $$\sqrt[k]{|C|} \leq \frac{\sum_{\sigma \in \Sigma} \lambda_\sigma}{\sqrt[k]{1 - q(C)}}.$$

Now $q(C) = 0$ if and only if C is stable in G^k. Minimizing over all Σ and probability distributions $p_{v,\sigma}$ then yields

(67.145) $$\sqrt[k]{|C|} \leq \overline{\chi}^*(G).$$

So this gives (67.138).

Shannon next observed that if a graph $G = (V, E)$ has a function $f : V \to V$ such that $f(u) \neq f(v)$ for any distinct nonadjacent vertices u and v, and such that $f(V)$ is a stable set, then $\Theta(G) = \alpha(G)$. The condition clearly is equivalent to: $\alpha(G) = \overline{\chi}(G)$. Shannon noticed that this yields the value of $\Theta(G)$ for all graphs G

with at most 5 vertices, except for C_5, for which he derived $\sqrt{5} \leq \Theta(C_5) \leq \frac{5}{2}$ from (67.138). Shannon observed that on 6 vertices all but four graphs have $\alpha(G) = \overline{\chi}(G)$, and that the Shannon capacity of these four graphs can be expressed in terms of $\Theta(C_5)$. On 7 vertices, he stated that 'at least one new situation arises', namely C_7.

Shannon proved that if G and H are disjoint graphs, then $\Theta(G + H) \geq \Theta(G)+\Theta(H)$ and $\Theta(G\cdot H) \geq \Theta(G)\cdot\Theta(H)$, and that equality holds if $\alpha(G) = \overline{\chi}(G)$. Moreover, he conjectured equality for all G, H, but for the product this was disproved by Haemers [1979], and for the sum by Alon [1998].

Berge

As remarked, in developing the concept of perfect graph Berge was motivated by Shannon's problem on the capacity of graphs. We quote from the article 'Motivations and history of some of my conjectures' of Berge [1997]:

> *June 1957:* When he heard that I was writing a book on graph theory, my friend M.P. Schützenberger drew my attention on an interesting paper of Shannon [51] which was presented at a meeting for engineers and statisticians, but which could have been missed by mathematicians working in algebra or combinatorics.

(Berge's reference [51] is Shannon [1956].)

In his book 'Théorie des graphes' (Theory of Graphs), Berge [1958b] called a function $\sigma : VG \to VG$ a *preserving function* ('application préservante'), if for any two distinct nonadjacent vertices u, v, also $\sigma(u)$ and $\sigma(v)$ are distinct and nonadjacent. Then, like Shannon, he considered graphs G having a preserving function σ mapping VG to a stable subset of VG. Clearly, these are exactly the graphs with $\alpha(G) = \overline{\chi}(G)$.

Berge [1958b] also mentioned that M.P. Schützenberger conjectured that

$$\Theta(G) = \lim_{k\to\infty} \sqrt[k]{\alpha(G^k)}, \tag{67.146}$$

which was shown by Lyubich [1964] to follow directly from Fekete's lemma (Corollary 2.2a).

According to Berge [1997], the problem of finding the minimal graphs G with $\alpha(G) < \Theta(G)$ was discussed in January 1960 at the Seminar of R. Fortet, where he asked (prompted by graphs found by A. Ghouila-Houri) if it is true that each graph G not having an odd hole or odd antihole satisfies $\alpha(G) = \Theta(G)$:

> This conjecture, somewhat weaker than the Perfect Graph Conjecture, was motivated by the remark that for the most usual channels, the graphs representing the possible confusions between a set of signals (in particular the interval graphs) have no odd holes and no odd antiholes, and are *optimal in the sense of Shannon.*

At the first international meeting on graph theory held at Dobogókő (Hungary) in October 1959, Hajnal and Surányi [1958] presented the result that $\alpha(G) = \chi(\overline{G})$ for each chordal graph G. This motivated Berge to show that the same holds for complements of chordal graphs. This result was announced, with partial proof, in the paper Berge [1960a], which moreover mentions that several known results yield other classes of graphs G with $\omega(G) = \chi(G)$. In particular, it is observed that theorems of Kőnig imply that $\omega(G) = \chi(G)$ if G or $\overline{G}$ is the line graph of a bipartite graph — 'propriétés remarquables' (remarkable properties) according to Berge.

These results were presented at the Second International Symposium on Graph Theory at the Martin-Luther-Universität in Halle an der Saale (German Democratic Republic) in April 1960. In his memoirs, Berge [1997] mentioned that[18]

> At that time, we were pretty sure that there were no other minimal obstructions; for that reason, at the end of my talk in Halle, I proposed the following open problem: *If a graph G and its complement are semi-Gallai graphs, is it ture that* $\gamma(G) = \omega(G)$*?*

where a graph is *semi-Gallai* if it has no odd hole, and where $\gamma(G)$ is Berge's notation for the colouring number of G.

So, according to Berge, the strong perfect graph conjecture was stated in 1960 in Halle. It seems however that Berge was hesitating in putting the conjecture in print. It is not quoted in the written abstract of the talk (Berge [1961]), which in this respect only says that

> Angesichts einer solchen Menge von Beispielen könnte man vermuten, daß für jeden semi-Gallaischen Graphen G die Beziehung $\omega(G) = \gamma(G)$ gilt. Aber das stimmt nicht, wie das folgende, von einem unserer Schüler, Herrn GHOUILA-HOURI, angegebene Gegenbeispiel zeigt:
> G ist ein Graph mit den Knoten a, b, c, d, e, f, g und den Kanten ac, ad, ae, af, bd, be, bf, bg, ce, cf, cg, df, dg, eg. Man kann leicht zeigen, daß G ein semi-Gallaischer Graph ist mit $\omega(G) = 3$, aber $\gamma(G) = 4$ (siehe Abbildung 1).[19]

(This example ($\overline{C}_7$) was also given by Shannon [1956].) Incidentally, in this paper, Berge called graphs G satisfying $\alpha(G) = \overline{\chi}(G)$ *perfect graphs of Shannon* ('vollkommenen Graphen von Shannon').

About the strong perfect graph conjecture, Berge and Chvátal [1984] wrote:

> An early effort of Alain Ghouila-Houri failed to produce a counterexample to this conjecture. Despite this encouraging sign, Berge felt that the conjecture might be too ambitious. Therefore he restricted himself to a weaker conjecture in the hope that it might be easier to settle.

According to Berge and Chvátal [1984] (where a triangulated graph is a chordal graph),

> After the meeting at Halle an der Saale in 1960, the Strong Perfect Graph Conjecture received the enthusiastic support of G. Hajós and T. Gallai. In fact, Gallai provided further evidence in support of the conjecture by strengthening the results on triangulated graphs: he proved that a graph is α-perfect and γ-perfect whenever each of its odd cycles of length at least five has at least two non-crossing chords.

In Gallai [1962], only a proof of $\alpha(G) = \overline{\chi}(G)$ is given, for graphs G in which any odd circuit of length at least 5 has two noncrossing chords. Berge [1997] reported that Gallai informed him in a letter that he knew that also $\omega(G) = \chi(G)$ holds for such graphs. However, Gallai's paper does not mention this, and no reference is made to Berge's conjectures.

Berge and Chvátal [1984] continued:

---

[18] As we aim at verbatim quotations, we leave the typo unchanged.

[19] In view of such a multitude of examples one could conjecture that for each semi-Gallai graph G the relation $\omega(G) = \gamma(G)$ holds. But that does not hold, as the following counterexample, presented by one of our students, Mr GHOUILA-HOURI, shows:
G is a graph with nodes a, b, c, d, e, f, g and edges ac, ad, ae, af, bd, be, bf, bg, ce, cf, cg, df, dg, eg. One can easily show, that G is a semi-Gallai graph with $\omega(G) = 3$, but $\gamma(G) = 4$ (see Figure 1).

> Nevertheless, Berge still felt that the weak conjecture was more promising. At a conference at Rand Corporation in the summer of 1961, he had fruitful discussions with Alan Hoffman, Ray Fulkerson and others. Later on, discussions between Alan Hoffman and Paul Gilmore led Gilmore to a rediscovery of the Strong Perfect Graph Conjecture and to an attempt to axiomatize the relevant properties of cliques in perfect graphs.

Berge [1997] wrote that the discussions at the RAND Corporation with Alan Hoffman encouraged him to write a paper 'in English'. This paper might have been the first version of the paper 'Some classes of perfect graphs' (Berge [1963a]), published in a booklet 'Six Papers on Graph Theory' by the Indian Statistical Institute in Calcutta, which Berge visited in March-April 1963 and where he gave a series of lectures. The booklet contains no year of publication, and the preface mentions that it is intended for private circulation, and that the papers will be given for publication by journals.

The paper contains as new results that $\omega(G) = \chi(G)$ for unimodular graphs and their complements, and also a full proof that it holds for chordal graphs (announced earlier). The paper seems to be the first written account of the concept of perfect graph, and of the perfect graph conjectures, in the last section of the paper:

> V. CONJECTURES
>
> The problem of characterizing α-perfect and γ-perfect graphs seems difficult, but the preceding results enable us to state several conjectures. For instance :
>
> Conjecture 1. A graph is α-perfect if and only if it is γ-perfect
>
> Conjecture 2. A graph is γ-perfect if and only if it does not contain an elementary odd cycle of one of the following types :
>
> type 1 : the cycle is of length greater than 3 and does not possess any chord ;
>
> type 2 : the cycle is of length greater than 3, and does not possess any triangular chord, but possesses all its non-triangular chords (a chord is triangular if it determines a triangle with the edges of the cycle)
>
> Conjecture 3. A graph is α-perfect if and only if it does not contain an elementary odd cycle of type 1 or 2.
>
> It is easy to show that conjecture 2 is equivalent to conjecture 3, and implies conjecture 1. It is also easy to show that if a graph is γ-perfect (or α-perfect), then it does not contain an elementary odd cycle of type 1 or 2.

At the General Assembly of the U.R.S.I. (Union Radio Scientifique Internationale) in Tokyo in September 1963, Berge developed further on the relations between perfection and optimum codes in the sense of Shannon. We quote the abstract (Berge [1963b]):

> 3. Claude Berge : *Sur une conjecture relative au problème des codes optimaux de Shannon*, on considère un émetteur qui peut émettre un ensemble de signaux, par suite du bruit chaque signal peut donner plusieurs interprétations à la réception. On trace le graphe dont les sommets représentent les différents signaux, deux points étant liés par une arête si les signaux correspondants peuvent être confondus à la réception. Le problème essentiel est de caractériser les graphes que l'on peut enrichir, on aboutit ainsi à une conjecture que l'on démontre pour certaines classes particulières.[20]

[20] 3. Claude Berge : *On a conjecture related to the problem of the optimal codes of Shannon*, we consider a transmitter that can transmit a set of signals, as a consequence of noise each signal can give several interpretations at the reception. We make the graph

Berge [1997] wrote that the paper Berge [1963a] was distributed to all participants of the U.R.S.I. meeting in 1963, and that a French version of it was published as Berge [1966], added with some new results and an appendix with some results proved in Berge [1967], in order to make the conjecture more plausible and more interesting.

The paper Berge [1966] is more descriptive, but gives more relations to the Shannon problem, and also mentions the strong perfect graph conjecture, attributing it jointly to P.C. Gilmore. After remarking that $\alpha(G) \neq \overline{\chi}(G)$ for odd circuits of length at least 5 and their complements, the paper states:

> Nous nous sommes proposés de voir si la réciproque était vraie, et sommes arrivés à la conjecture suivante avec P. GILMORE:
> **Conjecture.** *Soit G un graphe de signaux; il est parfait si et seulement s'il ne contient pas un cycle impair sans cordes (de longueur > 3), ni le complémentaire d'un cycle impair sans cordes (de longueur > 3).*[21]

Berge [1966] also claimed, without proof, that $\Theta(G) = \alpha(G)$ if and only if $\overline{\chi}(G) = \alpha(G)$:

> On voit aussi *que la condition nécessaire et suffisante pour que la capacité du graphe de signaux G soit égale à $\alpha(G)$ est que $\alpha(G) = \theta(G)$.*[22]

(Italics of Berge, who denoted the clique cover number $\overline{\chi}(G)$ of G by $\theta(G)$.) However, the line graph $L(K_6)$ of K_6 is a counterexample to this (it has $\alpha = \Theta = \overline{\chi}^* = 3$ and $\overline{\chi} = 4$).

The paper 'Some classes of perfect graphs' was published again in a book on *Graph Theory and Theoretical Physics* edited by F. Harary (Berge [1967]). According to Berge [1997], this paper is 'a final version' of the manuscript, with suggestions by Hoffman, and was handed over to Harary at the end of a NATO Advanced Study Institute on Graph Theory in Frascati, Italy in March-April 1964. Compared with Berge [1963a], the paper contains no new results, and moreover the last section with the perfect graph conjectures (quoted above) has been omitted.

This paper was published also in the Proceedings of a Conference on Combinatorial Mathematics and Its Applications at the University of North Carolina at Chapel Hill, 10–14 April 1967. It is followed by a 'Discussion on Professor Berge's Paper' by M.E. Watkins stating that 'it seems likely that G is perfect if and only if $\overline{G}$ is perfect'. Berge [1996] mentioned that this addendum

> contributed to make the perfect graph conjecture popular. Before the Chapel Hill conference, I did not get much interest for my problems from the mathematics community; the first symposium lecture about perfect graphs from other mathematicians was delivered by Horst Sachs [20] at the Calgary conference in 1969.

(Berge's reference [20] is Sachs [1970].)

---

the vertices of which represent the different signals, two points being connected by an edge if the corresponding signals can be confused at the reception. The essential problem is of characterizing the graphs that one can enrich, we arrive this way at a conjecture that we prove for certain particular classes.

[21] We have resolved to see if the reverse would be true, and have arrived at the following conjecture with P. GILMORE:

Conjecture. *Let G be a graph of signals; it is perfect if and only if it neither contains an odd circuit without chords (of length > 3), nor the complement of an odd circuit without chords (of length > 3).*

[22] One also sees *that the necessary and sufficient condition for that the capacity of the graph of signals G is equal to $\alpha(G)$ is that $\alpha(G) = \theta(G)$.*

Fulkerson

The results on perfect graphs obtained until then being restricted to specific classes of graphs, the first serious dent in solving the perfect graph conjectures in general was made by Fulkerson in a RAND Report of 1970 on antiblocking polyhedra. They led Fulkerson to prove a 'pluperfect graph theorem', but also to doubt the validity of the weak perfect graph conjecture, which blocked him finishing it off.

The RAND Report (Fulkerson [1970c]) was published as Fulkerson [1972a], and the results were presented at the Second Chapel Hill Conference on Combinatorial Mathematics and Its Applications at the University of North Carolina at Chapel Hill in May 1970 (Fulkerson [1970d]), and at the 7th International Mathematical Programming Symposium in 1970 in The Hague, for which a survey paper on blocking and antiblocking pairs of polyhedra was written (Fulkerson [1970a,1971a]).

Fulkerson called a graph G *γ-pluperfect* if $\chi(H) = \omega(H)$ for each graph H obtained from G by deleting and replicating vertices. In particular, if G is γ-pluperfect, then G is γ-perfect.

What Fulkerson [1970a,1971a] proved is that:

(67.147) $$G \text{ is } \gamma\text{-pluperfect} \iff \overline{G} \text{ is } \gamma\text{-pluperfect}.$$

The proof is not hard, but is based on a series of pioneering observations and general polyhedral insights that are now fundamental in polyhedral combinatorics. It uses the linear programming duality equality

(67.148) $$\max\{w^{\mathsf{T}}x \mid x \geq \mathbf{0}, Mx \leq \mathbf{1}\} = \min\{y^{\mathsf{T}}\mathbf{1} \mid y \geq \mathbf{0}, y^{\mathsf{T}}M \geq w^{\mathsf{T}}\},$$

where M is the incidence matrix of the stable sets of G and where $w : V \to \mathbb{R}_+$. Then:

(67.149) $G = (V, E)$ is γ-pluperfect
$\overset{1}{\iff}$ $\forall w : V \to \mathbb{Z}_+$, both optima in (67.148) are attained by integer solutions x and y
$\overset{2}{\iff}$ $\forall w : V \to \mathbb{Z}_+$, the maximum in (67.148) is attained by an integer solution x
$\overset{3}{\iff}$ $\forall w : V \to \mathbb{Q}_+$, the maximum in (67.148) is attained by an integer solution x
$\overset{4}{\iff}$ $\forall w : V \to \mathbb{R}_+$, the maximum in (67.148) is attained by an integer solution x
$\overset{5}{\iff}$ each vertex of the polytope $\{x \mid x \geq \mathbf{0}, Mx \leq \mathbf{1}\}$ is integer
$\overset{6}{\iff}$ the clique polytope of G is determined by the nonnegativity and stable set constraints.

The first equivalence in (67.149) follows by observing that a weight $w(v)$ of a vertex v corresponds to replacing v by a clique of size $w(v)$; this is equivalent to duplicating v $w(v) - 1$ times, or, if $w(v) = 0$, deleting v. The second equivalence can be derived by considering, for any $w : V \to \mathbb{Z}_+$ an inequality $x(S) \leq 1$ in $Mx \leq \mathbf{1}$ satisfied with equality by all optimum solutions; hence replacing w by $w - \chi^S$ the maximum decreases, hence by at least 1 (as it has an integer value); as the minimum decreases by at most 1, we obtain an integer optimum dual solution by induction. The third and fourth equivalences follow by scaling w and by continuity. The fifth equivalence is general polyhedral theory, and the sixth one follows by observing that the integer solutions of $x \geq \mathbf{0}$, $Mx \leq \mathbf{1}$ are precisely the incidence vectors of cliques.

Now by Fulkerson's theory of antiblocking polyhedra, the last statement in (67.149) is invariant under interchanging 'clique' and 'stable set'; that is, under replacing G by the complementary graph $\overline{G}$. Hence the same holds for the first statement.

Fulkerson [1970c,1970a,1971a,1972a] gave another, symmetrical characterization of γ-pluperfect graphs:

(67.150) a graph $G = (V, E)$ is γ-pluperfect if and only if for all $l, w : V \to \mathbb{Z}_+$, the maximum of $l(S)w(C)$ over all stable sets S and cliques C is at least $\sum_v l(v)w(v)$.

For this, Fulkerson was inspired by the length-width inequality for blocking pairs of hypergraphs given in a 1965 preprint of Lehman [1965,1979].

The weak perfect graph conjecture implies that each perfect graph G is γ-pluperfect, since trivially if $\chi(\overline{H}) = \omega(\overline{H})$ for each induced subgraph H of G, then $\chi(\overline{H}) = \omega(\overline{H})$ for each H obtained from G by deleting and replicating vertices. (Note that $\chi(\overline{H}) = \chi(\overline{G})$ and $\omega(\overline{H}) = \omega(\overline{G})$ if H arises from G by duplicating a vertex.)

So, as Fulkerson [1970a,1971a] remarked ('theorem 14'), the perfect graph conjecture is equivalent to: each γ-perfect graph is γ-pluperfect; or: γ-perfection is maintained under duplicating vertices (later called the *replication lemma*):

> Thus to prove the perfect graph conjecture, it would suffice to prove that γ-perfection implies γ-pluperfection. For this it would suffice to show that if G is γ-perfect, and if we duplicate an arbitrary vertex v in G and join v to its duplicate vertex, the new graph G' is again γ-perfect.

Another way of stating it is: if for each $w : V \to \{0, 1\}$ both optima in (67.148) have integer solutions, then likewise for each $w : V \to \mathbb{Z}_+$. This might seem too strong from a general polyhedral point of view, and it made Fulkerson [1970a,1971a] mistrust the conjecture:

> It is our feeling that theorem 14 casts some doubt on the validity of the perfect graph conjecture.

Lovász

The weak perfect graph conjecture was finally proved by Lovász [1972c], stating:

> Fulkerson [5] reduced the problem to the following conjecture, using the theory of antiblocking polyhedra:
> *Duplicating an arbitrary vertex of a perfect graph and joining the obtained two vertices by an edge, the arising graph is perfect.*
> In §1 we prove a theorem which contains this conjecture.

(Reference [5] is Fulkerson [1972a].) Lovász also wrote:

> It should be pointed out that thus the proof consists of two steps and the more difficult second step was done first by Fulkerson.

With respect to this, Fulkerson [1973] remarked in his comments 'On the perfect graph theorem':

> Concerning this proof, Lovász states: "It should be pointed out that thus the proof consists of two steps, and the most difficult second step was done first by Fulkerson." I would be less than candid if I did not say that I agree with this remark, at least in retrospect. But the fact remains that, while part of my aim in developing the anti-blocking theory had been to settle the perfect graph conjecture, and that while I had succeeded via this theory in reducing the conjecture to a simple lemma about graphs [3,4] (the "replication lemma", a proof of which is given in this paper) and had developed other seemingly more complicated equivalent versions of the conjecture [3,4,5], I eventually began to feel that the conjecture was probably false and thus spent several fruitless months trying to construct a counterexample. It is not altogether clear to me now just why I felt the conjecture was false, but I think it was due mainly to one equivalent version I had found [4,5], a version that does not explicitly mention graphs at all.

(The references [3,4,5] correspond to Fulkerson [1972a,1971a,1970d].)

In the preprint of this article, Fulkerson [1972b] wrote moreover, after stating the replication lemma:

> Actually I knew more: Namely that the truth or falsity of the perfect graph conjecture rested entirely on the truth or falsity of the replication lemma. I tried for awhile to prove this lemma, without success, and then, as was mentioned earlier, became convinced on other grounds that the perfect graph conjecture was probably false, and began to look for a graph that was perfect but not pluperfect. (I knew that it would do no good to look at known classes of perfect graphs, since I had been able to prove that all of these were pluperfect.) The fact is that such graphs don't exist, of course. After some months of sporadic effort along these lines, I quit working on the perfect graph conjecture, thinking that I would come back to it later. There were other aspects of anti-blocking pairs of polyhedra, and of blocking pairs of polyhedra, that I wanted to study, and, in any event, I felt that the pluperfect graph theorem was a beautiful result in its own right.
> In the spring of 1971 I received a postcard from Berge, who was then visiting the University of Waterloo, saying that he had just heard that Lovász had a proof of the perfect graph conjecture. This immediately rekindled my interest, naturally, and so I sat down at my desk and thought again about the replication lemma. Some four or five hours later, I saw a simple proof of it.

After having given a simple proof of the replication lemma, Fulkerson [1972b] continued:

> As can be seen, there is nothing deep or complicated about the proof of this lemma. Perhaps the fact that I saw a proof of it only after knowing it had to be true may say something about the psychology of invention (or, better yet, anti-invention) in mathematics, at least for me.

This is indeed an instructive illustration that believing a conjecture may help in proving it.

In a subsequent paper, Lovász [1972a] proved more strongly that a graph G is perfect if and only if $\alpha(H)\omega(H) \geq |VH|$ for each induced subgraph H of G. This generalizes the perfect graph theorem, and was suggested by A. Hajnal. It also sharpens Fulkerson's result (67.150), implying that one may restrict l and w to $\{0,1\}$-valued functions with $l = w$.

The problem of Shannon [1956] concerning the Shannon capacity of C_5 was solved by Lovász [1979d].

In May 2002, M. Chudnovsky, N. Robertson, P.D. Seymour, and R. Thomas announced that they found a proof of the strong perfect graph conjecture, by proving a number of deep results, and building on and inspired by earlier results of, among others, V. Chvátal, M. Conforti, G. Cornuéjols, W.H. Cunningham, A. Kapoor, F. Roussel, P. Rubio, N. Sbihi, K. Vušković, and G. Zambelli.

More historical notes are given by Berge and Ramírez Alfonsín [2001] and Reed [2001b].

Chapter 68

T-perfect graphs

The class of t-perfect graphs is defined polyhedrally: the stable set polytope should be determined by the nonnegativity, edge, and odd circuit constraints. It implies that a maximum-weight stable set in such graphs can be found in polynomial time. LP duality gives a min-max relation for the maximum-weight of a stable set in t-perfect graphs.
A characterization of t-perfect graphs is not known. The widest class of t-perfect graphs known consists of those not containing certain subdivisions of K_4 as subgraph.

68.1. T-perfect graphs

A graph $G = (V, E)$ is called *t-perfect*[23] if the stable set polytope of G is determined by

(68.1)
$$\begin{array}{rll} \text{(i)} & 0 \le x_v \le 1 & \text{for each } v \in V, \\ \text{(ii)} & x_u + x_v \le 1 & \text{for each edge } uv \in E, \\ \text{(iii)} & x(VC) \le \lfloor \frac{1}{2}|VC| \rfloor & \text{for each odd circuit } C. \end{array}$$

A prominent non-t-perfect graph is K_4. Below we shall see that, on the other hand, if K_4 does not occur in a graph in a certain way, then the graph is t-perfect. But no exact characterization of t-perfection is known.

A motivation for studying t-perfection is algorithmic, since the definition implies:

Theorem 68.1. *A maximum-weight stable set in a t-perfect graph can be found in strongly polynomial time.*

Proof. By Theorems 5.10 and 5.11, it suffices to show that the separation problem over the stable set polytope is polynomial-time solvable. Conditions (i) and (ii) in (68.1) can be tested one by one. If they are satisfied, define a function $y : E \to \mathbb{R}_+$ by:

(68.2)
$$y_e := 1 - x_u - x_v$$

for each $e = uv \in E$. Then condition (iii) is equivalent to:

[23] t stands for 'trou' (French for 'hole').

(68.3) $y(EC) \geq 1$ for each odd circuit C

(since $y(EC) = |EC| - 2x(VC)$). The latter condition can be checked in polynomial time: Consider y as a length function, and for each $u \in V$, find an odd circuit C through u with $y(EC)$ minimal. This can be done by replacing each vertex v by two vertices v', v'', and each edge $e = vw$ by two edges $v'w''$ and $v''w'$, each of length y_e; then a shortest path from u' to u'' gives the required circuit.

If $y(EC) < 1$, we have a violated inequality. ∎

A combinatorial polynomial-time algorithm to find the stable set number of a t-perfect graph was given by Eisenbrand, Funke, Garg, and Könemann [2002]. It is based on finding (by a greedy method similar to that used in the proof of Theorem 64.13) an approximative fractional dual solution to the problem of maximizing $\mathbf{1}^{\mathsf{T}}x$ over (68.1). with relative error less than $1/|V|$. Rounding then gives the stable set number. Applying this iteratively gives an explicit maximum-size stable set.

Notes. The construction given in the proof of Theorem 68.1 shows that the maximum-weight stable set problem in a t-perfect graph can be described by a 'compact' linear programming: the stable set polytope is the projection of a polytope whose dimension and number of facets are polynomially bounded. To see this, introduce, next to the variables $y \in \mathbb{R}_+^E$, a variable $z_{u,v}$ for each $u, v \in V$. Requiring:

(68.4)
$$\begin{aligned} & z_{v,v} \geq 1 && \text{for each } v \in V, \\ & z_{u,v} \leq y_{uv} && \text{for each edge } uv \in E, \\ & z_{t,w} \leq z_{t,u} + y_{uv} + y_{vw} && \text{for all } t, u, v, w \in V \text{ with } uv, vw \in E, \end{aligned}$$

is equivalent to the odd circuit constraints. (In fact, one can do without the variables y_e, as they can be expressed in the x_v.) So a maximum-weight stable set in a t-perfect graph can be found in polynomial time with any polynomial-time linear programming algorithm.

T-perfection can also be characterized in terms of the vertex cover polytope:

Theorem 68.2. *A graph $G = (V, E)$ is t-perfect if and only if the vertex cover polytope of G is determined by:*

(68.5)
$$\begin{aligned} &\text{(i)} && 0 \leq x_v \leq 1 && \text{for each } v \in V, \\ &\text{(ii)} && x_u + x_v \geq 1 && \text{for each edge } uv \in E, \\ &\text{(iii)} && x(VC) \geq \lceil \tfrac{1}{2}|VC| \rceil && \text{for each odd circuit } C. \end{aligned}$$

Proof. System (68.5) arises from (68.1) by the reflection $x \to \mathbf{1} - x$. So integrality of the two polytopes is equivalent. ∎

68.2. Strongly t-perfect graphs

A graph $G = (V, E)$ is called *strongly t-perfect* if system (68.1) is totally dual integral. So each strongly t-perfect graph is t-perfect (Theorem 5.22). It is unknown if the reverse implication holds:

(68.6) Is every t-perfect graph strongly t-perfect?

Strong t-perfection can be characterized by the weighted version of the stable set number and a certain weighted 'edge and circuit' cover number. Let $G = (V, E)$ be a graph and let $w : V \to \mathbb{Z}_+$. In this chapter, a *w-cover* is a family of vertices, edges, and odd circuits covering each vertex v at least $w(v)$ times. By definition, the *cost* of a vertex or edge is 1, and the *cost* of an odd circuit C is $\lfloor \frac{1}{2}|VC| \rfloor$. The *cost* of a w-cover $\mathcal{F}$ is the sum of the costs of the elements of $\mathcal{F}$. Define

(68.7) $\alpha_w(G) :=$ the maximum weight of a stable set in G,
$\tilde{\rho}_w(G) :=$ the minimum cost of a w-cover.

Obviously, $\alpha_w(G) \leq \tilde{\rho}_w(G)$ for any graph G. Moreover:

(68.8) G is strongly t-perfect $\iff$ $\alpha_w(G) = \tilde{\rho}_w(G)$ for each $w : V \to \mathbb{Z}_+$.

This follows directly from a combinatorial interpretation of total dual integrality.

Notes. W.R. Pulleyblank (cf. Gerards [1989a]) observed that, even for $w = \mathbf{1}$, determining $\tilde{\rho}_w(G)$ is NP-complete, since the vertex set of a graph G can be partitioned into triangles if and only if $\tilde{\rho}_w(G) = \frac{1}{3}|V|$ where $w = \mathbf{1}$. The problem of partitioning a graph into triangles is NP-complete. Since partitioning into triangles remains to be NP-complete for planar graphs (Dyer and Frieze [1986]), even determining $\tilde{\rho}_w(G)$ for planar graphs is NP-complete.

Again, strong t-perfection is equivalent to the total dual integrality of the vertex cover constraints (68.5).

68.3. Strong t-perfection of odd-K_4-free graphs

K_4 is the smallest graph that is not t-perfect. Gerards and Schrijver [1986] showed that any graph not containing an 'odd K_4-subdivision' is t-perfect — in fact, as Gerards [1989a] showed, strongly t-perfect. We will prove this in this section (with a method inspired by Geelen and Guenin [2001]).

Call a subdivision of K_4 *odd* if each triangle of K_4 has become an odd circuit — equivalently, if the evenly subdivided edges of K_4 form a cut of K_4. We say that a graph *contains no* odd K_4-subdivision if it has no subgraph which is an odd K_4-subdivision.

Theorem 68.3. *A graph containing no odd K_4-subdivision is strongly t-perfect.*

Proof. Let $G = (V, E)$ be a counterexample with $|V| + |E|$ minimum. Then G has no isolated vertices. So we can assume that any minimum-cost w-cover contains no vertices (for any w).

For any weight function $w : V \to \mathbb{Z}_+$, denote $\alpha_w := \alpha_w(G)$ and $\tilde{\rho}_w := \tilde{\rho}_w(G)$. As G is a counterexample, there exists a $w : V \to \mathbb{Z}_+$ with $\alpha_w < \tilde{\rho}_w$.

For any such w we have, for each edge $e = uv$,

(68.9) if S maximizes $w(S)$ over stable sets S of $G - e$, then S contains u and v.

Otherwise, S is a stable set of G, implying that (by the minimality of $|V| + |E|$):

(68.10) $$\alpha_w(G) \geq \alpha_w(G - e) = \tilde{\rho}_w(G - e) \geq \tilde{\rho}_w(G),$$

a contradiction.

This implies

(68.11) $$w \geq \mathbf{1},$$

since if $w(v) = 0$ for some vertex v, then for any edge e incident with v there is a stable set S of $G - e$ maximizing $w(S)$ and not containing v (since deleting v from S does not decrease $w(S)$). This contradicts (68.9).

We next show that we can assume w to have some additional properties (for an edge $e = uv$, χ^e is the incidence vector of the set $\{u, v\}$, that is, it is the $0, 1$ vector in $\mathbb{R}^V$ having 1's in positions u and v):

Claim 1. There exist $w : V \to \mathbb{Z}_+$ and $f \in E$ such that

(68.12) $$\tilde{\rho}_{w+\chi^f} = \alpha_w + 1 = \tilde{\rho}_w = \alpha_{w+\chi^f}$$

and such that

(68.13) $$\alpha_{w-\chi^{VC}} = \tilde{\rho}_{w-\chi^{VC}}$$

for each odd circuit C.

Proof of Claim 1. As G is not bipartite (by Theorem 19.7) and not just an odd circuit (as this is trivially strongly t-perfect), we know that H has a chordless odd circuit C_0 that has at least one vertex of degree at least 3. Let v be such a vertex, and let e be an edge incident with v but which is not on C_0.

Let $B := VC_0 \setminus \{v\}$. We choose w such that $w(V \setminus B)$ is minimal. There exists a $k \in \mathbb{Z}_+$ such that for $w' := w + k \cdot \chi^B$, each stable set S of $G - e$ maximizing $w'(S)$ satisfies $|S \cap B| = \frac{1}{2}|B|$. Hence no such set S contains v, and therefore, by (68.9), $\alpha_{w'} = \tilde{\rho}_{w'}$.

Now let M be the perfect matching in $C_0 - v$. For $y : M \to \mathbb{Z}_+$ define

(68.14) $$w^y := w + \sum_{f \in M} y_f \chi^f.$$

As $\alpha_{w'} = \tilde{\rho}_{w'}$, there exists a $y : M \to \mathbb{Z}_+$ such that

(68.15) $$\alpha_{w^y} = \tilde{\rho}_{w^y}.$$

We choose such a y with $\sum_{f\in M} y_f$ minimal. Since $\alpha_w < \tilde{\rho}_w$, there exists an $f \in M$ with $y_f \geq 1$. Then, by the minimality of y, we have $\alpha_{w^y-\chi^f} < \tilde{\rho}_{w^y-\chi^f}$. So we can assume that $y_f = 1$ and $y_{f'} = 0$ for each $f' \in M \setminus \{f\}$. We show that w and f are as required.

To show (68.12), we have $\alpha_{w+\chi^f} \leq \alpha_w + 1$, since any stable set S satisfies $(w + \chi^f)(S) = w(S) + |f \cap S| \leq w(S) + 1$. This implies

(68.16) $$\alpha_w + 1 \leq \tilde{\rho}_w \leq \tilde{\rho}_{w+\chi^f} = \alpha_{w+\chi^f} \leq \alpha_w + 1,$$

implying (68.12).

Next, consider any odd circuit C in G. Then $(w-\chi^{VC})(V\setminus B) < w(V\setminus B)$, since VC is not contained in B. Therefore, by the choice of w, we have (68.13).

End of Proof of Claim 1

As from now we fix w and f satisfying (68.12) and (68.13). Let f connect vertices u and u'. Since by the minimality of G, G has no isolated vertices, there exists a minimum-cost $w+\chi^f$-cover $\mathcal{F}$ consisting only of edges and odd circuits, say, $e_1, \ldots, e_t$, $C_1, \ldots, C_k$. We choose them such that

(68.17) $$|VC_1| + \cdots + |VC_k|$$

is as small as possible. Then:

(68.18) at least two of the C_i traverse f.

To see this, let $G' := G - f$ (the graph obtained by deleting edge f). If $\alpha_w(G') = \alpha_w(G)$, then by the minimality of G, G' has a w-cover of cost α_w. As this is a w-cover in G as well, this would imply $\alpha_w = \tilde{\rho}_w$, a contradiction.

So $\alpha_w(G') > \alpha_w(G)$. That is, there exists a stable set S in G' with $w(S) > \alpha_w$. Necessarily, S contains both u and u'. Then for any circuit C traversing f:

(68.19) $$|VC \cap S| \leq \lfloor \tfrac{1}{2}|VC| \rfloor + 1.$$

Also, f is not among $e_1, \ldots, e_t$, since otherwise $\mathcal{F} \setminus \{f\}$ is a w-cover of cost $\tilde{\rho}_{w+\chi^f} - 1 = \tilde{\rho}_w - 1$, contradicting the definition of $\tilde{\rho}_w$. Setting l to the number of C_i traversing f, we obtain:

(68.20) $$\begin{aligned}\tilde{\rho}_{w+\chi^f} &\leq \alpha_w + 1 \leq w(S) = (w + \chi^f)(S) - 2 \\ &\leq -2 + \sum_{j=1}^{t} |e_j \cap S| + \sum_{i=1}^{k} |VC_i \cap S| \leq -2 + t + \sum_{i=1}^{k} \lfloor \tfrac{1}{2}|VC_i| \rfloor + l \\ &= \tilde{\rho}_{w+\chi^f} + l - 2.\end{aligned}$$

So $l \geq 2$, which is (68.18).

By (68.18) we can assume that C_1 and C_2 traverse f. It is convenient to assume that $EC_1 \setminus \{f\}$ and $EC_2 \setminus \{f\}$ are disjoint; this can be achieved by adding parallel edges. So $EC_1 \cap EC_2 = \{f\}$.

Then:

(68.21) if C is an odd circuit with $EC \subseteq EC_1 \cup EC_2$, then $f \in EC$ and $EC_1 \triangle EC_2 \triangle EC$ is again an odd circuit.

Indeed, as $EC_1 \triangle EC_2 \triangle EC$ is an odd cycle, it can be decomposed into circuits $C'_2, \ldots, C'_p$, with $C'_2, \ldots, C'_q$ odd and $C'_{q+1}, \ldots, C'_p$ even ($q \geq 2$). Then

$$(68.22) \quad \begin{aligned} \sum_{i=2}^{p} |EC'_i| &= |EC_1 \triangle EC_2 \triangle EC| \\ &= |EC_1| + |EC_2| - |EC| - 2|\{f\} \setminus EC|. \end{aligned}$$

Choose for each $i = q+1, \ldots, p$ a perfect matching M_i in C'_i. Let $e'_1, \ldots, e'_r$ be the edges in the matchings M_i and in $\{f\} \setminus EC$. Then, defining $C'_1 := C$,

$$(68.23) \quad \chi^{VC_1} + \chi^{VC_2} = \sum_{i=1}^{q} \chi^{VC'_i} + \sum_{j=1}^{r} \chi^{e'_j}$$

and (using (68.22))

$$(68.24) \quad \begin{aligned} &\lfloor \tfrac{1}{2}|VC_1| \rfloor + \lfloor \tfrac{1}{2}|VC_2| \rfloor = \tfrac{1}{2}|EC_1| + \tfrac{1}{2}|EC_2| - 1 \\ &= -1 + |\{f\} \setminus EC| + \tfrac{1}{2}\sum_{i=1}^{p} |EC'_i| = -1 + r + \tfrac{1}{2}\sum_{i=1}^{q} |EC'_i| \\ &\geq r + \sum_{i=1}^{q} \lfloor \tfrac{1}{2}|VC'_i| \rfloor. \end{aligned}$$

So replacing C_1, C_2 by $C'_1, \ldots, C'_q$ and adding $e'_1, \ldots, e'_r$ to $e_1, \ldots, e_t$, gives again a $w + \chi^f$-cover of cost at most $\tilde{\rho}_{w+\chi^f}$. This also implies $q = 2$, since otherwise we have strict inequality in (68.24), and we would obtain a w-cover of cost less than $\tilde{\rho}_w$.

If $f \notin EC$, then f is among $e'_1, \ldots, e'_r$. Hence deleting f gives a w-cover of cost at most $\tilde{\rho}_{w+\chi^f} - 1 \leq \alpha_w$, contradicting (68.12). So $f \in EC$. As this is true for any odd circuit in $EC_1 \cup EC_2$ we know that $f \in EC'_i$ for $i = 1, 2$.

If $p \geq 3$ or $r \geq 1$, then $|EC'_1| + |EC'_2| < |EC_1| + |EC_2|$, contradicting the minimality of (68.17). So $p = q = 2$ and $r = 0$, which proves (68.21).

First, it implies

(68.25) a circuit in $EC_1 \cup EC_2$ is odd if and only if it traverses f.

A second consequence is as follows. Let P_i be the $u-u'$ path $C_i \setminus \{f\}$. Orient the edges occurring in the path $P_i := C_i \setminus \{f\}$ in the direction from u to u', for $i = 1, 2$. Then

(68.26) the orientation is acyclic.

For suppose that it contains a directed circuit C. Then $(EC_1 \cup EC_2) \setminus EC$ contains a directed $u-u'$ path, and hence an odd circuit C'. Hence by (68.21), $EC_1 \triangle EC_2 \triangle EC'$ is an odd circuit, however containing the even circuit EC, a contradiction.

Define

(68.27) $\quad W := VP_1 \cup VP_2$ and $F := EP_1 \cup EP_2$.

Consider the graph (W, F). It is bipartite, as it contains no odd circuits by (68.25). Moreover, u and u' belong to the same colour class. Let A and B be the colour classes of (W, F), such that $u, u' \in A$. So

(68.28) $\quad A := \{v \in W \mid$ there exists an even-length directed $u - v$ path$\}$,
$B := \{v \in W \mid$ there exists an odd-length directed $u - v$ path$\}$.

(Here and below, when speaking of a directed path, it is assumed to use only the edges in $EP_1 \cup EP_2$.) Define

(68.29) $\quad X := VP_1 \cap VP_2$ and

$$U := \{v \in V \mid w(v) = \sum_{j=1}^{t} |e_j \cap \{v\}| + \sum_{j=1}^{k} |VC_j \cap \{v\}|\}.$$

So $u, u' \notin U$, $u, u' \in X$, and $X \setminus \{u, u'\}$ is the set of vertices in W having degree 4 in the graph (W, F).

We next show the following technical, but straightforward to prove, claim:

Claim 2. Let $z \in A$, let Q be an even-length directed $u - z$ path, and let S be a stable set in G. Then

(68.30) $\quad (w - \chi^{VQ})(S) \geq \alpha_w - \lfloor \frac{1}{2}|VQ| \rfloor + 1$

if and only if

(68.31)
(i) $|e_j \cap S| = 1$ *for each* $j = 1, \ldots, t$,
(ii) $|VC_j \cap S| = \lfloor \frac{1}{2}|VC_j| \rfloor$ *for* $j = 3, \ldots, k$,
(iii) $S \subseteq U$,
(iv) S *contains* $B \setminus VQ$ *and is disjoint from* $A \setminus VQ$,
(v) S *contains* $B \cap X$ *and is disjoint from* $A \cap X$.

Proof of Claim 2. By rerouting C_1 and C_2, we can assume that $EQ \subseteq EC_1$. Define $Z := VC_1 \setminus VQ$. So $|Z|$ is even. Consider the following sequence of (in)equalities:

(68.32)
$$\begin{aligned}
(w - \chi^{VQ})(S) &= w(S) - |VQ \cap S| \\
&\leq \sum_{j=1}^{t} |e_j \cap S| + \sum_{j=1}^{k} |VC_j \cap S| - |VQ \cap S| \\
&= \sum_{j=1}^{t} |e_j \cap S| + \sum_{j=2}^{k} |VC_j \cap S| + |Z \cap S| \leq t + \sum_{j=2}^{k} \lfloor \tfrac{1}{2}|VC_j| \rfloor + |Z \cap S| \\
&= \tilde{\rho}_{w+\chi^f} - \lfloor \tfrac{1}{2}|VC_1| \rfloor + |Z \cap S| \leq \tilde{\rho}_{w+\chi^f} - \lfloor \tfrac{1}{2}|VC_1| \rfloor + \tfrac{1}{2}|Z| \\
&= \alpha_w + 1 - \lfloor \tfrac{1}{2}|VQ| \rfloor.
\end{aligned}$$

Hence (68.30) holds if and only if equality holds throughout in (68.32), which is equivalent to (68.31). Note that (68.31)(iv) and (v) are equivalent to: S contains $VC_2 \cap B$ and is disjoint from $VC_2 \cap A$, and S contains $Z \cap B$ and is disjoint from $Z \cap A$. Hence it is equivalent to (as $u, u' \notin S$ by (68.31)(iii)): $|VC_2 \cap S| = \lfloor \frac{1}{2}|VC_2| \rfloor$ and $|Z \cap S| = \frac{1}{2}|Z|$. *End of Proof of Claim 2*

By (68.26), we can order the vertices in X as $x_0 = u, x_1, \ldots, x_s = u'$ such that both P_1 and P_2 traverse them in this order. For $j = 0, \ldots, s$, let $\mathcal{P}_j$ be the collection of directed $u - x$ paths, where $x = x_j$ if $x_j \in A$, and x is an inneighbour of x_j if $x_j \in B$. So $x \in A$ and each path in each $\mathcal{P}_j$ has even length.

Let j be the largest index for which there exists a path $Q \in \mathcal{P}_j$ with

(68.33) $$\alpha_{w-\chi^{VQ}} \leq \alpha_w - \lfloor \tfrac{1}{2}|VQ| \rfloor.$$

Such a j exists, since (68.33) holds for the trivial directed $u - u$ path, as $\alpha_{w-\chi^u} \leq \alpha_w$. Also, $j < s$, since otherwise $VQ = VC$ for some odd circuit C, and hence, with (68.13) we have

(68.34) $$\tilde{\rho}_w \leq \tilde{\rho}_{w-\chi^{VC}} + \lfloor \tfrac{1}{2}|VC| \rfloor = \alpha_{w-\chi^{VC}} + \lfloor \tfrac{1}{2}|VC| \rfloor \leq \alpha_w,$$

contradicting (68.12).

Let Q_1 and Q_2 be the two paths in $\mathcal{P}_{j+1}$ that extend Q. By the maximality of j, we know

(68.35) $$\alpha_{w-\chi^{VQ_i}} \geq \alpha_w - \lfloor \tfrac{1}{2}|VQ_i| \rfloor + 1.$$

So there exist stable sets S_1 and S_2 with

(68.36) $$(w - \chi^{VQ_i})(S_i) \geq \alpha_w - \lfloor \tfrac{1}{2}|VQ_i| \rfloor + 1$$

for $i = 1, 2$. So for $i = 1, 2$, (68.31) holds for Q_i, S_i. By (68.31)(iv), S_1 and S_2 coincide on $W \setminus (VQ_1 \cup VQ_2)$, and they coincide on X. In other words:

(68.37) $$(S_1 \triangle S_2) \cap W \subseteq (VQ_1 \cup VQ_2) \setminus X.$$

Let H be the subgraph of G induced by $S_1 \triangle S_2$. So H is a bipartite graph, with colour classes $S_1 \setminus S_2$ and $S_2 \setminus S_1$. Define

(68.38) $$Y_i := VQ_i \setminus VQ$$

for $i = 1, 2$. Then

(68.39) H contains a path connecting Y_1 and Y_2.

For suppose not. Let K be the union of the components of H that intersect Y_1. So K is disjoint from Y_2. Define $S := S_1 \triangle K$. Then $S \cap Y_1 = S_2 \cap Y_1$ and $S \cap Y_2 = S_1 \cap Y_2$. This implies that Q, S satisfy (68.31). Hence (68.30) holds, contradicting (68.33). This proves (68.39).

Let C be the (even) circuit formed by the two directed $x_j - x_{j+1}$ paths. So Y_1 and Y_2 are subsets of VC. Let R be a shortest path in H that connects Y_1 and Y_2; say it connects $y_1 \in Y_1$ and $y_2 \in Y_2$.

Since $y_1, y_2 \in S_1 \triangle S_2$, we know by (68.37) that $y_1, y_2 \notin X$. By (68.31)(iv), if $y_1 \in S_1 \setminus S_2$, then $y_1 \in A$ (since if $y_1 \in B$, then $y_1 \in B \setminus VQ_2$, and so $y_1 \in S_2$), and if $y_1 \in S_2 \setminus S_1$, then $y_1 \in B$ (since if $y_1 \in A$, then $y_1 \in A \setminus VQ_2$, and so $y_1 \notin S_2$). Similarly, if $y_2 \in S_2 \setminus S_1$, then $y_2 \in A$ and if $y_2 \in S_1 \setminus S_2$, then $y_2 \in B$.

So if R is even, then y_1 and y_2 belong to the same set among $S_1 \setminus S_2$, $S_2 \setminus S_1$, and hence they belong to different sets A, B. Similarly, if R is odd, then y_1 and y_2 belong to the same set among A, B. Hence R forms with part of C an odd circuit.

By (68.37), there exist a directed $u - x_j$ path N' and a directed $x_{j+1} - u'$ path N'' that are (vertex-)disjoint from $S_1 \triangle S_2$. Concatenating N', f, and N'' makes an $x_{j+1} - x_j$ path N. Then N, R, and C make an odd K_4-subdivision, with 3-valent vertices x_j, x_{j+1}, y_1, y_2. ∎

(The above proof of Claim 1 was given by D. Gijswijt.)

Notes. Theorem 68.3 includes the t-perfection of series-parallel graphs (conjectured by Chvátal [1975a], and proved by M.J. Clancy in 1977 and by Mahjoub [1988]), the strong t-perfection of series-parallel graphs (Boulala and Uhry [1979], who also gave a polynomial-time algorithm to find a maximum-weight stable set in series-parallel graphs), the t-perfection of almost bipartite graphs — graphs G having a vertex v with $G - v$ bipartite (Fonlupt and Uhry [1982]), the strong t-perfection of almost bipartite graphs (this is implicit in Sbihi and Uhry [1984]), and the t-perfection of odd-K_4-free graphs (Gerards and Schrijver [1986]).

68.4. On characterizing t-perfection

The problem if a given graph $G = (V, E)$ is t-perfect, belongs to co-NP: non-t-perfection can be certified by a noninteger vertex x^* of the polytope determined by (68.1), together with a nonsingular system of constraints that are tight for x^*. One must check that x^* satisfies all constraints among (68.1) — this can be done in polynomial time by the methods described in the proof of Theorem 68.1. A polynomial-time algorithm for, or a combinatorial certificate of, non-t-perfection is not known.

T-perfection and strong t-perfection are not closed under taking subgraphs, as is shown by Figure 68.1. However, t-perfection is closed under taking induced subgraphs. This is easy to check, as well as that it is closed under the following operation:

(68.40) choose a vertex v with $N(v)$ a stable set, and contract all edges in $\delta(v)$.

So one may ask for the minimally non-t-perfect graphs — minimal with respect to taking induced subgraphs and applying operation (68.40). Known minimal graphs include the wheels[24] with an even number of vertices and the graphs consisting of a circuit of length $4k$ and all chords connecting a

[24] A *wheel* is a graph obtained from a circuit C by adding a new vertex, adjacent to all vertices in C.

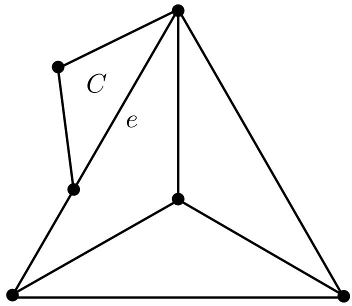

Figure 68.1
A strongly t-perfect graph G with $G - e$ not t-perfect. The strong t-perfection of G can be derived from the fact that each inclusionwise maximal stable set intersects the triangle C. Hence for any integer weight function, subtracting the incidence vector of VC, reduces the maximum weight of a stable set by 1. We therefore can assume that at least one of the vertices of C has weight 0, and hence we can delete it. We are left with a graph containing no odd K_4-subdivision — hence being strongly t-perfect (Theorem 68.3).

vertex with its opposite vertex ($k \geq 1$). Also strong t-perfection is closed under taking induced subgraphs and the operation (68.40). So one may ask a similar question for strong t-perfection.

A characterization that has been achieved is of those graphs for which each, also noninduced, subgraph is t-perfect. Here subdivisions of K_4 play a role. Call a subdivision of K_4 *bad* if it is not t-perfect.

It has been shown by Gerards and Shepherd [1998] that any graph without bad K_4-subdivision is t-perfect. Hence, each subgraph of a graph G is t-perfect if and only if G contains no bad K_4-subdivision. This was extended to: any graph without bad K_4-subdivision is strongly t-perfect (Schrijver [2002b]). So each subgraph of a graph is t-perfect if and only if each subgraph is strongly t-perfect.

The K_4-subdivisions that are bad have been characterized by Barahona and Mahjoub [1994c]. They showed that a K_4-subdivision is not t-perfect if and only if it is an odd K_4-subdivision such that the following does *not* hold: the edges of K_4 that have become an even path, form a 4-cycle in K_4, while the two other edges of K_4 are not subdivided. One may check that this is equivalent to the fact that one cannot obtain K_4 by the operations (68.40). So necessity in this characterization follows from the closedness of t-perfection under operation (68.40).

68.5. A combinatorial min-max relation

A subdivision of K_4 is called *totally odd* if it arises from K_4 be replacing each edge by an odd-length path. So a totally odd K_4-subdivision is an odd K_4-subdivision. A graph containing no totally odd K_4-subdivision need not be t-perfect (see Figure 68.2, from Chvátal [1975a]). However, Sewell and Trotter [1990,1993] showed that for weight function $w = \mathbf{1}$, the min-max relation is maintained for totally odd K_4-free graphs.

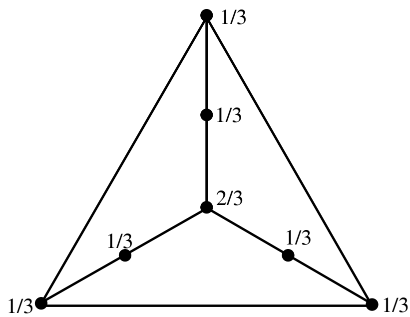

Figure 68.2
A graph containing no totally odd K_4-subdivision and not being t-perfect. The values at the vertices represent a vector satisfying (68.1) but not belonging to the stable set polytope.

This can be formulated in terms of the nonweighted version $\tilde{\rho}(G)$ of $\tilde{\rho}_w(G)$ defined in (68.7):

(68.41) $\tilde{\rho}(G) :=$ the minimum cost of a family of vertices, edges, and odd circuits covering V.

One easily checks that the minimum is attained by a vertex-disjoint family.

Obviously, for any graph G,

(68.42) $\alpha(G) \leq \tilde{\rho}(G)$.

So Sewell and Trotter [1990,1993] showed that equality holds for graphs without totally odd K_4-subdivision (generalizing a result of Gerards [1989a], who proved it for graphs without odd K_4-subdivision — a consequence of Theorem 68.3; Chvátal [1975a] proved it for series-parallel graphs).

Theorem 68.4. *For any graph G containing no totally odd K_4-subdivision, the stable set number $\alpha(G)$ is equal to $\tilde{\rho}(G)$.*

Proof. Let $G = (V, E)$ be a counterexample with $|V| + |E|$ minimal. Set $\alpha := \alpha(G)$. Then G is connected, and

(68.43) $\alpha(G - v) = \alpha$ for each $v \in V$ and $\alpha(G - e) > \alpha$ for each $e \in E$,

since otherwise $G - v$ or $G - e$ would be a smaller counterexample.

Hence for each vertex v, there exists a vertex-disjoint collection of vertices, edges, and odd circuits, covering $V \setminus \{v\}$ and of cost α. Let F_v be the set of edges contained in this collection or in one of the circuits in it. Let G_v be the graph $(V \setminus \{v\}, F_v)$. So

(68.44) $\alpha(G_v) = \alpha$,

and G_v has maximum degree at most 2. Moreover, the minimality of G implies:

(68.45) $F_u \cup F_v = E \setminus \{uv\}$ for each edge uv.

To see this, trivially, $uv \notin F_u \cup F_v$. Suppose that $e \neq uv$ is an edge not contained in $F_u \cup F_v$. As $\alpha(G - e) > \alpha$, $G - e$ has a stable set S of size $\alpha + 1$. By symmetry, we can assume that $v \notin S$. Then S is a stable set in the graph G_v, contradicting (68.44).

This proves (68.45), which gives:

(68.46) for each edge uv, each edge $e \neq uv$ incident with u belongs to F_v.

This follows directly from (68.45), since $e \notin F_u$ (as $u \in e$).

This is used in proving:

(68.47) G is 3-regular.

For if vertex v has degree 1, with neighbour u, then $\alpha(G - v - u) < \alpha$; since moreover $\tilde{\rho}(G) \leq \tilde{\rho}(G - u - v) + 1$ (since we can add edge uv to any collection attaining the minimum for $G - u - v$), we have $\alpha(G) \geq \alpha(G - u - v) + 1 = \tilde{\rho}(G - u - v) + 1 \geq \tilde{\rho}(G)$. This contradicts the fact that G is a counterexample.

If v has degree 2, let G' be the graph obtained by contracting the edges incident with v. Then G' contains no totally odd K_4-subdivision. Moreover, it is straightforward to check that $\alpha(G) \geq \alpha(G') + 1$ and $\tilde{\rho}(G) \leq \tilde{\rho}(G') + 1$. As G' is smaller than G, we have $\tilde{\rho}(G') = \alpha(G')$. Hence $\alpha(G) \geq \alpha(G') + 1 = \tilde{\rho}(G') + 1 \geq \tilde{\rho}(G)$. Again, this contradicts the fact that G is a counterexample.

So v has degree at least 3. Let u be one of its neighbours. Then $\delta(v) \subseteq F_u \cup \{uv\}$ by (68.46). As G_u has maximum degree at most 2, we have $|\delta(v)| = 3$. This proves (68.47).

By (68.45) and (68.47),

(68.48) for each edge uv of G, u is traversed by an odd circuit in F_v.

Moreover:

(68.49) Let uv be an edge of G and let C be the odd circuit in F_v traversing u. Consider any edge $e = xy$ on C with $e \notin F_u$. Then both x and y have even distance from u along $C - e$.

Let S be a stable set of $G-e$ of size $\alpha+1$. So $x, y \in S$. Moreover, $u \in S$, since otherwise $\alpha(G_u) > \alpha$ (since $e \notin F_u$), contradicting (68.44). So $v \notin S$, and hence $S \setminus \{y\}$ is a maximum-size stable set of $G-v$. Hence, $S \setminus \{y\}$ intersects C in $\lfloor \frac{1}{2}|VC| \rfloor$ vertices. Therefore, S intersects C in $\lceil \frac{1}{2}|VC| \rceil$ vertices. As $x, y \in S$, (68.49) follows.

Now choose a vertex, r say, and its neighbours, u_1, u_2, u_3 say. For each $i \in \{1,2,3\}$, F_{u_i} contains an odd circuit C_i traversing r (by (68.48)), and hence traversing the edges ru_{i+1} and ru_{i+2} (taking indices mod 3). We will construct a totally odd K_4-subdivision from them, which contradicts the condition of the theorem.

For $i = 1,2,3$, let P_i be the path in C_i from u_{i+1} to u_{i+2} obtained by deleting vertex r from C_i. Since $\alpha(G - ru_i) > \alpha$, G has a stable set S_i of size α, intersecting $\{r, u_1, u_2, u_3\}$ precisely in $\{u_i\}$. Then for all distinct $i, j \in \{1,2,3\}$:

(68.50) S_j contains all vertices along P_i at even distance from u_j.

To see this, we may assume that $i = 1$, $j = 2$. Since S_2 is a maximum-size stable set in $G - u_1$, it intersects C_1 in $\lfloor \frac{1}{2}|VC_1| \rfloor$ vertices. Since $r, u_3 \notin S_2$, S_2 contains all vertices along P_1 at even distance from u_2, proving (68.50).

This implies, for distinct $i, j, k \in \{1,2,3\}$:

(68.51) $VP_i \subseteq S_j \triangle S_k$.

One similarly shows, for distinct $i, j, k \in \{1,2,3\}$:

(68.52) P_i contains an edge that splits P_i into two even-length paths $P_{i,j}$ (containing u_j) and $P_{i,k}$ (containing u_k), in such a way that S_i contains all vertices along $P_{i,j}$ at odd distance from u_j and all vertices along $P_{i,k}$ at odd distance from u_k.

To prove this, we may assume that $i = 1$, $j = 2$, $k = 3$. Since $S := S_1 \setminus \{u_1\} \cup \{r\}$ is a maximum-size stable set in $G - u_1$, it intersects C_1 in $\lfloor \frac{1}{2}|VC_1| \rfloor$ vertices. Since S contains r, there is precisely one edge on P_1 not intersected by S. This gives the edge as required in (68.52).

This implies, for distinct $i, j \in \{1,2,3\}$:

(68.53) $VP_{i,j} = VP_i \cap (S_i \triangle S_j)$,

and hence, for distinct $i, j, k \in \{1,2,3\}$:

(68.54) $VP_i \cap VP_j = VP_{i,k} \cap VP_{j,k}$,

since

(68.55) $VP_{i,k} \cap VP_{j,k} = VP_i \cap (S_i \triangle S_k) \cap VP_j \cap (S_j \triangle S_k) = VP_i \cap VP_j$

(using (68.51)).

For each $i = 1,2,3$, vertex u_{i+2} is on P_i and P_{i+1}. Hence there is a first vertex v_i on P_i (starting from u_{i+1}), that also belongs to P_{i+1}. By (68.54), v_i occurs after v_{i+2} along P_i (seen from u_{i+1}), since $v_i \in VP_i \cap VP_{i+1} \subseteq VP_{i,i+2}$ and $v_{i+2} \in VP_{i+2} \cap VP_i \subseteq VP_{i,i+1}$. Moreover, (68.56) v_i has even distance from u_{i+2} along P_i and along P_{i+1}.

To prove this, we may assume that $i = 1$. Suppose that v_1 has odd distance from u_3 along P_1. Let f and e be the previous and next edge along P_1 (seen from u_2) and let g be the third edge incident with v_1. Since v_1 is the first vertex along P_1 belonging to P_2, we know that f is not on P_2. So $f \notin F_{u_2}$, and hence (by (68.45)) $f \in F_r$. Since g is not on P_1, we have $g \notin F_{u_1}$, and hence (again by (68.45)) $g \in F_r$. Therefore (as F_r has maximum degree at most degree 2), $e \notin F_r$. Then (68.49) implies that v_1 has even distance from u_3 along P_1. Hence $v_1 \in S_3$, and so v_1 has also even distance from u_3 along P_2 (by (68.50)). This proves (68.56).

For $i = 1, 2, 3$, let Q_i be the $u_{i+1} - v_i$ part of P_i. Then Q_i and Q_{i+1} intersect each other only in v_i (since v_i is the first vertex along P_i that is on P_{i+1}). This implies that Q_1, Q_2, Q_3 together with the edges ru_1, ru_2, and ru_3, form a totally odd K_4-subdivision, a contradiction. ∎

Recall that a graph is bipartite if and only if for each subgraph H, the stable set number $\alpha(H)$ is equal to the edge cover number $\rho(H)$. An extension of this is implied by the theorem above:

Corollary 68.4a. *A graph G contains no totally odd K_4-subdivision if and only $\alpha(H) = \tilde{\rho}(H)$ for each subgraph H of G.*

Proof. Necessity follows from Theorem 68.4. Sufficiency follows from the fact that if G is a totally odd K_4-subdivision, then $\alpha(G) < \tilde{\rho}(G)$. This can be seen by induction on $|VG|$. If $|VG| = 4$, then $G = K_4$, and $\alpha(G) = 1$, $\tilde{\rho}(G) > 1$. If $|VG| > 4$, G has a vertex v of degree 2. Let G' arise by contracting the two edges incident with v. Then, using the induction hypothesis, $\alpha(G) \leq \alpha(G') + 1 < \tilde{\rho}(G') + 1 \leq \tilde{\rho}(G)$. ∎

Theorem 68.4 also implies (in fact, is equivalent to) the following. A graph $G = (V, E)$ is called *α-critical* if $\alpha(G - e) > \alpha(G)$ for each $e \in E$. Then each connected α-critical graph is either K_1, or K_2, or an odd circuit, or contains a totally odd K_4-subdivision (answering a question of Chvátal [1975a]).

We note that Theorem 68.4 implies that the stable set number $\alpha(G)$ of a graph G without totally odd K_4-subdivision can be determined in polynomial time, as $\alpha(G)$ is equal to the maximum of $\mathbf{1}^\mathsf{T}x$ over (68.1) (since the separation problem is polynomial-time solvable — see Theorem 68.1). This implies that an explicit maximum-size stable set can be found in polynomial time (just by deleting vertices as long as the stable set number does not decrease).

The vertex cover number. Another consequence of Theorem 68.4 concerns the vertex cover number $\tau(G)$ of a graph $G = (V, E)$. Trivially, $\tau(G) + \alpha(G) = |V|$. Define the *profit* of an edge to be 1, and the *profit* of a circuit C to be $\lceil \frac{1}{2}|VC| \rceil$. The *profit* of a family of edges and circuits is equal to the sum of the profits of its elements. Let $\tilde{\nu}(G)$ denote the maximum profit of a collection of pairwise vertex-disjoint edges and odd circuits in G. Then there is the following analogue to Gallai's theorem (Theorem 19.1):

Theorem 68.5. *For any graph $G = (V, E)$: $\tilde{\nu}(G) + \tilde{\rho}(G) = |V|$.*

Proof. Define the profit of any vertex to be 0. Then $\tilde{\nu}(G)$ is equal to the maximum profit of a collection of vertices, edges, and circuits partitioning V. Similarly, $\tilde{\rho}(G)$ is equal to the minimum cost of a collection of vertices, edges, and circuits partitioning V. Now for any collection $\mathcal{C}$ of vertices, edges, and circuits partitioning V we have $\text{cost}(\mathcal{C})+\text{profit}(\mathcal{C}) = |V|$. Hence the minimum cost over all such collections equals $|V|$ minus the maximum profit over all such collections. This gives the required equality. ∎

With Theorem 68.4, this implies a min-max relation for the vertex cover number of totally-odd-K_4-free graphs:

Corollary 68.5a. *For any graph G containing no totally odd K_4-subdivision, the vertex cover number $\tau(G)$ is equal to $\tilde{\nu}(G)$.*

Proof. Directly from Theorems 68.4 and 68.5, and from the fact that $\alpha(G)+\tau(G) = |V|$ for any graph G. ∎

68.6. Further results and notes

68.6a. The w-stable set polyhedron

The t-perfection of odd-K_4-free graphs can be extended to apply to w-stable sets. Given a graph $G = (V, E)$ and a function $w : E \to \mathbb{Z}_+$, a *w-stable set* is a function $x : V \to \mathbb{Z}_+$ such that $x_u + x_v \leq w_e$ for each edge $e = uv$. So if $w = \mathbf{1}$ and G has no isolated vertices, w-stable sets are the incidence vectors of stable sets. The *w-stable set polyhedron* is the convex hull of the w-stable sets.

Theorem 68.3 implies a characterization of the w-stable set polyhedron of odd-K_4-free graphs. Consider the following system:

(68.57)
$$\begin{array}{rll} \text{(i)} & x_v \geq 0 & \text{for each } v \in V, \\ \text{(ii)} & x(e) \leq w_e & \text{for each } e \in E, \\ \text{(iii)} & x(VC) \leq \lfloor \frac{1}{2} w(EC) \rfloor & \text{for each odd circuit } C, \end{array}$$

where $x(e) = x_u + x_v$ for $e = uv$.

Theorem 68.6. *For any graph $G = (V, E)$ containing no odd K_4-subdivision and for any $w : E \to \mathbb{Z}_+$, system* (68.57) *determines the w-stable set polyhedron.*

Proof. We show that (68.57) determines an integer polyhedron, and hence is equal to the w-stable set polyhedron. Let x be a noninteger vertex of P. By resetting $w_e := w_e - \lfloor x_u \rfloor - \lfloor x_v \rfloor$ for $e = uv \in E$ and $x_v := x_v - \lfloor x_v \rfloor$ for $v \in V$, x remains a noninteger vertex of the new P. So we can assume that $0 \leq x_v < 1$ for each $v \in V$.

Let E' be the set of edges e of G with $w_e = 1$. Then $G' = (V, E')$ contains no odd K_4-subdivision, and hence is t-perfect (Theorem 68.3). So x is a convex combination of incidence vectors of stable sets of G'. As each such incidence vector satisfies (i) and (ii) of (68.57) (since $x_u + x_v \le 1+1 = 2 \le w_e$ for each edge $e = uv$ in $E \setminus E'$), it also satisfies (iii) (as it is integer). Hence x is a convex combination of integer solutions of (68.57). So P is integer. ∎

It was shown by Gijswijt and Schrijver [2002] that system (68.57) is totally dual integral for each $w : E \to \mathbb{Z}_+$ if and only if G contains no bad K_4-subdivision.

68.6b. Bidirected graphs

We saw bidirected graphs before in Chapter 36. We recall some definitions and terminology. A *bidirected graph* is a triple $G = (V, E, \sigma)$, where (V, E) is an undirected graph and where σ assigns to each $e \in E$ and each $v \in e$ a 'sign' $\sigma_{e,v} \in \{+1, -1\}$. The graph (V, E) may have loops, but we will assume that the 'two' ends of the loop have the same sign. (Other loops will be meaningless in our discussion.)

The edges e for which $\sigma_{e,v} = 1$ for each $v \in e$ are called the *positive edges*, those with $\sigma_{e,v} = -1$ for each $v \in e$ are the *negative edges*, and the remaining edges are the *directed edges*.

Clearly, undirected graphs and directed graphs can be considered as special cases of bidirected graphs. Graph terminology extends in an obvious way to bidirected graphs. The undirected graph (V, E) is called the *underlying undirected graph* of G. We also will need the *underlying signed graph* $G = (V, E, \Sigma)$, where Σ is the family of positive and negative edges. We call a circuit C in (V, E) *odd* or *even*, if $|EC \cap \Sigma|$ is odd or even, respectively.

A signed graph $G = (V, E, \Sigma)$ is called an *odd K_4-subdivision* if (V, E) is a subdivision of K_4 such that each triangle has become an odd circuit (with respect to Σ). A bidirected graph is called an *odd K_4-subdivision* if its underlying signed graph is an odd K_4-subdivision.

The $E \times V$ *incidence matrix* of a bidirected graph $G = (V, E, \sigma)$ is the $E \times V$ matrix M defined by, for $e \in E$ and $v \in V$:

(68.58)
$$M_{e,v} := \begin{cases} \sigma_{e,v} & \text{if } e \text{ is not a loop,} \\ 2\sigma_{e,v} & \text{if } e \text{ is a loop,} \end{cases}$$

setting $\sigma_{e,v} := 0$ if $v \notin e$.

For $b \in \mathbb{Z}^E$, we consider integer solutions of the system $Mx \le b$. To this end, define for any circuit C (in the undirected graph (V, E)) and any vertex v:

(68.59)
$$a_{C,v} := \tfrac{1}{2} \sum_{e \in EC} M_{e,v} \text{ and } d_C := \lfloor \tfrac{1}{2} \sum_{e \in EC} b_e \rfloor.$$

As C is a circuit, $a_{C,v}$ is an integer. Hence each integer solution x of $Mx \le b$ satisfies

(68.60)
$$\sum_{v \in V} a_{C,v} x_v = \tfrac{1}{2} \sum_{e \in EC} \sum_{v \in V} M_{e,v} x_v \le \lfloor \tfrac{1}{2} \sum_{e \in EC} b_e \rfloor = d_C.$$

Therefore, each integer solution of $Mx \le b$ satisfies:

(68.61)
(i) $Mx \le b$,
(ii) $\sum_{v \in V} a_{C,v} x_v \le d_C$ for each odd circuit C.

(Again, 'odd' is with respect to Σ.) Then Theorem 68.6 implies:

Corollary 68.6a. *If a bidirected graph G contains no odd K_4-subdivision, then system* (68.61) *determines an integer polyhedron.*

Proof. Make from the bidirected graph $G = (V, E, \sigma)$ the following auxiliary undirected graph $G' = (V', E')$. For each $e \in E$ which is not a positive loop, let $c_e := 1$ if e is positive, $c_e := 2$ if e is directed, and $c_e := 3$ if e is negative. Then replace e by a path P_e of length c_e connecting the two vertices in V incident with e. Let $\tilde{e}$ be the unique edge on P_e that is not incident with a vertex v of G with $\sigma_{e,v} = -1$.

If e is a positive loop at v, make a circuit P_e of length 3 starting and ending at v. Let $\tilde{e}$ be one of the two edges on P_e incident with v.

Let F be the set of edges f of G' that are on P_e for some $e \in E$ and satisfy $f \neq \tilde{e}$. As G has no odd K_4-subdivision (as a bidirected graph), G' has no odd K_4-subdivision (as an undirected graph). Hence by Theorem 68.6, the following system (in $x \in \mathbb{R}^{V'}$) determines an integer polyhedron:

$$\text{(68.62)} \qquad \begin{array}{rll} \text{(i)} & x(\tilde{e}) \leq b_e & \text{for each edge } e \in E, \\ \text{(ii)} & x(f) = 0 & \text{for each edge } f \in F, \\ \text{(iii)} & x(VC) \leq \lfloor \frac{1}{2}|VC| \rfloor & \text{for each odd circuit } C \text{ in } G'. \end{array}$$

(Here 'odd' refers to the length of the circuit. As usual, $x(f) := x_u + x_v$ where u and v are the ends of f for $f \in E'$.) This implies that system (68.61) determines an integer polyhedron, since the conditions (68.62)(ii) allow elimination of the variables x_v for $v \in V' \setminus V$. ∎

This theorem may be used to characterize odd-K_4-free bidirected graphs. Let $G = (V, E, \sigma)$ be a bidirected graph, with $E \times V$ incidence matrix M. For $a, b \in \mathbb{Z}^E$ consider integer solutions of

$$\text{(68.63)} \qquad a \leq Mx \leq b.$$

As the matrix

$$\text{(68.64)} \qquad \begin{pmatrix} M \\ -M \end{pmatrix}$$

is again the incidence matrix of some bidirected graph, we can consider the inequalities (68.61)(ii) corresponding to matrix (68.64). They amount to:

$$\text{(68.65)} \qquad \sum_{v \in V} \tfrac{1}{2}\Big(\sum_{e \in F} M_{e,v} - \sum_{e \in EC \setminus F} M_{e,v}\Big)x_v \leq \Big\lfloor \tfrac{1}{2}\Big(\sum_{e \in F} b_e - \sum_{e \in EC \setminus F} a_e\Big)\Big\rfloor \text{ for each odd circuit } C \text{ and each } F \subseteq EC.$$

To describe the characterization, we define 'minor' of a signed graph $G = (V, E, \Sigma)$. For $e \in E$, *deletion* of e means resetting E and Σ to $E \setminus \{e\}$ and $\Sigma \setminus \{e\}$. *Deletion* of a vertex v means deleting all edges incident with v, and deleting v from V. If e is not a loop, *contraction* of e means the following. Let e have ends u and v. If $e \in \Sigma$, reset $\Sigma := \Sigma \triangle \delta(u)$. Otherwise, let Σ be unchanged. Next contract e in (V, E). This definition depends on the choice of the end u of e, but for the application below this will be irrelevant. A *resigning* means choosing $U \subseteq V$ and resetting Σ to $\Sigma \triangle \delta(U)$. A signed graph H is called a *minor* of a signed graph G if

H arises from G by a series of deletions of edges and vertices, contractions of edges, and resignings.

Then we have the following characterization (Gerards and Schrijver [1986]), where odd-K_4 stands for the signed graph (VK_4, EK_4, EK_4).

Corollary 68.6b. *For any bidirected graph G the following are equivalent:*

(68.66) (i) *G contains no odd K_4-subdivision as subgraph;*
(ii) *the signed graph underlying G has no odd-K_4 minor;*
(iii) *for all integer vectors a, b, system* (68.63)(68.65) *determines a box-integer polyhedron.*

Proof. The implication (ii)$\Rightarrow$(i) follows from the easy fact that any odd K_4-subdivision in G would yield an odd-K_4 minor of the signed graph underlying G.

The implication (i)$\Rightarrow$(iii) can be derived from Corollary 68.6a as follows. Replace any 'box' constraint $d_v \leq x_v \leq c_v$ by $2d_v \leq 2x_v \leq 2c_v$, and incorporate it into M, by adding loops at v. Then the constraint (68.65) corresponding to such a loop C at v is $x_v \leq c_v$ or $-x_v \leq -d_v$. This gives a reduction to Corollary 68.6a.

To see the implication (iii)$\Rightarrow$(ii), note that (iii) is invariant under deleting rows of M and under multiplying rows or columns by -1. It is also closed under contractions of any edge e, as it amounts to taking $a_e = b_e = 0$ in (68.63). So, in proving (iii)$\Rightarrow$(ii), if the signed graph underlying G has an odd-K_4 minor, we may assume that it is odd-K_4. By multiplying rows and columns of M by -1, we may assume that M is nonnegative. Then we do not have an integer polytope for $a = \mathbf{0}$, $b = \mathbf{1}$, $d = \mathbf{0}$, $c = \mathbf{1}$. ∎

In other words, the bidirected graphs without odd K_4-subdivision are precisely those whose $E \times V$ incidence matrix has strong Chvátal rank at most 1 (cf. Section 36.7a, where it is shown that the transpose of *each* such matrix has strong Chvátal rank at most 1).

68.6c. Characterizing odd-K_4-free graphs by mixing stable sets and vertex covers

A similar characterization can be formulated in terms of just undirected graphs, by mixing stable sets and vertex covers. Call a graph H an *odd minor* of a graph G if H arises from G by deleting edges and vertices, and by contracting all edges in some cut $\delta(U)$ (in the graph without the deleted edges). The following is easy to show:

(68.67) A graph G contains an odd K_4-subdivision $\iff$ G contains K_4 as odd minor.

For a graph $G = (V, E)$ and $F \subseteq E$, a subset U of V is called F-*stable* if U is a stable set of the graph (V, F). U is called an F-*cover* if U is a vertex cover of (V, F). Let F_1 and F_2 be disjoint subsets of E, and consider the system:

$$(68.68)\qquad \begin{array}{ll} 0 \leq x_v \leq 1 & \text{for } v \in V, \\ x(e) \leq 1 & \text{for } e \in F_1, \\ x(e) \geq 1 & \text{for } e \in F_2, \\ \displaystyle\sum_{e \in EC \cap F_1} x(e) - \sum_{e \in EC \cap F_2} x(e) \leq |EC \cap F_1| - |EC \cap F_2| - 1 & \\ & \text{for each odd circuit } C \text{ with } EC \subseteq F_1 \cup F_2 \end{array}$$

(where $x(e) := x_u + x_v$ for $e = uv \in E$).

Corollary 68.6c. *For any graph $G = (V, E)$ the following are equivalent:*

(68.69) (i) *G contains no odd K_4-subdivision;*
(ii) *for all disjoint $F_1, F_2 \subseteq E$, the convex hull of the incidence vectors of the F_1-stable F_2-covers is determined by* (68.68).

Proof. The implication (i)⇒(ii) follows from Corollary 68.6a. To see (ii)⇒(i), we first show that (ii) is maintained under taking odd minors. Maintenance under deletion of edges or vertices is trivial. To see that it is maintained under contraction of cuts, let $U \subseteq V$ and let $G' = (V', E')$ be the contracted graph. Let F_1' and F_2' be disjoint subsets of E', and let x' satisfy (68.68) for G', F_1', F_2'. Define $x : V \to \mathbb{R}$ as follows, where, for $v \in V$, v' denotes the vertex of G' to which v is contracted:

$$(68.70)\qquad x_v := \begin{cases} x'_{v'} & \text{if } v \in U, \\ 1 - x'_{v'} & \text{if } v \in V \setminus U. \end{cases}$$

Moreover, define F_1 and F_2 by:

$$(68.71)\qquad \begin{array}{l} F_1 := (F_1' \cap E[U]) \cup (F_2' \cap E[V \setminus U]) \cup \delta(U), \\ F_2 := (F_2' \cap E[U]) \cup (F_1' \cap E[V \setminus U]). \end{array}$$

Then x satisfies (68.68) with respect to G, F_1, F_2. Hence x is a convex combination of integer solutions of (68.68). Applying the construction in reverse to (68.70), we obtain x' as a convex combination of integer solutions of (68.68) with respect to G', F_1', F_2'.

This shows that (68.69)(ii) is maintained under taking odd minors. Moreover, K_4 violates the condition (taking $F_1 := E$, $F_2 := \emptyset$, $x_v := \frac{1}{3}$ for each $v \in V$). This shows sufficiency of the condition. ∎

68.6d. Orientations of discrepancy 1

A directed graph $D = (V, A)$ is said to have *discrepancy k* if for each (undirected) circuit, the number of forward arcs differs by at most k from the number of backward arcs.

The proof of Gerards [1989a] of the strong t-perfection of odd-K_4-free graphs (Theorem 68.3) is by showing that each such graph can be decomposed into graphs that have an orientation of discrepancy 1, using a characterization of Gerards [1994] of orientability of discrepancy 1 and a decomposition theorem of Gerards, Lovász, Schrijver, Seymour, Shih, and Truemper [1993] (cf. Gerards [1990]). As the graphs having an orientation of discrepancy 1 can be shown to be strongly t-perfect with minimum-cost flow techniques (see Theorem 68.7 below), and as the composition maintains total dual integrality of (68.1), the required result follows.

It is not difficult to show that the underlying undirected graph of any digraph of discrepancy 1, contains no odd K_4-subdivision. So, by Theorem 68.3, any undirected graph having an orientation of discrepancy 1, is strongly t-perfect. Gerards gave a direct proof of the strong t-perfection of such graphs, based on the following minimum-cost circulation argument:

Lemma 68.7α. *Let $D = (V, A)$ be a directed graph and let $b : A \to \mathbb{Z}_+$. Then the following system is totally dual integral:*

(68.72) (i) $x_v \geq 0$ for $v \in V$,
(ii) $x(VC) \leq b(AC)$ for each directed circuit C in D.

Proof. Choose $w : V \to \mathbb{Z}_+$. We must show that the dual of maximizing $w^\mathsf{T} x$ over (68.72) has an integer optimum solution.

Make another directed graph $\widetilde{D} = (\widetilde{V}, \widetilde{A})$ as follows. For each vertex v of D, make two vertices v', v'' and an arc (v', v''), and for each arc (u, v) of D, make an arc (u'', v'). This defines $\widetilde{D}$.

Define $g, f : \widetilde{A} \to \mathbb{Z}_+$ by:

(68.73) $g(v', v'') := w(v)$ and $f(v', v'') := 0$ for $v \in V$,
$g(u'', v') := 0$ and $f(u'', v') := b(u, v)$ for $(u, v) \in A$.

Then the maximum of $w^\mathsf{T} x$ over (68.72) is equal to the maximum of $g^\mathsf{T} z$ where $z : \widetilde{A} \to \mathbb{R}_+$ satisfies

(68.74) $z(A\widetilde{C}) \leq f(A\widetilde{C})$ for each directed circuit $\widetilde{C}$ in $\widetilde{D}$.

So if we consider $f - z$ as length function on $\widetilde{A}$, then (68.74) says that each directed circuit in $\widetilde{D}$ has nonnegative length. Hence, by Theorem 8.2, the maximum is equal to the maximum of $g^\mathsf{T} z$ over $z : \widetilde{A} \to \mathbb{R}_+$ for which there exists a $p : \widetilde{V} \to \mathbb{R}$ such that

(68.75) $z(\tilde{a}) + p(t) - p(s) \leq f(\tilde{a})$ for each $\tilde{a} = (s, t) \in \widetilde{A}$.

The latter system has a totally unimodular constraint matrix, and hence the LP has integer optimum primal and dual solutions. The dual asks for the minimum of $y^\mathsf{T} f$ where $y : \widetilde{A} \to \mathbb{Z}_+$ satisfies

(68.76) $y(\tilde{a}) \geq g(\tilde{a})$ for each $\tilde{a} \in \widetilde{A}$,
$y(\delta^{\text{in}}(\tilde{v})) = y(\delta^{\text{out}}(\tilde{v}))$ for each $\tilde{v} \in \widetilde{V}$.

So y is a circulation in $\widetilde{D}$. Hence y is a nonnegative integer combination of incidence vectors of directed circuits $\widetilde{C}$ in $\widetilde{D}$:

(68.77) $$y = \sum_{\widetilde{C}} \lambda_{\widetilde{C}} \chi^{A\widetilde{C}}.$$

For each directed circuit $\widetilde{C}$ in $\widetilde{D}$, let C denote the corresponding directed circuit in D (obtained by contracting all arcs (v', v'') occurring in $\widetilde{C}$). Then

(68.78) $$y^\mathsf{T} f = \sum_{\widetilde{C}} \lambda_{\widetilde{C}} (\chi^{A\widetilde{C}})^\mathsf{T} f = \sum_{\widetilde{C}} \lambda_{\widetilde{C}} f(A\widetilde{C}) = \sum_{\widetilde{C}} \lambda_{\widetilde{C}} b(AC)$$

and

(68.79) $$\sum_{\widetilde{C}} \lambda_{\widetilde{C}} \chi^{VC} \geq w.$$

Hence we have obtained an integer dual solution for the problem of maximizing $w^{\mathsf{T}}x$ over (68.72). ∎

This lemma implies:

Theorem 68.7. *Let $G = (V, E)$ be an undirected graph having an orientation D of discrepancy 1. Then G is strongly t-perfect.*

Proof. Let $D' = (V, A')$ be the digraph obtained from D by adding a reverse arc (v, u) for each arc (u, v) of D, defining $b(u, v) := 1$ and $b(v, u) := 0$. Then the total dual integrality of (68.1) follows directly from the total dual integrality of (68.72). Note that each directed circuit C' in D' gives an undirected circuit C in D, with $b(AC')$ equal to the number of forward arcs in C. As D has discrepancy 1, $\lfloor \frac{1}{2}|VC| \rfloor$ is equal to the minimum value of $b(AC')$ and $b(AC'^{-1})$. ∎

This immediately implies the strong t-perfection of *almost bipartite* graphs — graphs having a vertex v with $G - v$ bipartite, since they have an orientation of discrepancy 1, as one easily checks.

68.6e. Colourings and odd K_4-subdivisions

Zang [1998] and Thomassen [2001] showed that any graph G without totally odd K_4-subdivision satisfies $\chi(G) \leq 3$.[25] We may interpret this in terms of the integer decomposition and rounding properties. Consider the antiblocking polytope Q of the stable set polytope of a graph $G = (V, E)$:

(68.80)
$$\begin{array}{ll} x_v \geq 0 & \text{for each } v \in V, \\ x(S) \leq 1 & \text{for each stable set } S. \end{array}$$

If G is t-perfect, the vertices of Q are: the origin, the unit base vectors, the incidence vectors of the edges, and the vectors $\chi^{VC}/\lfloor \frac{1}{2}|VC| \rfloor$ where C is an odd circuit. (This follows from the definition of t-perfection with antiblocking polyhedra theory.) Hence the fractional colouring number $\chi^*(G)$ of G, which is equal to the maximum of $\mathbf{1}^{\mathsf{T}}x$ over (68.80) (cf. Section 64.8), is equal to

(68.81) $$\max\{2, \max\{\frac{|VC|}{\lfloor \frac{1}{2}|VC| \rfloor} \mid C \text{ odd circuit}\}\}$$

(assuming $E \neq \emptyset$). For nonbipartite graphs, this value is equal to 3. So for graphs G without totally odd K_4-subdivision, the colouring number $\chi(G)$ is equal to the round-up $\lceil \chi^*(G) \rceil$ of the fractional colouring number.

---

[25] This was conjectured by Toft [1975], and extends results of Hadwiger [1943] that a 4-chromatic graph contains a K_4-subdivision, of Catlin [1979] that it contains an odd K_4-subdivision, and of Gerards and Shepherd [1998] that it contains a bad K_4-subdivision. Zeidl [1958] showed that any vertex of a minimally 4-chromatic graph lies in a subdivided K_4 that contains an odd circuit. Other partial and related results were found by Krusensjterna-Hafstrøm and Toft [1980], Thomassen and Toft [1981], and Jensen and Shepherd [1995].

A.M.H. Gerards (personal communication 2001) showed that system (68.80) has the integer rounding property if G has no odd K_4-subdivision. It implies that the corresponding stable set polytope has the integer decomposition property. This is equivalent to:

(68.82) $\chi_w(G) = \lceil \chi_w^*(G) \rceil$

for each odd-K_4-free graph G and each $w : VG \to \mathbb{Z}_+$.

This does not hold for any t-perfect graph: M. Laurent and P.D. Seymour showed in 1994 that the complement of the line graph of a prism (complement of C_6) is t-perfect, but is not 3-colourable; hence its stable set polytope does not have the integer decomposition property.

68.6f. Homomorphisms

Let G and H be simple graphs. A *homomorphism* $G \to H$ is a function $\phi : VG \to VH$ such that if $uv \in EG$, then $\phi(u)\phi(v) \in EH$ (in particular, $\phi(u) \neq \phi(v)$). Obviously, if there exists a homomorphism $G \to H$, then $\chi(G) \leq \chi(H)$.

For any k, let $K_4^{(k)}$ be the graph obtained from K_4 by replacing each edge by a path of length k. Then one may check that for odd k there is no homomorphism $K_4^{(k)} \to C_{2k+1}$.

Catlin [1985] showed that this is essentially the only counterexample: if G is a connected graph of maximum degree 3 and $k \in \mathbb{Z}_+$, such that any two vertices of G of degree 3 have distance at least k, and such that there is no homomorphism $G \to C_{2k+1}$, then k is odd and $G = K_4^{(k)}$. (This extends Brooks' theorem (Theorem 64.3) for $k = 1$.)

Gerards [1988] extended this to: if a nonbipartite graph G has no odd minor equal to K_4 or to the graph obtained from the triangle by adding for each edge a new vertex adjacent to the ends of the edge, then there is a homomorphism $G \to C_t$, where t is the shortest length of an odd circuit of G. Further results are given by Catlin [1988].

68.6g. Further notes

Sbihi and Uhry [1984] call a graph $G = (V, E)$ *h-perfect*[26] if the stable set polytope is determined by

(68.83)
$$\begin{array}{rll} \text{(i)} & x_v \geq 0 & \text{for } v \in V, \\ \text{(ii)} & x(C) \leq 1 & \text{for each clique } C, \\ \text{(iii)} & x(VC) \leq \lfloor \frac{1}{2}|VC| \rfloor & \text{for each odd circuit } C. \end{array}$$

So perfect graphs and t-perfect graphs are h-perfect. Sbihi and Uhry showed that substituting bipartite graphs for edges of a series-parallel graph preserves h-perfection.

The t-perfection of line graphs, and classes of graphs that are h-perfect but not t-perfect, were studied by Cao and Nemhauser [1998]. Gerards [1990] gave a survey on signed graphs without odd K_4-subdivision.

[26] h stands for 'hole' (English for 'trou').

Chapter 69

Claw-free graphs

Claw-free graphs are graphs not having $K_{1,3}$ as induced subgraph. We show the result of Minty and Sbihi that a maximum-size stable set in a claw-free graph can be found in strongly polynomial time, and the extension of Minty to the weighted case.

69.1. Introduction

A graph $G = (V, E)$ is called *claw-free* if no induced subgraph of G is isomorphic to $K_{1,3}$. Minty [1980] and Sbihi [1980] showed that a maximum-size stable set in a claw-free graph can be found in polynomial time. Since the line graph of any graph is claw-free, this generalizes Edmonds' polynomial-time algorithm for finding a maximum-size matching in a graph.

Sbihi's algorithm is an extension of Edmonds' blossom shrinking technique, while Minty gave a reduction to the maximum-size matching problem. Minty [1980] also indicated that his algorithm can be extended to the weighted case by reduction to Edmonds' weighted matching algorithm. The final argument for this was given by Nakamura and Tamura [2001].

In Section 69.2, we describe Minty's method for finding a maximum-size stable set in claw-free graphs, and in Section 69.3 we describe the extension to the weighted case.

69.2. Maximum-size stable set in a claw-free graph

An important property of claw-free graphs is that any vertex has at most two neighbours in any stable set. This enables us to augment stable sets by S-augmenting paths, which we define now.

Let $G = (V, E)$ be a graph and let S be a stable set in G. A walk $P = (v_0, v_1, \ldots, v_k)$ (given by its vertex-sequence) is called *S-alternating* if precisely one of v_{i-1}, v_i belongs to S, for each $i = 1, \ldots, k$. It is an *S-augmenting path* if moreover P is a path, $v_0, v_k \notin S$, and $(S \setminus \{v_1, v_3, \ldots, v_{k-1}\}) \cup \{v_0, v_2, \ldots, v_k\}$ is stable. This implies that (if $k \geq 2$) each of v_0 and v_k has precisely one neighbour in S, and each of $v_2, v_4, \ldots, v_{k-2}$ precisely two.

It is easy to see that if G is claw-free, then there is a stable set larger than S if and only if there exists an S-augmenting path. Indeed, sufficiency follows from the definition of S-augmenting path. To see necessity, let S' be a stable set larger than S. Then the subgraph of G induced by $S \triangle S'$ has a component K with more vertices in S' than in S. Since G is claw-free, this subgraph has maximum degree 2, and hence K forms an S-augmenting path.

So in order to find a maximum-size stable set, it suffices to have a polynomial-time algorithm to find for given S, an S-augmenting path, if any. For this, it suffices to describe a polynomial-time algorithm to find an S-augmenting $a-b$ path for prescribed $a, b \in V \setminus S$ (if any). Varying over all $a, b \in V \setminus S$, we find an S-augmenting path (if any).

Therefore, from now on we fix $a, b \in V \setminus S$. Then we can assume:

(69.1) $a \neq b$; a and b have degree 1, each with neighbour in S, say s_a and s_b; $s_a \neq s_b$; each $v \in V \setminus S$ with $v \neq a, b$ has precisely two neighbours in S; for each $s \in S$ with $s \neq s_a, s_b$ there are at least two vertices in S at distance two from s; G is connected.

Indeed, otherwise finding an S-augmenting path is trivial, or it does not exist; moreover, we can delete all neighbours of a or b distinct from s_a or s_b, and all vertices in $S \setminus \{s_a, s_b\}$ that have less than two vertices in S at distance two.

The assumptions (69.1) imply that any S-augmenting path connects a and b. Consider an S-alternating path

(69.2) $P = (v_0, s_1, v_1, \ldots, s_k, v_k)$

(given by its vertex-sequence), with $v_0 = a$ and $v_k = b$. So $s_1 = s_a$ and $s_k = s_b$. Then (under the assumptions (69.1)):

Lemma 69.1α. *P is S-augmenting if and only if v_{i-1} and v_i are nonadjacent for each $i = 2, \ldots, k-1$.*

Proof. Necessity being trivial, we show sufficiency. It suffices to show that $(S \setminus \{s_1, \ldots, s_k\}) \cup \{v_0, \ldots, v_k\}$ is a stable set. Any two vertices in S are nonadjacent. All neighbours in S of any v_i are among $s_1, \ldots, s_k$. Finally, suppose that any v_i, v_j are adjacent, with $i < j$. Then $j \geq i + 2$, since v_i and v_{i+1} are nonadjacent by the condition. But then v_i is adjacent to the three pairwise nonadjacent vertices s_i, s_{i+1}, and v_j. This contradicts the claw-freeness of G. ∎

We next prove a basic lemma of Minty [1980]. Define, for $u, v \in V \setminus S$:

(69.3) $u \sim v \iff N(u) \cap S = N(v) \cap S.$

Clearly, $\sim$ is an equivalence relation. We call any equivalence class a *similarity class*, and if $u \sim v$ we say that u and v are *similar*. So for each $s \in S$, $N(s)$ is a union of similarity classes.

We call a vertex $s \in S$ *splittable* if $N(s)$ can be partitioned into two classes X, Y such that

(69.4) $\qquad uv \in E \iff u, v \in X$ or $u, v \in Y$

for all $u, v \in N(s)$ with $u \not\sim v$. If s is splittable, we call X and Y the *classes* of s. Define

(69.5) $\qquad S' := \{s \in S \mid s$ is splittable$\}$ and $S'' := S \setminus S'$.

Then $s_a, s_b \in S'$, since $N(s_a) \setminus \{a\}$ is a clique, as a has no neighbours in $N(s_a)$ (by assumption (69.1)) and as G is claw-free — similarly for s_b. Moreover:

Lemma 69.1β. *Each vertex $s \in S$ having at least three vertices in S at distance two, belongs to S'.*

Proof. Since $s_a, s_b \in S'$, we may assume that $s \neq s_a, s_b$. Let $G' = (N(s), F)$ be the subgraph of G with

(69.6) $\qquad F := \{uv \in E \mid u, v \in N(s), u \not\sim v\}$.

Then

(69.7) $\qquad$ each component of G' induces a clique of G.

Suppose not. Let $P = (v_0, v_1, \ldots, v_k)$ be a shortest path in G' with $v_0v_k \notin E$. If $k = 2$, then $v_0 \not\sim v_1 \not\sim v_2$, and hence v_1 has a neighbour $t \in S$ which is not a neighbour of v_0 or v_2. But then v_1 is adjacent to the pairwise nonadjacent t, v_0, v_2, contradicting the claw-freeness of G.

If $k = 3$, then as P is shortest, $v_0v_2, v_1v_3 \in E \setminus F$. So $v_0 \sim v_2$ and $v_1 \sim v_3$. Choose a vertex p with $p \not\sim v_0$ and $p \not\sim v_1$. (This is possible since $N(s)$ contains at least three similarity classes.) Then p has a neighbour t in S which is not a neighbour of any of v_0, v_1, v_2, v_3. Since $N(s)$ contains no three pairwise nonadjacent vertices (as G is claw-free), we know that $v_0p \in E$ or $v_3p \in E$. By symmetry, we can assume that $v_0p \in E$, and hence $v_0p \in F$. Then, by the minimality of k, we know successively that $v_1p \in F$, $v_2p \in F$, and $v_3p \in F$. But then v_0p and pv_3 are in F, and hence, by the minimality of k, $v_0v_3 \in E$.

If $k \geq 4$, then $v_0v_2, v_0v_3 \in E$, hence (since $v_2 \not\sim v_3$) $v_0v_2 \in F$ or $v_0v_3 \in F$, contradicting the minimality of k. This proves (69.7).

Since G is claw-free, G' has at least one component, X say, that intersects at least two of the similarity classes. If G' has at most two components, or if X contains all but at most one similarity class, we are done, taking $Y := N(s) \setminus X$. If G' has at least three components and $N(s) \setminus X$ intersects at least two similarity classes, then G' has two other components Y, Z for which there exist $x \in X$, $y \in Y$, and $z \in Z$ with $x \not\sim y \not\sim z \not\sim x$, as one easily checks[27]. But then s is adjacent to the three pairwise nonadjacent vertices x, y, z, contradicting the claw-freeness of G. ∎

[27] Let $y \in N(s) \setminus X$ be such that there exist $x', x'' \in X$ with $y \not\sim x' \not\sim x'' \not\sim y$. Let Y be the component of G' containing y. Let Z be a third component, if possible containing

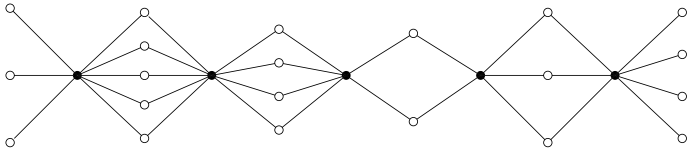

Figure 69.1
A typical bone

Now consider the subgraph

(69.8) $\qquad (V \setminus S', \delta(S''))$

of G. It is a bipartite graph, with colour classes S'' and $V \setminus S$. We call each component of this graph a *bone*. (A typical bone is depicted in Figure 69.1.) By Lemma 69.1β, each $s \in S''$ has at most two vertices in S at distance two. Hence any bone B consists of a series of vertices $s_1, \ldots, s_k$ in S'', together with disjoint nonempty sets $V_0, V_1, \ldots, V_k$ of vertices such that s_i is incident with each vertex in $V_{i-1} \cup V_i$ for each $i = 1, \ldots, k$. Moreover, B has two neighbours in S', say s and t, where s is adjacent to all vertices in V_0 and t is adjacent to all vertices in V_k. (It might be that $s = t$.) The degenerate case is that $k = 0$, where B is a singleton vertex in $V \setminus S$ with two neighbours in S'.

The relevance of bones is that if we leave out from any S-augmenting path the vertices that belong to S', we are left with a number of subpaths, each of which is an S''-augmenting path contained in some bone. So in constructing or analyzing an S-augmenting path, we can decompose it into S''-augmenting paths, glued together at vertices in S'. Here the classes of the vertices in S' come in, since the ends of the two subpaths glued together at $s \in S'$ should belong to different classes of s. This motivates the following graph H (called the *Edmonds graph* by Minty [1980])[28].

H has vertex set

(69.9) $\qquad \{(s, X) \mid s \in S',\ X \text{ class of } s\} \setminus \{(s_a, \{a\}), (s_b, \{b\})\}$

and the following edges:

(69.10) $\qquad$ (i) $\{(s, X), (s, Y)\}$ for $s \in S' \setminus \{s_a, s_b\}$ and X, Y the classes of s;

a vertex nonsimilar to y. Then, if Z contains a vertex $z \not\sim y$, we can take for x one of x', x''. If Z contains no such vertex, let $z \in Z$. Then Y contains a vertex $y' \not\sim z$. As $z \not\sim x'$ and $z \not\sim x''$, we are done again.

[28] We note that in constructing H we could restrict S' to those vertices in S that have at least 3 vertices in S at distance two, together with s_a and s_b. However, for the extension to the weighted case, we need S' as defined above (namely, by being splittable).

(ii) $\{(s,X),(t,Y)\}$ for vertices $(s,X),(t,Y)$ of H such that there exists an S''-augmenting $X-Y$ path P.

So the path P is contained in the bone B containing x and y for some $x \in X$ and some $y \in Y$. Its existence can be checked as follows. Let $V_0, V_1, \ldots, V_k$ be as above. Make the digraph D on $V_0 \cup V_1 \cup \ldots \cup V_k$ with an arc from $u \in V_{i-1}$ to $v \in V_i$ if $uv \notin E$ (for $i = 1, \ldots, k$). Then a directed $X-Y$ path in D gives a path P as required, and conversely.

Let M be the matching of edges in (69.10)(i). So M covers all vertices of H, except the vertices $(s_a, N(s_a) \setminus \{a\})$ and $(s_b, N(s_b) \setminus \{b\})$. Then (under the assumptions (69.1)):

Lemma 69.1γ. *G has an S-augmenting path $\Longleftrightarrow$ H has an M-augmenting path. We can obtain one from the other in polynomial time.*

Proof. Let $P = (v_0, s_1, v_1, \ldots, s_k, v_k)$ be an S-augmenting path in G, with $v_0 = a$ and $v_k = b$. Let $s_{i_1}, \ldots, s_{i_t}$ be those vertices in P that belong to S' (in order). So $i_1 = 1$ and $i_t = k$. For $j = 1, \ldots, t$, let X_j and Y_j be the classes of s_{i_j} that contain $v_{i_j - 1}$ and v_{i_j}, respectively. Then $X_j \neq Y_j$, since v_{i_j-1} and v_{i_j} are nonsimilar and nonadjacent. Moreover, the subpath of P between any two s_{i_j} and $s_{i_{j+1}}$ forms an S''-augmenting $Y_j - X_{j+1}$ path. Hence

(69.11) $$((s_{i_1}, Y_1), (s_{i_2}, X_2), (s_{i_2}, Y_2), \ldots, (s_{i_{t-1}}, X_{t-1}), (s_{i_{t-1}}, Y_{t-1}), (s_{i_t}, X_t))$$

is an M-augmenting path in H.

We can reverse this construction. Indeed, any M-augmenting path Q yields an S-alternating $a-b$ walk P in G, by inserting appropriate S''-augmenting paths.

In fact, P is a path. For suppose that P traverses some vertex u of G more than once. Then u belongs to two of the inserted paths. Necessarily, they belong to the same bone B. Hence B has a neighbour in S' that is traversed more than once. But then Q traverses some matching edge more than once, a contradiction.

So P is a path. Moreover, any two vertices at distance two in P are nonadjacent, by construction of P. So P is S-augmenting, by Lemma 69.1α. ∎

Concluding, we have obtained the result of Minty [1980] and Sbihi [1980]:

Theorem 69.1. *A maximum-size stable set in a claw-free graph can be found in polynomial time.*

Proof. From Lemma 69.1γ, since finding an M-augmenting path in H is equivalent to finding a perfect matching in M. The latter problem is polynomial-time solvable by Corollary 24.4a. ∎

69.3. Maximum-weight stable set in a claw-free graph

There is an obvious way of extending the above construction to the weighted case, but there is a catch in it. The idea was noted by Minty [1980], and finalized by Nakamura and Tamura [2001].

Let $G = (V, E)$ be a graph and let $w : V \to \mathbb{R}_+$ be a weight function. Call a stable set S *extreme* if it has maximum weight among all stable sets of size $|S|$. It suffices to describe an algorithm to derive from any extreme stable set S, an extreme set of size $|S| + 1$, if any (since then we can start with $S := \emptyset$, enumerate extreme stable sets of all possible sizes, and choose one of maximum weight among them).

The following observations are basic:

Lemma 69.2α. *Let $G = (V, E)$ be a claw-free graph, let $w : V \to \mathbb{R}_+$, and let S be an extreme stable set. Then:*

(69.12) (i) *each S-alternating chordless circuit satisfies $w(VC \setminus S) \leq w(VC \cap S)$;*
(ii) *if P is an S-augmenting path maximizing $w(VP \setminus S) - w(VP \cap S)$, then $S \triangle VP$ is an extreme stable set of size $|S| + 1$.*

Proof. (i) follows from the fact that $S \triangle VC$ is a stable set of size $|S|$, and hence $w(S) \geq w(S \triangle VC) = w(S) + w(VC \setminus S) - w(VC \cap S)$.

(ii) can be seen as follows. Let $\widetilde{S}$ be an extreme stable set of size $|S|+1$. The subgraph induced by $S \triangle \widetilde{S}$ has a component K with $|K \cap \widetilde{S}| > |K \cap S|$. Since G is claw-free, K has maximum degree at most 2. So K is an S-augmenting path, and hence $|K \cap \widetilde{S}| = |K \cap S| + 1$. Let $L := (S \triangle \widetilde{S}) \setminus K$. Then $S \triangle L$ and $\widetilde{S} \triangle L$ are stable sets of size $|S|$ and $|S| + 1$ respectively. Since S is extreme, $w(L \cap \widetilde{S}) \leq w(L \cap S)$. Hence $w(\widetilde{S} \triangle L) \geq w(\widetilde{S})$. So $\widetilde{S} \triangle L$ is extreme again. Hence we can assume that $L = \emptyset$. Then, since K is an S-augmenting path:

(69.13)
$$\begin{aligned} w(S \triangle VP) &= w(S) + w(VP \setminus S) - w(VP \cap S) \\ &\geq w(S) + w(K \setminus S) - w(K \cap S) = w(\widetilde{S}). \end{aligned}$$

So $S \triangle VP$ is extreme. ∎

Statement (ii) of Lemma 69.2α implies that, to find an extreme stable set of size $|S| + 1$, it suffices to find an S-augmenting path P maximizing $w(VP \setminus S) - w(VP \cap S)$. By enumerating over all pairs $a, b \in V \setminus S$, it suffices to find, for each fixed $a, b \in V \setminus S$, an S-augmenting $a - b$ path P maximizing $w(VP \setminus S) - w(VP \cap S)$ (if any). Then we can make again the assumptions (69.1), and construct the graph H. Define a weight function ω on the edges of H (following the items in (69.10)) as follows:

(69.14) (i) $\omega(\{(s, X), (s, Y)\}) := w(s)$,
(ii) $\omega(\{(s, X), (t, Y)\}) :=$ the maximum of $w(VP \setminus S'') - w(VP \cap S'')$ over all S''-augmenting $X - Y$ paths P.

The maximum in (69.14)(ii) can be found in strongly polynomial time, since it amounts to finding a longest directed $X-Y$ path in the acyclic digraph D described just after (69.10).

Now a maximum-weight perfect matching in H need not yield a maximum-weight stable set in G, as was pointed out by Nakamura and Tamura [2001], since there might exist M-alternating circuits that increase the weight of M, while they do not correspond to a chordless S-alternating circuit. However, this can be avoided by preprocessing as follows.

We can assume that for each $v \in V \setminus S$ with $v \neq a, b$:

(69.15) (i) there exist s, t, x, y such that (x, s, v, t, y) is a chordless S-alternating path and such that $N(x) \cap N(y) \cap S = \emptyset$;
(ii) there exist $s, t \in S'$ and classes X of s and Y of t such that there exists an S''-augmenting $X-Y$ path and such that each S''-augmenting $X-Y$ path P attaining the maximum in (69.14)(ii), traverses v.

Otherwise v is on no maximum-weight S-augmenting path, and hence we can delete v. The conditions (69.15) can be tested in strongly polynomial time (for (ii) using digraph D). Hence the deletions take strongly polynomial time only.

Fix for each edge e of H in (69.14)(ii), a path P_e attaining the maximum. Then we can transform any M-alternating path or circuit to an S-alternating walk or closed walk, by replacing each such edge e by P_e. We call this the *corresponding* walk or closed walk in G.

Lemma 69.2β. *Under the assumptions* (69.15)*, each M-alternating circuit C in H satisfies $\omega(EC \setminus M) \leq \omega(EC \cap M)$.*

Proof. Suppose not. Choose C maximizing $\omega(EC \setminus M) - \omega(EC \cap M)$. Let Γ be the corresponding S-alternating closed walk in G. Then Γ is not a chordless circuit, since otherwise

(69.16) $$w(V\Gamma \setminus S) - w(V\Gamma \cap S) = \omega(EC \setminus M) - \omega(EC \cap M) > 0,$$

which contradicts (i) of Lemma 69.2α.

Since each P_e is simple and chordless, it follows that $EC \setminus M$ contains distinct edges e, f for which there exist $u \in VP_e$ and $v \in VP_f$ with $u = v$ or $uv \in E$. This implies that C has length 4, and that e and f are the only edges in $EC \setminus M$. So P_e and P_f are in the same bone B. Let s and t be the neighbours of B in S'. Let s have classes Y, Z and t have classes W, X such that P_e connects Y and W and P_f connects Z and X. Write

(69.17) $$P_e = (u_0, s_1, u_1, \ldots, s_k, u_k) \text{ and } P_f = (v_0, s_1, v_1, \ldots, s_k, v_k)$$

for some $k \geq 0$ and $s_1, \ldots, s_k \in S''$, where $u_0 \in Y$, $u_k \in W$, $v_0 \in Z$, $v_k \in X$. We define $s_0 := s$ and $s_{k+1} := t$. Now

(69.18) for each $i = 1, \ldots, k$: $u_{i-1}v_i \in E$ or $v_{i-1}u_i \in E$.

Otherwise, we can 'switch' P_e and P_f at s_i to obtain the S''-augmenting paths

(69.19) $$Q := (u_0, s_1, \ldots, u_{i-1}, s_i, v_i, \ldots, s_k, v_k) \text{ and}$$
$$R := (v_0, s_1, \ldots, v_{i-1}, s_i, u_i, \ldots, s_k, u_k).$$

Hence H has edges $\{(s,Y),(t,X)\}$ and $\{(s,Z),(t,W)\}$, and

(69.20) $$\omega(\{(s,Y),(t,X)\}) + \omega(\{(s,Z),(t,W)\})$$
$$\geq \omega(\{(s,Y),(t,W)\}) + \omega(\{(s,Z),(t,X)\}).$$

By the choice of C, we have equality, and hence the paths Q and R attain the corresponding maxima in (69.14)(ii). It implies, by assumption (69.15)(ii), that u_{i-1}, v_{i-1}, u_i, and v_i are the only neighbours of s_i. Since none of u_{i-1}, v_{i-1} are adjacent to any of u_i, v_i, we have that s_i is splittable, that is, $s_i \in S'$, a contradiction. This proves (69.18).

Next

(69.21) $$u_0 v_0 \notin E \text{ and } u_k v_k \notin E.$$

For suppose that (say) $u_0 v_0 \in E$. By (69.15)(i), there exist $x, y \in V \setminus S$ such that (x, s, u_0, s_1, y) is a chordless path and such that $N(x) \cap N(y) \cap S = \emptyset$. As x is nonadjacent to u_0, and as $u_0 \in X$, we have $x \in Y$, and so (as $v_0 \in Y$) $x v_0 \in E$.

If $k = 0$, we have similarly $y v_0 \in E$. Then v_0 is adjacent to the pairwise nonadjacent x, u_0, y, a contradiction.

So $k \geq 1$. Then $y \sim u_1$ and $N(y) \cap S = \{s_1, s_2\}$. So $x s_1, x s_2 \notin E$ (since $N(x) \cap N(y) \cap S = \emptyset$). This implies $x u_1 \notin E$, since otherwise u_1 is adjacent to the pairwise nonadjacent s_1, s_2, x. Hence $v_0 u_1 \notin E$, since otherwise v_0 is adjacent to the pairwise nonadjacent x, u_0, u_1. By symmetry, also $u_0 v_1 \notin E$. This contradicts (69.18), and hence proves (69.21).

Moreover,

(69.22) there is an i with $0 \leq i \leq k$ and $u_i v_i \in E$,

as otherwise each circuit $(s_i, u_i, s_{i+1}, v_i, s_i)$ is S-alternating and chordless, which implies $w(u_i) + w(v_i) - w(s_i) - w(s_{i+1}) \leq 0$ by Lemma 69.2α. This gives the contradiction

(69.23) $$0 < \omega(EC \setminus M) - \omega(EC \cap M)$$
$$= w(VP_e \setminus S'') - w(VP_e \cap S'') + w(VP_f \setminus S'') - w(VP_f \cap S'')$$
$$- w(s) - w(t) = \sum_{i=0}^{k} (w(u_i) + w(v_i) - w(s_i) - w(s_{i+1})) \leq 0,$$

proving (69.22).

Now let i be the smallest index with $u_i v_i \in E$. By (69.21), we know $1 \leq i \leq k-1$. By (69.18) and by symmetry we can assume that $v_i u_{i+1} \in E$. Since s_i is adjacent to u_{i-1}, v_{i-1}, and v_i, and since $u_{i-1} v_{i-1} \notin E$ and $v_{i-1} v_i \notin E$, we know $u_{i-1} v_i \in E$. Then v_i is adjacent to the pairwise nonadjacent u_{i-1}, u_i, and u_{i+1}, a contradiction. ∎

Now find a maximum-weight perfect matching N in H, with the maximum-weight perfect matching algorithm (Chapter 26). By Lemma 69.2β, we can assume that $N = M \triangle EQ$ for some M-augmenting path Q in H (since if $N \triangle M$ contains a circuit C, then $N \triangle EC$ again is a maximum-weight perfect matching in H). Then Q maximizes $\omega(EQ \setminus M) - \omega(EQ \cap M)$ over all M-augmenting paths. Let P be the corresponding path in G. Then P is an S-augmenting path in G maximizing $w(VP \setminus S) - w(VP \cap S)$, as required.

We conclude:

Theorem 69.2. *A maximum-weight stable set in a claw-free graph can be found in strongly polynomial time.*

Proof. See above. ∎

69.4. Further results and notes

69.4a. On the stable set polytope of a claw-free graph

The polynomial-time solvability of the maximum-weight stable set problem for claw-free graphs implies that the optimization problem over the stable set polytope $P_{\text{stable set}}(G)$ of a claw-free graph $G = (V, E)$ is polynomial-time solvable. Hence also the separation problem is polynomial-time solvable (with the ellipsoid method (Theorem 5.10)). It implies (cf. Theorem 5.11) that, given a vector $x \in \mathbb{Q}^V$, one can decide in strongly polynomial time if x belongs to $P_{\text{stable set}}(G)$, and if not, find a facet-inducing inequality violated by x.

So in this respect, the stable set polytope of a claw-free graph is under control. However, no explicit description is known of a system that determines $P_{\text{stable set}}(G)$. As we saw in Section 25.2, such a description is known for the special case where G is the line graph of some graph H — that is, for the matching polytope of H. In this special case, each facet can be described by an inequality with coefficients in $\{0, 1\}$.

The latter fact does not generalize to claw-free graphs. Giles and Trotter [1981] showed that for each $k \in \mathbb{Z}_+$ there exists a claw-free graph such that its stable set polytope has a facet that is described by a linear inequality with coefficients k and $k + 1$. (This refutes a conjecture of Sbihi [1978].)

Galluccio and Sassano [1997] characterized those facets of the stable set polytope of a claw-free graph that can be described by an inequality with all coefficients in $\{0, 1\}$ (the *rank facets*).

More on facets of the stable set polytope of special classes of claw-free graphs can be found in Ben Rebea [1981] and Oriolo [2002] (for graphs such that for each vertex v, the graph induced by $N(v)$ is the complement of a bipartite graph) and Pulleyblank and Shepherd [1993] (for claw-free graphs such that no vertex has three pairwise nonadjacent vertices at distance two).

69.4b. Further notes

Minty [1980] observed that finding a maximum-size stable set in a graph without induced $K_{1,4}$ is NP-complete. This follows from the fact that the 3-dimensional assignment problem can be reduced to it (its intersection graph has no induced $K_{1,4}$).

Poljak [1974] showed that finding a maximum-size stable set in a triangle-free graph is NP-complete. It implies that finding a maximum-size clique in a claw-free graph is NP-complete.

Shepherd [1995] characterized the stable set polytope of *near-bipartite graphs*, that is, graphs with $G - N(v)$ bipartite for each $v \in VG$. They include the complements of line graphs, and the complement of any near-bipartite graph is claw-free.

Ben Rebea [1981] showed that each connected claw-free graph G with $\alpha(G) \geq 3$ not containing an induced C_5, contains no odd antihole. This was extended by Fouquet [1993] who showed that each connected claw-free graph G with $\alpha(G) \geq 4$ contains no odd antihole with at least 7 vertices.

Lovász and Plummer [1986] gave a variant of Minty's reduction of the maximum-size stable set problem in claw-free graphs to the maximum-size matching problem.

Beineke [1970] (for simple graphs), N. Robertson (unpublished), Hemminger [1971] (abstract only), and Bermond and Meyer [1973] characterized line graphs by means of forbidden induced subgraphs (six graphs next to $K_{1,3}$).

The polynomial-time solvability of the weighted stable set problem for claw-free graphs was extended to claw-free bidirected graphs by Nakamura and Tamura [1998]. A linear-time algorithm for 'triangulated' bidirected graphs was given by Nakamura and Tamura [2000].

Part VII

Multiflows and Disjoint Paths

Part VII: Multiflows and Disjoint Paths

The problem of finding a maximum flow from one source s to one sink t in a directed graph is highly tractable. There is a very efficient algorithm, which outputs an integer maximum flow if all capacities are integer. Moreover, the maximum flow value is equal to the minimum capacity of a cut separating s and t. If all capacities are equal to 1, the problem reduces to finding arc-disjoint paths. Some direct transformations give similar results for vertex capacities, for vertex-disjoint paths, and for undirected graphs.

Often in practice however, one is not interested in connecting only one pair of source and sink by a flow or by paths, but several pairs of sources and sinks simultaneously. One may think of a large communication or transportation network, where several messages or goods must be transmitted all at the same time over the same network, between different pairs of terminals. Also railway circulation with different types of rolling stock gives a multicommodity flow problem. A recent application is the design of *very large-scale integrated* (VLSI) circuits, where several pairs of pins must be interconnected by wires on a chip, in such a way that the wires follow a given grid and that the wires connecting different pairs of pins do not intersect each other. This leads to the area of multicommodity flows (briefly: multiflows) and disjoint paths. Most polyhedral and polynomial-time methods for 1-commodity flows and paths do not extend to multicommodity flows and paths. Yet a number of cases can be solved efficiently, in particular when the terminals have a special structure or when the graph is planar or, more generally, can be embedded in a specific surface.

Chapters:

Chapter 70

Multiflows and disjoint paths

We discuss basic, general facts and terminology on multiflows and disjoint paths. In particular, we study general interrelations between fractional multiflows, integer multiflows, disjoint paths, the 'cut condition', and the 'Euler condition'.

70.1. Directed multiflow problems

Given two directed graphs, a *supply digraph* $D = (V, A)$ and a *demand digraph* $H = (T, R)$ with $T \subseteq V$, a *multiflow* is a function f on R where f_r is an $s-t$ flow in D for each $r = (s, t) \in R$.[1] In this context, each pair in R is called a *net*, and each vertex covered by R is called a *terminal*.

For $k := |R|$, we also speak of a *k-commodity flow*. Occasionally, we will list the nets as $(s_1, t_1), \ldots, (s_k, t_k)$. Then for $r = (s_i, t_i)$ we denote f_r also by f_i. The indices $1, \ldots, k$ are called the *commodities*.

The *value* of f is the function $\phi : R \to \mathbb{R}_+$ where ϕ_r is the value of f_r. The *total value*, or (if no confusion may arise) just the *value*, is $\sum_{r \in R} \phi_r$.

Given a 'capacity' function $c : A \to \mathbb{R}_+$, we say that a multiflow f is *subject to* c if

(70.1) $$\sum_{r \in R} f_r(a) \leq c(a)$$

for each arc a.

The *multiflow problem* or *k-commodity flow problem* (for $k := |R|$) is:

(70.2) given: a supply digraph $D = (V, A)$, a demand digraph $H = (T, R)$ with $T \subseteq V$, a capacity function $c : A \to \mathbb{R}_+$, and a demand function $d : R \to \mathbb{R}_+$,
find: a multiflow subject to c of value d.

Given c and d, a multiflow subject to c of value d is called a *feasible multiflow*, or just a *multiflow* if no confusion is expected to arise. We call the problem *feasible* if there exists a feasible multiflow.

[1] Throughout, we use the terms 'multicommodity flow' and 'multiflow' as synonyms.

If we require each f_r to be an integer flow, the problem is called the *integer multiflow problem* or the *integer k-commodity flow problem*. Similarly for *half-integer*, *quarter-integer*, etc. For clarity, we sometimes add the adjective *fractional* if no integrality is required.

Related is the *maximum-value multiflow problem* or *maximum-value k-commodity flow problem*:

(70.3) given: a supply digraph $D = (V, A)$, a demand digraph $H = (T, R)$ with $T \subseteq V$, and a capacity function $c : A \to \mathbb{R}_+$,
find: a multiflow subject to c, of maximum total value.

Again we add *integer* (*half-integer*, etc) if we require the f_r to be integer (half-integer, etc.).

We can reduce a multiflow problem with demands $d_1, \ldots, d_k$ to a maximum-value multiflow problem, by extending the graph by an arc from a new vertex s_i' to s_i of capacity d_i (for $i = 1, \ldots, k$). Then the multiflow problem in the original graph is feasible if and only if the maximization problem in the new graph, with nets (s_i', t_i), has maximum total value equal to $d_1 + \cdots + d_k$.

70.2. Undirected multiflow problems

The problems described above have a natural analogue for undirected graphs. Let be given two undirected graphs, a *supply graph* $G = (V, E)$ and a *demand graph* $H = (T, R)$ with $T \subseteq V$. Again, each pair in R is called a *net*, and each vertex covered by R is called a *terminal*.

For $s, t \in V$, a function $f : E \to \mathbb{R}_+$ is called an *$s - t$ flow* if there exists an orientation (V, A) of G such that f is an $s - t$ flow in D.

A *multiflow* is a function f on R such that f_r is an $s - t$ flow for each $r = st \in R$. For $k := |R|$, the multiflow is also called a *k-commodity flow*. Again, occasionally we will list the nets as $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$.

The *value* of a multiflow f is the function $\phi : R \to \mathbb{R}_+$ where ϕ_r is the value of f_r. The *total value*, or just the *value*, is $\sum_{r \in R} \phi_r$.

Given a capacity function $c : E \to \mathbb{R}_+$, we say that a multiflow f is *subject to c* if

(70.4) $$\sum_{r \in R} f_r(e) \leq c(e)$$

for each edge e. Note that generally for each $r = st \in R$, there is a different orientation D_r of G that makes f_r into an $s - t$ flow in D_r. So in (70.4), the sum of the flows through both orientations of a given edge e are bounded above by $c(e)$.

In this way we obtain the *undirected multiflow problem* or *undirected k-commodity flow problem*, and the *undirected maximum-value multiflow problem* or *undirected maximum-value k-commodity flow problem*. Again, we add *integer* (*half-integer*, etc.) if we require the f_r to be integer (half-integer, etc.) flows. We skip the adjective 'undirected' if it is clear from the context.

70.3. Disjoint paths problems

If all capacities and demands are equal to 1, the integer multiflow problem is equivalent to the *(k) arc-* or *edge-disjoint paths problem*:

(70.5) given: a directed (or undirected) graph $D = (V, A)$ and pairs $(s_1, t_1), \ldots, (s_k, t_k)$ of vertices of G,
find: arc- (or edge-)disjoint paths $P_1, \ldots, P_k$ where P_i is an $s_i - t_i$ path $(i = 1, \ldots, k)$.

For undirected graphs, the pairs s_i, t_i need not be ordered.

A *fractional solution* (*half-integer solution* respectively) of the arc- or edge-disjoint paths problem is a fractional (half-integer respectively) multiflow for all capacities and demands 1.

Related is the *(vertex-)disjoint paths problem* (or k *(vertex-)disjoint paths problem*):

(70.6) given: a (directed or undirected) graph $D = (V, A)$ and pairs $(s_1, t_1), \ldots, (s_k, t_k)$ of vertices of G,
find: vertex-disjoint paths $P_1, \ldots, P_k$ where P_i is an $s_i - t_i$ path $(i = 1, \ldots, k)$.

70.4. Reductions

Above we mentioned two versions of the multiflow problem: directed and undirected, and four versions of the disjoint paths problem: directed vertex-disjoint, directed arc-disjoint, undirected vertex-disjoint, and undirected edge-disjoint. There are a number of constructions that reduce versions among them.

First, the *undirected edge-disjoint* paths problem can be reduced to the *undirected vertex-disjoint* paths problem by replacing the graph by its line graph. Similarly, the *directed arc-disjoint* paths problem can be reduced to the *directed vertex-disjoint* paths problem by replacing the digraph by its line digraph.

Conversely, the *directed vertex-disjoint* paths problem can be reduced to the *directed arc-disjoint* paths problem by replacing each vertex

(70.7)  by  .

So far, these reductions do not maintain planarity.

The *undirected vertex-disjoint* paths problem can be reduced to the *directed vertex-disjoint* paths problem by replacing each edge

(70.8)  by  .

Trivially, this construction maintains planarity.

Finally, there is the following reduction of the *undirected edge-disjoint* paths problem to the *directed arc-disjoint* paths problem: replace each edge

(70.9) by  .

This reduction also applies to (integer, half-integer, fractional) multiflow problems. Again, this construction maintains planarity.

We represent these reductions in the following diagram, where a double arrow means a reduction maintaining planarity:

(70.10)
$$\begin{array}{ccc} \boxed{\text{undirected edge-disjoint}} & \longrightarrow & \boxed{\text{undirected vertex-disjoint}} \\ \Downarrow & & \Downarrow \\ \boxed{\text{directed arc-disjoint}} & \longleftrightarrow & \boxed{\text{directed vertex-disjoint}} \end{array}$$

Notes. These reductions maintain the set of nets and the demand values. Even, Itai, and Shamir [1975,1976] gave an interesting construction reducing the *directed arc-disjoint* paths problem to the *undirected edge-disjoint* paths problem. It reduces the directed arc-disjoint paths problem with k commodities of demands $d_1, \ldots, d_k$ in a digraph $D = (V, A)$, to the undirected edge-disjoint paths problem with k commodities of demands $d_1 + |A|, \ldots, d_k + |A|$. The construction does not maintain planarity.

70.5. Complexity of the disjoint paths problem

In Section 70.6 we shall see that the fractional multiflow problem is solvable in strongly polynomial time, since it is a linear programming problem.

The integer multiflow problem is NP-complete, even the disjoint paths problem is NP-complete, in any mode (directed/undirected, vertex/edge-disjoint), even for planar graphs. In some cases, however, the problem is polynomial-time solvable if we fix the number k of commodities. We survey the complexity results in the following table:

	directed		*undirected*	
	arc-disjoint	*vertex-disjoint*	*edge-disjoint*	*vertex-disjoint*
general	NP-complete[2]	NP-complete[2]	NP-complete[3]	NP-complete[2]
planar	NP-complete[4]	NP-complete[5]	NP-complete[4]	NP-complete[5]
		for fixed k:		
general	NP-complete[6]	NP-complete[6]	polynomial-time[7]	polynomial-time[7]
planar	?[8]	polynomial-time[9]	polynomial-time[7]	polynomial-time[7]

Complexity of the k disjoint paths problem

By the reduction described at the end of Section 70.1, the NP-completeness of the integer multiflow and disjoint paths problems implies that also the corresponding maximization problems are NP-complete.

70.6. Complexity of the fractional multiflow problem

The fractional multiflow problem can easily be described as one of solving a system of linear inequalities in the variables $f_i(a)$ for $i = 1, \ldots, k$ and $a \in A$. The constraints are the flow conservation laws and the demand constraint for each flow f_i separately, together with the capacity constraints (70.1). Therefore, the fractional multiflow problem can be solved in polynomial time with any polynomial-time linear programming algorithm. Tardos [1986] showed that the fractional multiflow problem is solvable in strongly polynomial time,

[2] D.E. Knuth, 1974 (cf. Karp [1975]), who proved the NP-completeness of the undirected vertex-disjoint version. It implies the NP-completeness of the directed vertex-disjoint case (by reduction (70.8)), which in turn implies the NP-completeness of the directed arc-disjoint version (by reduction (70.7)). Even, Itai, and Shamir [1975,1976] showed that the directed arc-disjoint paths problem is NP-complete even if the digraph is acyclic and $s_2 = \cdots = s_k$ and $t_2 = \cdots = t_k$.

[3] Even, Itai, and Shamir [1975,1976] — NP-complete even if $|\{\{s_1, t_1\}, \ldots, \{s_k, t_k\}\}| = 2$; equivalently, the integer 2-commodity flow problem is NP-complete even if all capacities are 1.

[4] Kramer and van Leeuwen [1984], who proved the NP-completeness of the planar undirected edge-disjoint paths problem, implying the NP-completeness of the planar directed arc-disjoint paths problem, by reduction (70.9). Kramer and van Leeuwen showed NP-completeness even if the graphs are restricted to rectangular grids.

[5] Lynch [1975], who proved the NP-completeness of the planar undirected vertex-disjoint paths problem. It implies the NP-completeness of the planar directed vertex-disjoint paths problem, by reduction (70.8). The problems remain NP-complete for cubic planar graphs (Richards [1984]), and also if the graph together with the nets is planar and cubic (Middendorf and Pfeiffer [1993]).

[6] Fortune, Hopcroft, and Wyllie [1980] — NP-complete even for $k = 2$ opposite nets (s, t) and (t, s).

[7] Robertson and Seymour [1995], who proved the polynomial-time solvability of the k vertex-disjoint paths problem in undirected graphs, for any fixed k. By replacing a graph by its line graph, it implies the polynomial-time solvability of the k edge-disjoint paths problem in undirected graphs, for any fixed k.

[8] unknown also if $k = 2$ and the two nets are opposite.

[9] Schrijver [1994a].

by proving that any linear programming problem with $\{0, \pm 1\}$ constraint matrix is solvable in strongly polynomial time.

Onaga [1970] gave the following good characterization for the feasibility of the fractional multiflow problem, which can be derived (as Iri [1971] observed) from Farkas' lemma ($\mathrm{dist}_l(s,t)$ denotes the length of a shortest $s-t$ path with respect to a length function l):

Theorem 70.1. *The (directed or undirected) fractional multiflow problem* (70.2) *has a solution if and only if*

$$(70.11) \qquad \sum_{i=1}^{k} d_i \cdot \mathrm{dist}_l(s_i, t_i) \leq \sum_{a \in A} l(a)c(a)$$

for each length function $l : A \to \mathbb{Z}_+$.

Proof. For $i = 1, \ldots, k$, let $\mathcal{P}_i$ denote the collection of arc sets of $s_i - t_i$ paths. Then there is a feasible multiflow if and only if there exist $\lambda_{i,P} \geq 0$ (for $i = 1, \ldots, k$ and $P \in \mathcal{P}_i$), such that

$$(70.12) \qquad \begin{aligned} &\sum_{P \in \mathcal{P}_i} \lambda_{i,P} = d_i && \text{for } i = 1, \ldots, k, \\ &\sum_{i=1}^{k} \sum_{P \in \mathcal{P}_i} \lambda_{i,P} \chi^P(a) \leq c(a) && \text{for } a \in A. \end{aligned}$$

By Farkas' lemma, this is equivalent to: for all $b_1, \ldots, b_k \in \mathbb{R}$ and $l : A \to \mathbb{R}_+$, if

$$(70.13) \qquad b_i \leq \sum_{a \in P} l(a) \text{ for } i = 1, \ldots, k \text{ and } P \in \mathcal{P}_i,$$

then

$$(70.14) \qquad \sum_{i=1}^{k} b_i d_i \leq \sum_{a \in A} l(a)c(a).$$

Now we may assume that each b_i is chosen maximal such that it satisfies (70.13). Then b_i is equal to the minimum of $\sum_{a \in P} l(a)$ taken over all $P \in \mathcal{P}_i$, that is, to $\mathrm{dist}_l(s_i, t_i)$. Hence the condition is equivalent to (70.11). ∎

(Onaga and Kakusho [1971] gave an alternative proof. If we restrict l to $\{0,1\}$-valued functions, we obtain a necessary condition (a 'multicut condition'), as was observed by Naniwada [1969], who raised the question if the above theorem may hold.)

A min-max relation for the maximum-value multiflow problem can be derived similarly from LP-duality (cf. Lomonosov [1978a]):

Theorem 70.2. *Let $D = (V, A)$ be a directed or undirected graph, let $(s_1, t_1), \ldots, (s_k, t_k)$ be nets, and let $c : A \to \mathbb{R}_+$ be a capacity function. Then* *the maximum total value of a multiflow subject to c is equal to the minimum value of $\sum_{a \in A} l(a)c(a)$ taken over all $l : A \to \mathbb{R}_+$ satisfying*

(70.15) $\quad \operatorname{dist}_l(s_i, t_i) \geq 1$ *for each* $i = 1, \ldots, k$.

Proof. Let $\mathcal{P}$ denote the collection of arc sets of paths running from s_i to t_i for some $i = 1, \ldots, k$. Then the maximum total value of a multiflow is equal to the maximum of $\sum_{P \in \mathcal{P}} \lambda_P$, where $\lambda_P \geq 0$ for $P \in \mathcal{P}$, such that

(70.16) $$\sum_{P \in \mathcal{P}} \lambda_P \chi^P(a) \leq c(a) \text{ for } a \in A.$$

By LP-duality, this value is equal to the minimum value of $\sum_{a \in A} l(a)c(a)$ where $l : A \to \mathbb{R}_+$ such that

(70.17) $$\sum_{a \in P} l(a) \geq 1 \text{ for each } P \in \mathcal{P}.$$

As (70.17) is equivalent to (70.15), we have the theorem. ∎

70.7. The cut condition for directed graphs

In Theorem 70.1 we saw a good characterization for the feasibility of the fractional multiflow problem. In some cases, it can be replaced by a weaker condition, the *cut condition*:

(70.18) $$c(\delta_A^{\text{out}}(U)) \geq d(\delta_R^{\text{out}}(U)) \text{ for each } U \subseteq V.$$

The cut condition indeed is a direct consequence of condition (70.14) described in Theorem 70.1. For define $l(a) := 1$ if $a \in \delta^{\text{out}}(U)$, and $l(a) := 0$ otherwise. Then (70.11) implies:

(70.19) $$c(\delta_A^{\text{out}}(U)) = \sum_{a \in A} l(a)c(a) \geq \sum_{i=1}^{k} d_i \cdot \operatorname{dist}_l(s_i, t_i) \geq d(\delta_R^{\text{out}}(U)).$$

However, the cut condition is in general not sufficient, even not in the two simple cases given in Figure 70.1.

For directed graphs, the cut condition is known to be sufficient for the existence of a fractional multiflow only if $s_1 = \cdots = s_k$ or $t_1 = \cdots = t_k$ (this follows from the (one-commodity) max-flow min-cut theorem). In a sense, this is the only case:

Theorem 70.3. *Let $H = (T, R)$ be a demand digraph, where R contains no loops. Then for each supply digraph $D = (V, A)$ with $V \supseteq T$, the cut condition* (70.18) *is sufficient for the existence of a fractional multiflow if and only if all arcs of H have a common head, or they all have a common tail.*

Proof. Let $R = \{(s_1, t_1), \ldots, (s_k, t_k)\}$.

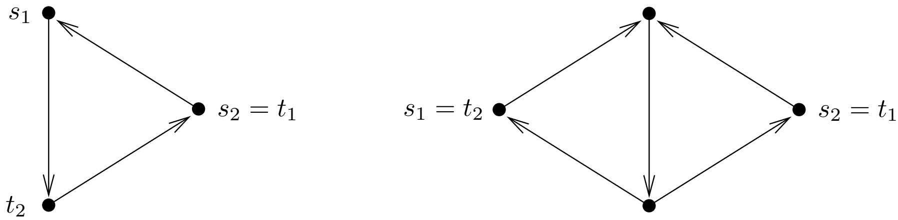

Figure 70.1
Two digraphs where the cut condition holds, but no fractional multiflow exists (taking all capacities and demands equal to 1). The nonexistence of a fractional multiflow can be shown with Theorem 70.1, by taking $l(a) := 1$ for each arc a.

To see sufficiency, by symmetry we can assume that $s_1 = \cdots = s_k$. Let $s := s_1$, and let t be a new vertex. For $i = 1, \ldots, k$, add a new arc (t_i, t), with capacity d_i. Then, by the max-flow min-cut theorem, the cut condition implies that the extended graph has an $s-t$ flow of value $d_1+\cdots+d_k$, subject to the capacity. Restricted to the original graph, we can decompose the flow into a feasible k-commodity flow of values $d_1, \ldots, d_k$.

To see necessity, if the condition is not met, then there exist nets (s_i, t_i) and (s_j, t_j) with $s_i \neq s_j$ and $t_i \neq t_j$. We can assume that $i = 1$, $j = 2$. Then $\{s_1, t_2\}$ is disjoint from $\{s_2, t_1\}$, and then the second example in Figure 70.1 can be adapted to obtain an example with net set R, and where the cut condition holds but no fractional multiflow exists. ∎

As for maximizing the total value of a multiflow, in a directed triangle, with as nets the opposites of all arcs and all capacities equal to 1, the maximum total value is $\frac{3}{2}$, while the minimum capacity of an arc set disconnecting all nets is 2.

70.8. The cut condition for undirected graphs

Similarly, one can formulate the cut condition in the undirected case:

(70.20) $\quad c(\delta_E(U)) \geq d(\delta_R(U))$ for each $U \subseteq V$.

In the special case of the edge-disjoint paths problem (where all capacities and demands are equal to 1), the cut condition amounts to:

(70.21) $\quad d_E(U) \geq d_R(U)$ for each $U \subseteq V$.

As was observed by Tang [1965], in the undirected case the cut condition is equivalent to the 'disconnecting set condition':

(70.22) $\quad c(F) \geq d(\mathrm{disc}_R(F))$ for each $F \subseteq E$, where $\mathrm{disc}_R(F)$ denotes the family of nets st where s and t are in different components of $G - F$.

Indeed, trivially, the cut condition is implied by (70.22). To see the reverse implication, let $\mathcal{K}$ be the set of components of $G-F$. Then the cut condition implies

$$(70.23)\qquad c(F) \geq \tfrac{1}{2}\sum_{K\in\mathcal{K}} c(\delta_E(K)) \geq \tfrac{1}{2}\sum_{K\in\mathcal{K}} d(\delta_R(K)) = d(\mathrm{disc}_R(F)),$$

which is (70.22).

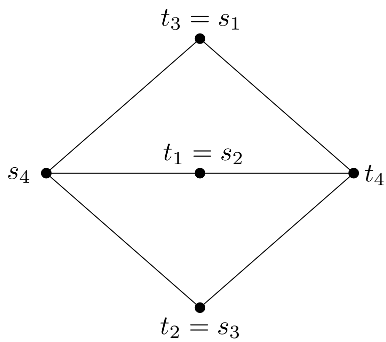

Figure 70.2
An undirected graph where the cut condition holds, but no fractional multiflow exists (taking all capacities and demands equal to 1). This last can be shown with Theorem 70.1, by taking $l(e) := 1$ for each edge e.

Figure 70.2 shows that, also in the undirected case, the cut condition is not sufficient[10]. Hu [1963] showed that, in the undirected case, if $k = 2$, then the cut condition is sufficient for the existence of a fractional multiflow. This is *Hu's 2-commodity flow theorem* (Theorem 71.1b). In Section 70.11, we will list more cases where the cut condition is sufficient for the existence of a fractional multiflow.

Hu's 2-commodity flow theorem implies the *max-biflow min-cut theorem* (Corollary 71.1d): in the undirected case with $k = 2$, the maximum value of a 2-commodity flow is equal to the minimum capacity of a cut separating both s_1 and t_1 and s_2 and t_2.

[10] Hakimi [1962b] and Tang [1962] claimed erroneously to give proofs that the cut condition is sufficient for any number k of commodities. According to Hu [1963], a counterexample was first found by L.R. Ford, Jr.

A strengthening of the cut condition that Hu [1964] claimed to be necessary (and conjectured to be sufficient) for the existence of a fractional multiflow, was shown to be not necessary by Tang [1965].

A similar ‘maximum-triflow min-cut theorem’ does not hold, even not if the three nets form a triangle: take $K_{1,3}$ and all pairs of end vertices as nets, all capacities being 1; then the minimum number of edges disconnecting each commodity is equal to 2, while the maximum total value of a fractional multiflow is equal to $\frac{3}{2}$ (example of Ford and Fulkerson [1954,1956b]).

Anyway, if the nets form a triangle, finding a minimum-size set of edges disconnecting each net, is NP-complete (Dahlhaus, Johnson, Papadimitriou, Seymour, and Yannakakis [1992,1994]).

It will be useful to note that the cut condition only needs to be required for cuts with both sides connected (if G is connected):

Theorem 70.4. *Let $G = (V, E)$ an $H = (T, R)$ be a supply and demand graph, with G connected. Let $c : E \to \mathbb{R}_+$ and $d : R \to \mathbb{R}_+$. If the cut condition* (70.20) *is violated, then it is violated by some $U \subseteq V$ for which both $G[U]$ and $G[V \setminus U]$ are connected.*

Proof. Let U violate the cut condition; that is, $c(\delta_E(U)) < d(\delta_R(U))$. Choose U such that $|\delta_E(U)|$ is as small as possible. We show that $G[U]$ and $G[V \setminus U]$ are connected. By symmetry, it suffices to show that $G[U]$ is connected. Let $K_1, \ldots, K_t$ be the components of $G[U]$. Suppose $t \geq 2$. Then

(70.24) $$\sum_{j=1}^{t} c(\delta_E(K_j)) = c(\delta_E(U)) < d(\delta_R(U)) \leq \sum_{j=1}^{t} d(\delta_R(K_j)).$$

So $c(\delta_E(K_j)) < d(\delta_R(K_j))$ for at least one j. As $|\delta_E(K_j)| < |\delta_E(U)|$ (by the connectivity of G), this contradicts the minimality of $|\delta_E(U)|$. ∎

Notes. Călinescu, Fernandes, and Reed [1998] gave a polynomial-time approximation algorithm for finding a minimum multicut in an unweighted graph of bounded degree and bounded ‘tree-width’. More on the minimum multicut problem can be found in Klein, Agrawal, Ravi, and Rao [1990], Garg, Vazirani, and Yannakakis [1993a,1993b,1996,1997], Tardos and Vazirani [1993], Klein, Rao, Agrawal, and Ravi [1995], and Naor and Zosin [1997,2001].

70.9. Relations between fractional, half-integer, and integer solutions

There are the following implications for the multiflow problem:

(70.25) $\exists$ integer multiflow $\Longrightarrow$ $\exists$ half-integer multiflow $\Longrightarrow$ $\exists$ fractional multiflow.

As the existence of a fractional multiflow can be tested in strongly polynomial time, it yields a useful necessary condition for the existence of an integer multiflow.

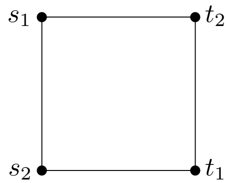

Figure 70.3
There is a half-integer, but no integer multiflow (where all capacities and demands are 1).

As has been discussed in Chapter 10, for 1-commodity flow problems with integer capacities, we can turn all implications around in (70.25). For general multiflow problems, however, this is not the case. For undirected graphs, Figure 70.3 shows that a half-integer multiflow does not imply the existence of an integer multiflow (for integer capacities and demands). Middendorf and Pfeiffer [1993] showed that the half-integer multiflow problem in undirected graphs is NP-complete, even if all capacities and demands are equal to 1.

For undirected 2-commodity flows, Hu [1963] showed that the existence of a fractional multiflow implies the existence of a half-integer multiflow, if all capacities and demands are integer. Figure 70.3 shows that an integer multiflow need not exist. In fact, the undirected integer 2-commodity flow problem is NP-complete (Even, Itai, and Shamir [1975,1976]).

Hu's theorem prompted Jewell [1967] to conjecture that if a k-commodity flow problem with integer capacities and demands has a fractional solution, then it has a $1/p$-integer solution for some $p \leq k$. More strongly, Seymour [1981d] conjectured that a fractional multiflow implies the existence of a half-integer multiflow (for integer capacities and demands).

This was disproved by a series of examples of Lomonosov [1985], which even imply that there is no integer p such that each undirected 3-commodity flow problem has a $1/p$-integer solution when it has a fractional solution (for integer capacities and demands). A simplified version of Lomonosov's example is given in Figure 70.4. It consists of an integer-capacitated 3-commodity flow problem with demands 1, $2k$, and $2k$, such that each feasible multiflow has $\frac{1}{2k}$ among its values.

A simpler counterexample to Seymour's conjecture was given by Pfeiffer [1990] — see Figure 70.5, showing that a quarter-integer multiflow need not imply the existence of a half-integer multiflow (for integer capacities and demands).

With construction (70.9) we obtain similar results for directed graphs.

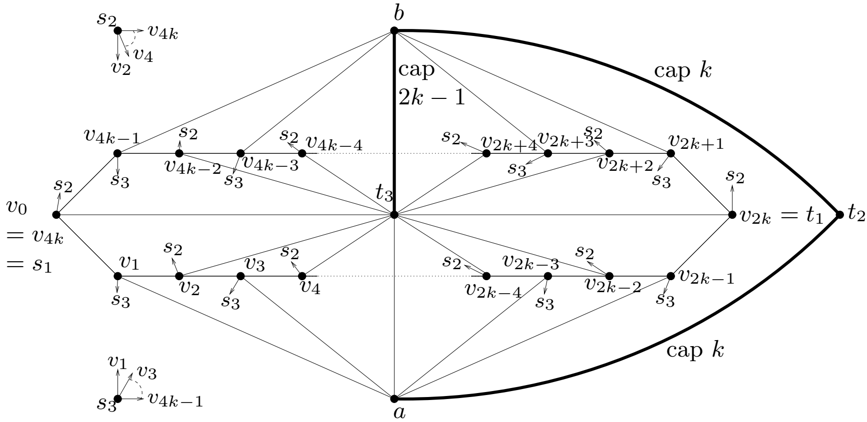

Figure 70.4

A feasible integer-capacitated 3-commodity flow problem with demands 1, $2k$, and $2k$, such that each feasible multiflow has $\frac{1}{2k}$ among its values. The nets are the pairs s_1t_1, s_2t_2, and s_3t_3. The graph consists of a circuit C of length $4k$, with vertices $v_1, \ldots, v_{4k}$ (in order), vertices s_2 and t_3 adjacent to each v_i with i even, a vertex s_3 adjacent to each v_i with i odd, a vertex a adjacent to t_3 and to each v_i with i odd and $0 < i < 2k$, a vertex b adjacent to t_3 and to each v_i with i odd and $2k < i < 4k$, and a vertex t_2 adjacent to a and b. Set $s_1 := v_0 := v_{4k}$ and $t_1 := v_{2k}$. Let P and Q be the paths $v_0, v_1, \ldots, v_{2k}$ and $v_{4k}, v_{4k-1}, \ldots, v_{2k}$, respectively.

Edges t_2a and t_2b have capacity k, and edge bt_3 capacity $2k-1$. All other edges have capacity 1. Let $d(s_1t_1) := 1$ and $d(s_2t_2) := d(s_3t_3) := 2k$.

To see that there exists a feasible multiflow, reset (temporarily) the capacities of at_3 and bt_3 to 0 and $2k$ respectively. Then a feasible multiflow (f_1, f_2, f_3) is given as follows. Flow f_1 consists of the incidence vector of path Q. Flow f_2 takes value 1 on the edges t_3v_i for $i = 2k+2, 2k+4, \ldots, 4k-2$, on av_i for $i = 1, 3, \ldots, 2k-1$, and on s_2v_i for $i = 2, 4, \ldots, 4k$, value $\frac{1}{2}$ on the edges of P, and on t_3v_0 and t_3v_{2k}, value k on t_3b, t_2a, and t_2b, and value 0 on all other edges. Flow f_3 takes value 1 on t_3v_i for $i = 2, 4, \ldots, 2k-2$, on s_3v_i for $i = 1, 3, \ldots, 4k-1$, and on bv_i for $i = 2k+1, 2k+3, \ldots, 4k-1$, value $\frac{1}{2}$ on the edges of P, and on t_3v_0 and t_3v_{2k}, and value k on bt_3. By symmetry, also after resetting the capacities of at_3 and bt_3 to $2k$ and 0 respectively, there exists a feasible solution. Hence also the original capacity function (which is a convex combination of the modified capacity functions) has a feasible solution.

To see that any feasible multiflow contains a value $\frac{1}{2k}$, note that the $s_1 - t_1$ flow can only use edges on the circuit C: each edge leaving C is in a tight cut (= a cut having equality in the cut condition) not separating s_1 and t_1 (consider the cuts determined by $\{s_2\}$, $\{s_3\}$, and $\{t_2, t_3, a, b\}$). So in any feasible multiflow, the $s_1 - t_1$ flow f_1 is a convex combination of the incidence vectors of P and Q. Consider now the cut determined by $U := \{t_2, s_3, a, v_1, v_3, \ldots, v_{2k-1}\}$. It has capacity $4k+1$ and demand $4k$, it does not split s_1 and t_1, and contains all edges of P. Hence the capacity left for f_1 is at most 1. As P has length $2k$, it implies that f_1 can send a flow of value at most $\frac{1}{2k}$ along P. Similarly, the cut determined by

$U := \{t_2, s_3, b, v_{2k+1}, v_{2k+3}, \ldots, v_{4k-1}\}$ has capacity $6k-1$ and demand $4k$, it does not split s_1 and t_1, and contains all edges of Q. Hence the capacity left for f_1 is at most $2k-1$. As Q has length $2k$, it implies that f_1 can send a flow of value at most $1-\frac{1}{2k}$ along Q. Concluding, f_1 sends $\frac{1}{2k}$ flow along P and $1-\frac{1}{2k}$ flow along Q.

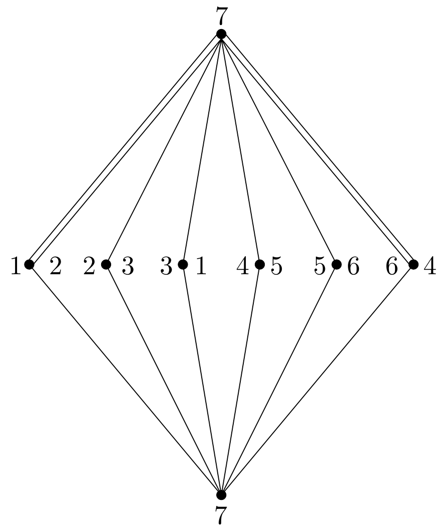

Figure 70.5

There is a quarter-integer, but no half-integer multiflow. The 7 nets are indicated by indices $1, \ldots, 7$ at the terminals. All capacities and demands are equal to 1.

In fact, there is a unique fractional multiflow. Since the distance between the terminals in any net is 2 and since there are 14 edges, any multiflow uses the capacity of each edge fully, and each of the flows is a convex combination of incidence vectors of paths of length 2. Also, the edges incident with any vertex v of degree 2 can only be used by the nets that have a terminal at v.

Let β be the fraction of flow for net 7 that traverses the leftmost vertex. For $i = 1, \ldots, 6$, let α_i be the fraction of flow for net i that traverses the topmost vertex. Then $\alpha_2 + \alpha_3 = 1$ and $\alpha_1 + \alpha_3 = 1$, and hence $\alpha_1 = \alpha_2$. So $\beta + \alpha_1 + \alpha_2 = 2$ and $\beta + (1-\alpha_1) + (1-\alpha_2) = 1$, hence $\alpha_1 + \alpha_2 = 1 + \beta = 2 - \beta$. So $\beta = \frac{1}{2}$ and $\alpha_1 = \alpha_2 = \frac{3}{4}$.

70.10. The Euler condition

In some cases adding the following *Euler condition* turns out to be of help:

(70.26) $\qquad c(\delta_E(v)) + d(\delta_R(v))$ is even, for each vertex v.

In case all capacities and demands are equal to 1, that is, for the edge-disjoint paths problem, the Euler condition is equivalent to

(70.27) the graph $G + H = (V, E \cup R)$ is Eulerian

(taking multiplicities into account).

If $k = 2$ and the capacities and demands are integer and satisfy the Euler condition, then the cut condition implies the existence of an integer multiflow. This result, also due to Rothschild and Whinston [1966a], implies Hu's 2-commodity flow theorem, as mentioned in Section 70.8 (by multiplying all capacities and demands by 2, so as to achieve the Euler condition).

We will see several other cases where the existence of a half-integer multiflow, together with the Euler condition, implies the existence of an integer multiflow. But it is not sufficient in general, as otherwise a quarter-integer multiflow would always imply the existence of a half-integer multiflow (by multiplying all capacities and demands by 2), and to this we saw the counterexample of Pfeiffer [1990] in Figure 70.5[11]. The NP-completeness of the half-integer multiflow problem, with all capacities and demands equal to 1 (Middendorf and Pfeiffer [1993]), implies that the edge-disjoint paths problem is NP-complete even if the Euler condition holds.

Fractional and integer multiflows for digraphs. As for the *directed* case, Figure 70.5 implies with construction (70.9) that a quarter-integer multiflow does not imply the existence of a half-integer multiflow. The graph in Figure 70.6 (Hurkens, Schrijver, and Tardos [1988]) shows that a half-integer multiflow does not imply the existence of an integer multiflow, even if the directed analogue of the Euler condition holds (the graph obtained from the supply digraph and the reverse of the demand digraph is an Eulerian digraph). Note that in Figure 70.6 the union $D+H$ of D and H is planar.

70.11. Survey of cases where a good characterization has been found

Let $G = (V, E)$ be an undirected graph and let $R = \{s_1t_1, \ldots, s_kt_k\}$ be a family of nets. Let $c : E \to \mathbb{R}_+$ be a capacity function and let $d_1, \ldots, d_k$ be demands (so $d(s_it_i) := d_i$).

In the following cases of the undirected multiflow problem, the cut condition has been proved to imply the existence of a fractional multiflow; if moreover the capacities and demands are integer, there is a half-integer multiflow; if moreover the Euler condition holds, there is an integer solution[12]:

(70.28) (i) if there exist two vertices u, v such that each s_it_i intersects uv (Hu [1963], E.A. Dinits — see Corollary 71.1b),

[11] A more complicated (planar) example satisfying the Euler condition and where a half-integer but no integer multiflow exists, was given by Hurkens, Schrijver, and Tardos [1988]. Earlier, a nonplanar example with these properties was given by P.D. Seymour (personal communication).

[12] For graphs $G = (V, E)$ and $H = (T, R)$, $G + H$ is the graph $(V \cup T, E \cup R)$, where $E \cup R$ is the disjoint union (as families).

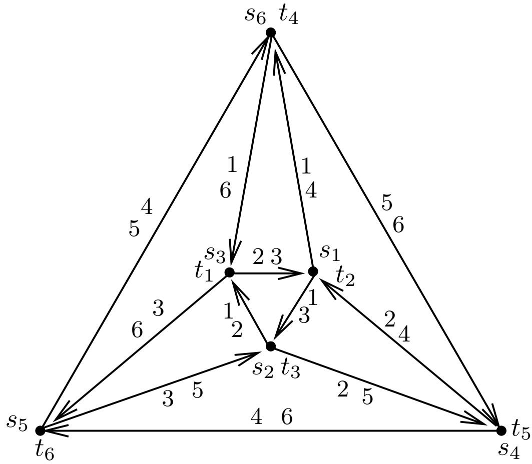

Figure 70.6

A directed example where the Euler condition holds, with $D + H$ is planar, and where a half-integer, but no integer multiflow exists. All capacities and demands are 1. The half-integer multiflow is indicated by the indices of the nets: index i at arc a means $f_i(a) = \frac{1}{2}$.

(ii) if $|\{s_1, t_1, \ldots, s_k, t_k\}| \leq 4$ or $s_1t_1, \ldots, s_kt_k$ form a five-circuit (Papernov [1976], Lomonosov [1976,1985], Seymour [1980c] — see Section 72.1),

(iii) if $G + H$ has no K_5 minor, in particular if $G + H$ is planar (Seymour [1981a] — see Sections 74.2 and 75.6),

(iv) if G is planar and there exist two faces F_1 and F_2 such that for each $i = 1, \ldots, k$: $s_i, t_i \in \text{bd}(F_1)$ or $s_i, t_i \in \text{bd}(F_2)$ (Okamura and Seymour [1981], Okamura [1983] — see Theorems 74.1 and 74.4),

(v) if G is planar and has a vertex r on the outer boundary such that for each i either both s_i and t_i are on the outer boundary, or $r \in \{s_i, t_i\}$ (Okamura [1983] — Theorem 74.5).

(vi) if G is planar and has two bounded faces F_1 and F_2 such that $s_1, \ldots, s_k$ occur clockwise around $\text{bd}(F_1)$ and $t_1, \ldots, t_k$ occur clockwise around $\text{bd}(F_2)$ (Schrijver [1989b] — cf. Section 74.3b).

Here $\text{bd}(F)$ denotes the boundary of F.

In particular, in each of these cases, if the capacities and demands are integer and satisfy the Euler condition, the existence of a fractional multiflow implies the existence of an integer multiflow. Next to the cases listed in (70.28), this property has been proved in the following cases (extending (70.28)(ii) and (iv)):

(70.29) (i) if $|\{s_1, t_1, \ldots, s_k, t_k\}| \leq 5$ (Karzanov [1987a] — see Section 72.2a),
(ii) if G is planar and there exist faces F_1, F_2, F_3 such that for each $i = 1, \ldots, k$ there is a $j \in \{1, 2, 3\}$ such that $s_i, t_i \in \mathrm{bd}(F_j)$ (Karzanov [1994b] — see Section 74.3c).

This in particular implies that if the capacities and demands are integer and there exists a fractional multiflow, then there exists a half-integer multiflow.

In the following case (extending (70.29)(ii)), it has been proved that if c and d are integer and a fractional multiflow exists, then a quarter-integer multiflow exists; if moreover the Euler condition holds, then a half-integer solution exists:

(70.30) if G is planar and there are four faces such that each net is spanned by one of these faces (Karzanov [1995] — see Section 74.3c).

(We say that a pair of vertices is *spanned* by a face F if it is spanned by the boundary of F.)

In Section 73.1c we shall see that an integer multiflow can be found in polynomial time also if the nets form a triangle (no Euler condition is required).

70.12. Relation between the cut condition and fractional cut packing

As was noted by Karzanov [1984] and Seymour [1979b], if the cut condition is sufficient for the existence of a fractional multiflow, one can derive an interesting polarity relation between multiflows and fractional packing of cuts.

Let $G = (V, E)$ and $H = (V, R)$ be graphs. Consider the cone K in $\mathbb{R}^R \times \mathbb{R}^E$ generated by the vectors[13]

(70.31) $(\chi^r; \chi^{EP})$ for $r \in R$ and r-path P in G,
$(\mathbf{0}; \chi^e)$ for $e \in E$.

Here EP denotes the set of edges of P. For any $r = st \in R$, an *r-path* is a path connecting s and t. χ^r and χ^e denote the rth and eth unit base vectors in $\mathbb{R}^R$ and $\mathbb{R}^E$, respectively.

For any $c : E \to \mathbb{R}_+$ and $d : R \to \mathbb{R}_+$, the existence of a feasible multiflow subject to c and of value d is equivalent to the fact that $(d; c)$ belongs to K. So we have that the property:

[13] We write $(x; y)$ for $\begin{pmatrix} x \\ y \end{pmatrix}$.

(70.32) for each $c : E \to \mathbb{R}_+$ and $d : R \to \mathbb{R}_+$, the cut condition implies the existence of a feasible multiflow,

is equivalent to the fact that K consists of all vectors $(d; c) \in \mathbb{R}^R \times \mathbb{R}^E$ satisfying:

(70.33)
$$\begin{array}{ll} d(\delta_R(U)) \leq c(\delta_E(U)) & \text{for } U \subseteq V, \\ d_r \geq 0 & \text{for } r \in R, \\ c_e \geq 0 & \text{for } e \in E. \end{array}$$

Let K^* be the polar cone of K (cf. Section 5.7). Then (70.32) is equivalent to $-K^*$ being generated by the vectors:

(70.34)
$$\begin{array}{ll} (-\chi^{\delta_R(U)}; \chi^{\delta_E(U)}) & \text{for } U \subseteq V, \\ (\chi^r; \mathbf{0}) & \text{for } r \in R, \\ (\mathbf{0}; \chi^e) & \text{for } e \in E. \end{array}$$

Also, by definition of K, $-K^*$ consists of all vectors $(m; l) \in \mathbb{R}^R \times \mathbb{R}^E$ satisfying:

(70.35)
$$\begin{array}{ll} m_r + l(EP) \geq 0 & \text{for } r \in R \text{ and } r\text{-path } P \text{ in } G, \\ l_e \geq 0 & \text{for } e \in E. \end{array}$$

This implies the following theorem relating the cut condition to distances and fractional packings of cuts:

Theorem 70.5. *Let $G = (V, E)$ and $H = (V, R)$ be supply and demand graphs. Then for each $c : E \to \mathbb{R}_+$ and $d : R \to \mathbb{R}_+$, the cut condition implies the existence of a feasible fractional multiflow if and only if for each length function $l : E \to \mathbb{R}_+$ there exist $\lambda_U \geq 0$ for $U \subseteq V$ such that*

(70.36)
$$\sum_U \lambda_U \chi^{\delta_E(U)} \leq l$$

and

(70.37)
$$\mathrm{dist}_l(s, t) = \sum_U \lambda_U \chi^{\delta_R(U)}(r),$$

for each $r = st \in R$. Here $\mathrm{dist}_l(s, t)$ denotes the minimum length of an $s - t$ path in G, with respect to l.

Proof. As we saw above, (70.32) is equivalent to the fact that $-K^*$ is generated by the vectors (70.34). It is equivalent to: each $(m; l) \in \mathbb{R}^R \times \mathbb{R}^E$ satisfying (70.35) is a nonnegative combination of vectors (70.34). Since $(\chi^r; \mathbf{0})$ is one of the vectors (70.34), we can restrict the $(m; l)$ to those for which m_r is smallest so as to satisfy (70.35). That is, we can assume that $m_r = -\mathrm{dist}_l(s, t)$ where $r = st$. Hence (70.32) is equivalent to: for each $l : E \to \mathbb{R}_+$, the vector $(-\mathrm{dist}_l; l)$ is a nonnegative combination of vectors (70.34). This is equivalent to the condition stated in the theorem. ∎

This is based on interpreting *feasibility* of multiflows in terms of *cones*. We next consider an interpretation of the *maximization* of multiflows in terms of *polyhedra*.

Let $\mathcal{P}$ be the collection of r-paths for all $r \in R$. Let $\mathcal{B}$ be the collection of subsets of E that intersect each path in $\mathcal{P}$.

Consider the inequality system:

$$(70.38) \qquad \begin{array}{ll} x_e \geq 0 & \text{for } e \in E, \\ x(EP) \geq 1 & \text{for } P \in \mathcal{P}. \end{array}$$

Then by the theory of blocking polyhedra:

Theorem 70.6. *The up hull of the incidence vectors of the sets in $\mathcal{B}$ is determined by (70.38) if and only if the up hull of the incidence vectors of paths in $\mathcal{P}$ is determined by*

$$(70.39) \qquad \begin{array}{ll} x_e \geq 0 & \text{for } e \in E, \\ x(B) \geq 1 & \text{for } B \in \mathcal{B}. \end{array}$$

Proof. Directly from the theory of blocking polyhedra. ∎

In terms of flows this is equivalent to:

Corollary 70.6a. *Let $G = (V, E)$ and $H = (V, R)$ be supply and demand graphs. For each $c : E \to \mathbb{R}_+$, the maximum total value of a multiflow subject to c is equal to the minimum capacity of a set in $\mathcal{B}$ if and only if for each length function $l : E \to \mathbb{R}_+$ satisfying $\mathrm{dist}_l(s, t) \geq 1$ for each $r = st \in R$, there exist $\lambda_B \geq 0$ for $B \in \mathcal{B}$ such that*

$$(70.40) \qquad \sum_{B \in \mathcal{B}} \lambda_B = 1 \textit{ and } \sum_{B \in \mathcal{B}} \lambda_B \chi^B \leq l.$$

Proof. The first statement is equivalent to the fact that the up hull of the incidence vectors of sets in $\mathcal{B}$ is determined by (70.38). The second statement is equivalent to the fact that the up hull of the incidence vectors of paths in $\mathcal{P}$ is determined by (70.39). The equivalence is stated by Theorem 70.6. ∎

70.12a. Sufficiency of the cut condition sometimes implies an integer multiflow

As was also noted by Karzanov [1984,1987a] and Seymour [1979b], in certain collections of graphs+nets, if the cut condition implies the existence of a fractional multiflow, we can derive integrality of solutions. This can be made explicit as follows.

Consider an Eulerian graph $G = (V, E)$, and let e and f be distinct edges incident with a vertex v of degree ≥ 4. We describe the operation of separating e and f at v: introduce a new vertex v', rejoin half of the edges incident with v to

v', such that e remains incident with v and f becomes incident with v', and add $\frac{1}{2}\deg_E(v) - 2$ parallel edges connecting v and v'.

Call any graph G' arising in this way a *splitting* of G *separating* e *and* f *at* v. Note that, if $G' = (V', E')$ denotes the new graph, then $\deg_{E'}(v) = \deg_{E'}(v') = \deg_E(v) - 2$.

Let $\mathcal{I}$ be a collection of pairs (G, R) of an Eulerian graph $G = (V, E)$ and a subset R of E, with the following property:

(70.41) for each $(G, R) \in \mathcal{I}$, for each vertex v of G of degree at least 4 with $\deg_{E \setminus R}(v) > \deg_R(v)$, and for each two edges e and f of G incident with v, not both in R, $\mathcal{I}$ contains a pair (G', R') where G' is a splitting of G separating e and f at v, and where R' is the set of edges arising from R by this splitting.

As examples we can take for $\mathcal{I}$ the set of all pairs (G, R) consisting of an Eulerian graph $G = (V, E)$ and $R \subseteq E$ such that one of the following holds (the first four examples follow from the fact that for each fixed graph $H = (T, R)$, the class of pairs (G, R) with $G = (V, E)$ Eulerian and $R \subseteq E$ satisfies (70.41)):

(70.42)
(i) R consists of two parallel classes of edges;
(ii) there are two vertices intersecting all edges in R;
(iii) R covers at most four vertices;
(iv) the edges in R form a pentagon, with parallel edges added;
(v) (V, E) is planar;
(vi) $(V, E \setminus R)$ is planar, such that all vertices covered by R are on the outer boundary of $(V, E \setminus R)$;
(vii) $(V, E \setminus R)$ is planar, such that it has two faces with the property that each edge in R is spanned by one of these faces.

As we shall see in later chapters, in each of these cases the premise, and hence the conclusion, of the following theorem hold. The theorem applies to the multiflow problem with supply graph $(V, E \setminus R)$ and demand graph (V, R), with all capacities and demands equal to 1 (so to the edge-disjoint paths problem):

Theorem 70.7. *Let* $\mathcal{I}$ *satisfy* (70.41) *and have the property that for each* $(G, R) \in \mathcal{I}$*, the cut condition implies the existence of a fractional multiflow. Then, for each* $(G, R) \in \mathcal{I}$*, the cut condition implies the existence of an integer multiflow.*

Proof. Consider a counterexample $(G, R) \in \mathcal{I}$ with

(70.43) $$\sum_{v \in V} 2^{\deg_G(v)}$$

minimal. So the cut condition holds, and hence there is a fractional multiflow. It implies that there is a collection $\mathcal{C}$ of circuits in G, each intersecting R in exactly one edge, and, for each $C \in \mathcal{C}$, there is a $\lambda_C > 0$ such that for each edge e:

(70.44) $$\sum_{C \in \mathcal{C}} \lambda_C \chi^C(e) \leq 1,$$

with equality if $e \in R$. Here we consider circuits as edge sets.

Note that:

(70.45) for each $C \in \mathcal{C}$ and each $U \subseteq V$ with $|\delta_R(U)| = |\delta_{E\setminus R}(U)|$, if U splits at least one edge of C, then U splits the edge in $C \cap R$ and exactly one edge in $C \setminus R$.

(Here U *splits* e if $e \in \delta(U)$.) This follows from the fact that if U splits an edge in C, then it splits at least one edge in $C \setminus R$, and hence

(70.46) $$|\delta_R(U)| = \sum_C \lambda_C \chi^C(\delta_R(U)) \leq \sum_C \lambda_C \chi^C(\delta_{E\setminus R}(U)) \leq |\delta_{E\setminus R}(U)|.$$

Here we use $|C \cap \delta_R(U)| \leq |C \cap \delta_{E\setminus R}(U)|$, since $|C \cap \delta_R(U)| \leq 1$ and $|C \cap \delta_E(U)|$ is even. Equality throughout in (70.46) implies (70.45).

Now it suffices to show that

(70.47) for any two $C, D \in \mathcal{C}$, if $(C \setminus R) \cap (D \setminus R) \neq \emptyset$, then $C \setminus R = D \setminus R$.

That this is sufficient follows from the following. (70.47) implies that for each parallel class in R consisting of (say) μ edges connecting s and t, there are at least μ different $s-t$ paths among the $C \setminus R$ for $C \in \mathcal{C}$. Since they are edge-disjoint (by (70.47)), there exists an obvious integer solution.

To prove (70.47), suppose to the contrary that $C \setminus R$ and $D \setminus R$ have an edge in common and that $C \setminus R \neq D \setminus R$. Then (possibly after exchanging C and D), there is a vertex v on the paths made by $C \setminus R$ and $D \setminus R$ such that $C \setminus R$ and $D \setminus R$ have an edge f incident with v in common and such that $C \setminus R$ contains another edge, e say, incident with v with $e \notin D$. Let g be the edge in D incident with v and satisfying $g \neq f$. So $g \neq e$. Possibly $g \in R$.

So v has degree at least 4. Moreover, $\deg_{E\setminus R}(v) > \deg_R(v)$, by (70.45), since C contains two edges in $E \setminus R$ incident with v. Let $G' = (V', E')$ be a splitting of e and g at v with $(G', R') \in \mathcal{I}$, where R' is the set of edges arising from R by this splitting. By symmetry, we can assume that, in G', edge f is incident with v'. (We leave open which of e and g is incident with v'.) Then (G', R') has no integer multiflow, as it would give an integer multiflow in (G, R) (by contracting the new edges). Hence, as for G' the sum (70.43) is reduced, the cut condition is violated for (G', R'). Let $U \subseteq V'$ violate the cut condition. That is, $|\delta_{R'}(U)| > |\delta_{E'\setminus R'}(U)|$. Then, as G' is Eulerian, $|\delta_{R'}(U)| \geq |\delta_{E'\setminus R'}(U)| + 2$. Also, U separates v and v', since otherwise it would give a cut violating the cut condition for G, R. So we can assume that $v \in U$ and $v' \notin U$. Hence $U \subseteq V$.

Let G' have γ parallel edges connecting v and v'. So $\deg_{E'}(v') = 2\gamma + 2$. Let $\alpha := \deg_{R'}(v')$. Then:

(70.48) $$\begin{aligned} &|\delta_R(U)| \leq |\delta_{E\setminus R}(U)| = |\delta_{E'\setminus R'}(U \cup \{v'\})| \\ &\leq |\delta_{E'\setminus R'}(U)| + \deg_{E'\setminus R'}(v') - 2\gamma \\ &= |\delta_{E'\setminus R'}(U)| + \deg_{E'}(v') - 2\gamma - \deg_{R'}(v') = |\delta_{E'\setminus R'}(U)| + 2 - \alpha \\ &\leq |\delta_{R'}(U)| - \alpha \leq |\delta_R(U)|. \end{aligned}$$

Hence we have equality throughout. In particular, $|\delta_R(U)| = |\delta_{E\setminus R}(U)|$ (as the first inequality is an equality), U splits all edges in $E \setminus R$ that become incident in G' with v' (as the second inequality becomes equality), and U splits no edge in R that becomes incident in G' with v' (as the last inequality becomes equality). In particular, U splits f.

Now one of e and g is (in G') incident with v'. If e is incident with v', then U splits e, and we have a contradiction with (70.45) for circuit C. If g is incident with v', then if $g \in E \setminus R$, U splits g, and if $g \in R$, U does not split g; in both cases we have a contradiction with (70.45) for circuit D. ∎

70.12b. The cut condition and integer multiflows in directed graphs

Nagamochi and Ibaraki [1989] showed that for directed graphs, if the cut condition implies the existence of a fractional multiflow, and if this holds in a certain hereditary way, then it implies the existence of an integer multiflow:

Theorem 70.8. *Let $D = (V, A)$ and $H = (V, R)$ be a supply and demand digraph, respectively. Suppose that for each $c : A \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$, the cut condition implies the existence of a fractional multiflow. Then it implies the existence of an integer multiflow.*

Proof. Let c and d be such that the cut condition holds, but no integer multiflow exists. Choose such c, d with $c(A) + d(R)$ minimal. By assumption, there exists a fractional multiflow $(f_r : A \to \mathbb{R}_+ \mid r \in R)$. Then for each $a \in A$ we have

$$c(a) = \sum_{r\in R} f_r(a), \tag{70.49}$$

for otherwise we have, for any $U \subseteq V$ with $a \in \delta^{\text{out}}_A(U)$:

$$\begin{aligned} c(\delta^{\text{out}}_A(U)) &= \sum_{a\in\delta^{\text{out}}_A(U)} c(a) > \sum_{a\in\delta^{\text{out}}_A(U)} \sum_{r\in R} f_r(a) \geq \sum_{r\in\delta^{\text{out}}_R(U)} d(r) \\ &= d(\delta^{\text{out}}_R(U)). \end{aligned} \tag{70.50}$$

Hence (by integrality of c and d), we can replace $c(a)$ by $c(a) - 1$ without violating the cut condition, and obtain a smaller counterexample — a contradiction.

This proves (70.49). It implies that the directed analogue of the Euler condition holds, since for any vertex v:

$$\begin{aligned} c(\delta^{\text{out}}_A(v)) - c(\delta^{\text{in}}_A(v)) &= \sum_{r\in R}(f_r(\delta^{\text{out}}_A(v)) - f_r(\delta^{\text{in}}_A(v))) \\ &= d(\delta^{\text{out}}_R(v)) - d(\delta^{\text{in}}_R(v)). \end{aligned} \tag{70.51}$$

The latter equality holds as each f_r is a flow.

Now consider any $r' \in R$ with $d(r') \geq 1$, say $r' = (s, t)$. Replacing $d(r')$ by $d(r') - 1$, the cut condition is maintained. Hence (by the minimality of c, d) there is an integer multiflow $(f'_r \mid r \in R)$ satisfying the new demands. Consider the capacity function

$$c' := c - \sum_{r\in R} f'_r. \tag{70.52}$$

By (70.51), there is at least one $s - t$ path traversing only arcs a with $c'(a) \geq 1$. Hence we can increase $f'_{r'}$ along this path by 1, to obtain an integer multiflow satisfying the original demands. ∎

70.13. Further results and notes

70.13a. Fixing the number of commodities in undirected graphs

Robertson and Seymour [1995] showed that for each fixed k, the k vertex-disjoint paths problem in undirected graphs is polynomial-time solvable.[14] Describing the algorithm would require more space than fits within the limits of this book. The methods are quite different in nature from the more polyhedral methods discussed here, and are based on the deep graph minors techniques developed by Robertson and Seymour. For an outline of the disjoint paths algorithm, see Robertson and Seymour [1990].

The running time of Robertson and Seymour's algorithm is bounded by $O(n^3)$ (where the constant depends (heavily) on k). It implies a polynomial-time algorithm for the k edge-disjoint paths problem for fixed k, by considering the line graph.

More generally, Robertson and Seymour gave for each fixed k an $O(n^3)$-time algorithm for the *vertex-disjoint trees problem*:

(70.53) given: a graph $G = (V, E)$ and subsets $W_1, \ldots, W_p$ of V,
find: vertex-disjoint subtrees $T_1, \ldots, T_p$ in G such that T_i spans W_i, for $i = 1, \ldots, p$,

taking $k := |W_1 \cup \cdots \cup W_p|$.

For *planar* graphs, Reed, Robertson, Schrijver, and Seymour [1993] gave a linear-time algorithm for the disjoint trees problem, fixing $|W_1 \cup \cdots \cup W_p|$. Moreover, Schrijver [1991c] showed that for each fixed q, there is a polynomial-time algorithm for the disjoint trees problem in planar graphs such that $W_1 \cup \cdots \cup W_p$ can be covered by the boundary of at most q faces. The method is based on enumerating homotopy classes (see Section 76.7a), and here the degree of the polynomial depends on q.

Sebő [1993c] showed that for each fixed k, if $G + H$ is planar and $|VH| \leq k$, then the integer multiflow problem is polynomial-time solvable. (The demands and capacities can be arbitrarily large, so there is no reduction to the edge-disjoint paths problem for a fixed number of paths.) Sebő showed this by proving a more general result on the complexity of packing T-cuts for fixed $|T|$.

Related is the following. For any k, let $f(k)$ be the smallest number such that in any $f(k)$-connected graph, any instance of the k vertex-disjoint paths problem has a solution. Jung [1970] showed that $f(k) \leq 2^{3k}$ (a larger bound was shown by Larman and Mani [1970]). Thomassen [1980] proved $f(2) = 6$ and conjectures that $f(k) = 2k + 2$ for $k \geq 2$.

For any k, let $g(k)$ be the smallest number such that in each $g(k)$-edge-connected graph, any instance of the k edge-disjoint paths problem has a solution. This value is finite — in fact, $g(k) \leq 2k$, since a $2k$-edge-connected graph has k edge-disjoint spanning trees (by the Tutte-Nash-Williams disjoint trees theorem (Corollary 51.1a)). These trees contain k edge-disjoint paths as required.

Trivially $g(k) \geq k$. Moreover, for even k one has $g(k) \geq k + 1$, as is shown by replacing each edge of the circuit C_{2k} by $\frac{1}{2}k$ parallel edges, taking as nets the

[14] The correctness of the algorithm depends on a lemma proved in the preprint Robertson and Seymour [1992], which did not appear yet.

k pairs of opposite vertices. Cypher [1980] and Thomassen [1980] conjecture that $g(k) = k$ if k is odd and $g(k) = k + 1$ if k is even.

It is known that $g(2) = 3$ (as follows from a result of Dinits and Karzanov [1979] and Seymour [1980b] (see Section 71.4a)), $g(3) = 3$ (Okamura [1984a]), $g(4) = 5$ (Mader [1985], Hirata, Kubota, and Saito [1984], H. Enomoto and A. Saito (cf. Hirata, Kubota, and Saito [1984])), $g(k) \leq k + 1$ if k is odd, and $g(k) \leq k + 2$ if k is even (Huck [1991]).

Earlier, partial results were obtained by Cypher [1980] showing that $g(k) \leq k+2$ for $k \leq 5$, Hirata, Kubota, and Saito [1984] showing that $g(k) \leq 2k - 3$ if $k \geq 4$, and Okamura [1987,1988,1990]. Related results can be found in Enomoto and Saito [1984] and Huck [1992]. See also the notes in Section 72.2b.

The corresponding result for *directed* graphs has been shown for any k — see Section 70.13b.

70.13b. Fixing the number of commodities in directed graphs

For directed graphs, Fortune, Hopcroft, and Wyllie [1980] showed that deciding if two given vertices of a digraph belong to a directed circuit, is NP-complete. It implies that the arc-disjoint paths problem is NP-complete for $k = 2$ commodities, even if the nets are 'opposite' (that is, $s_2 = t_1$ and $t_2 = s_1$). It also implies that the directed vertex-disjoint paths problem is NP-complete (as the arc-disjoint problem can be reduced to vertex-disjoint by considering the line digraph).

Shiloach [1979a] observed that Edmonds' disjoint arborescences theorem implies that in any k-arc-connected digraph the k arc-disjoint problem always has a solution. (This can be shown by adding a new vertex r and new arcs (r, s_i) for each beginning terminal s_i. As the original digraph is k-arc-connected, by Edmonds' disjoint arborescences theorem (Corollary 53.1b) the new digraph has k arc-disjoint r-arborescences. They contain paths as required.)

If we restrict ourselves to *planar* digraphs, then for each fixed k, the k vertex-disjoint paths problem is polynomial-time solvable (Schrijver [1994a]). The method is based again on enumerating homotopy types of paths. (The polynomial-time solvability for $k = 2$ opposite nets (requiring only *internally* vertex-disjoint paths), was shown by Seymour [1991].)

It can be extended to the polynomial-time solvability, for any fixed q, of the problem of finding vertex-disjoint rooted subarborescences in a planar graph, with prescribed roots and terminals to be covered, provided that these roots and terminals can be covered by the boundaries of at most q faces.

An open problem is the complexity of the k *arc*-disjoint paths problem in directed planar graphs, for any fixed $k \geq 2$. This is even unknown for $k = 2$, also if we restrict ourselves to two opposite nets.

For *acyclic* digraphs, the k vertex-disjoint paths problem is polynomial-time solvable for each fixed k. This was shown by Fortune, Hopcroft, and Wyllie [1980] (extending an earlier result for $k = 2$ of Perl and Shiloach [1978]) — see Section 70.13c. By considering line digraphs, it implies the polynomial-time solvability of the k arc-disjoint paths problem in acyclic digraphs for each fixed k.

70.13c. Disjoint paths in acyclic digraphs

Fortune, Hopcroft, and Wyllie [1980] showed that the vertex-disjoint paths problem is NP-complete for digraphs, even when fixing the number of paths to $k = 2$. Moreover, Even, Itai, and Shamir [1975,1976] showed that the arc-disjoint paths problem in acyclic digraphs is NP-complete, even if the nets form two parallel classes. By taking the line digraph, it implies that the vertex-disjoint paths problem is NP-complete for acyclic digraphs. Vygen [1995] showed that the arc-disjoint paths problem in acyclic digraphs remains NP-complete, even if the nets form three parallel classes and the Euler condition holds; and also if the digraphs are restricted to acyclic and planar.

On the other hand, Fortune, Hopcroft, and Wyllie [1980] proved that for each fixed k, the k vertex-disjoint paths problem in acyclic digraphs can be solved in polynomial time. (This was proved for $k = 2$ by Perl and Shiloach [1978].)

Theorem 70.9. *For each fixed k, there exists a polynomial-time algorithm for the k vertex-disjoint paths problem for acyclic digraphs.*

Proof. Let $D = (V, A)$ be an acyclic digraph and let $(s_1, t_1), \ldots, (s_k, t_k)$ be pairs of vertices of D (the nets), all distinct. To solve the disjoint paths problem we may assume that each s_i is a source of D and each t_i is a sink of D.

Make an auxiliary digraph $D' = (V', A')$ as follows. The vertex set V' consists of all k-tuples $(v_1, \ldots, v_k)$ of distinct vertices of D. In D' there is an arc from $(v_1, \ldots, v_k)$ to $(w_1, \ldots, w_k)$ if and only if there exists an $i \in \{1, \ldots, k\}$ such that:

(70.54) (i) $v_j = w_j$ for all $j \neq i$;
(ii) (v_i, w_i) is an arc of D;
(iii) for each $j \neq i$ there is no directed path in D from v_j to v_i.

Now the following holds:

(70.55) D contains vertex-disjoint directed paths $P_1, \ldots, P_k$ such that P_i runs from s_i to t_i $(i = 1, \ldots, k)$ $\Longleftrightarrow$ D' contains a directed path P from $(s_1, \ldots, s_k)$ to $(t_1, \ldots, t_k)$.

To see $\Longrightarrow$, let P_i follow the vertices $v_{i,0}, v_{i,1}, \ldots, v_{i,p_i}$ for $i = 1, \ldots, k$. So $v_{i,0} = s_i$ and $v_{i,p_i} = t_i$ for each i. Choose $j_1, \ldots, j_k$ such that $0 \leq j_i \leq p_i$ for each i and such that:

(70.56) (i) D' contains a directed path from $(s_1, \ldots, s_k)$ to $(v_{1,j_1}, \ldots, v_{k,j_k})$,
(ii) $j_1 + \cdots + j_k$ is as large as possible.

Let $I := \{i \mid j_i < p_i\}$. If $I = \emptyset$ we are done, so assume $I \neq \emptyset$. Then by the definition of D' and the maximality of $j_1 + \cdots + j_k$ there exists for each $i \in I$ an $i' \neq i$ such that there is a directed path in D from $v_{i',j_{i'}}$ to v_{i,j_i}. Since $t_{i'}$ is a sink we know that $v_{i',j_{i'}} \neq t_{i'}$ and that hence i' belongs to I. So each vertex in $\{v_{i,j_i} \mid i \in I\}$ is end vertex of a directed path in D starting at another vertex in $\{v_{i,j_i} \mid i \in I\}$. This contradicts the fact that D is acyclic.

To see $\Longleftarrow$ in (70.55), let P be a directed path from $(s_1, \ldots, s_k)$ to $(t_1, \ldots, t_k)$ in D'. Let P follow the vertices $(v_{1,j}, \ldots, v_{k,j})$ for $j = 0, \ldots, p$. So $v_{i,0} = s_i$ and $v_{i,p} = t_i$ for $i = 1, \ldots, k$. For each $i = 1, \ldots, k$, let P_i be the path in D following $v_{i,j}$ for $j = 0, \ldots, p$, taking repeated vertices only once. So P_i is a directed path from s_i to t_i.

Then $P_1, \ldots, P_k$ are vertex-disjoint. For suppose that P_1 and P_2 (say) have a vertex in common. That is $v_{1,j} = v_{2,j'}$ for some $j \neq j'$. Without loss of generality, $j < j'$ and $v_{1,j} \neq v_{1,j+1}$. By definition of D', there is no directed path in D from $v_{2,j}$ to $v_{1,j}$. However, this contradicts the facts that $v_{1,j} = v_{2,j'}$ and that there exists a directed path in D from $v_{2,j}$ to $v_{2,j'}$. ∎

One can derive from Theorem 70.9 that for fixed k also the k *arc*-disjoint paths problem is solvable in polynomial time for acyclic digraphs (by considering the line digraph).

Similarly to the proof of Theorem 70.9, one can prove that for each fixed k, the following problem is solvable in polynomial time: given an acyclic digraph $D = (V, A)$, pairs $(s_1, t_1), \ldots, (s_k, t_k)$ of vertices, and subsets $A_1, \ldots, A_k$ of A, find arc-disjoint directed paths $P_1, \ldots, P_k$, where P_i runs from s_i to t_i and traverses only arcs in A_i $(i = 1, \ldots, k)$.

Thomassen [1985] characterized the solvability of the 2 vertex-disjoint paths problem for acyclic digraphs, similarly to characterization (71.26). (Metzlar [1993] gave a generalization.)

70.13d. A column generation technique for multiflows

The (fractional) multiflow problem is a linear programming problem, and hence can be solved with linear programming techniques (in strongly polynomial time). Ford and Fulkerson [1958a] suggested a different LP-formulation of the multiflow problem, and a column generation technique to solve it with the simplex method.

As we saw in Section 70.1, the multiflow (feasibility) problem can be reduced to the maximum-value multiflow problem. This is equivalent to the following LP-problem. Let $D = (V, A)$ be a digraph, let $(s_1, t_1), \ldots, (s_k, t_k)$ be nets, and let $c : A \to \mathbb{R}_+$ be a capacity function. Let $\mathcal{P}$ denote the collection of all $s_i - t_i$ paths for all $i = 1, \ldots, k$ (taken as arc sets). Then the maximum-value multiflow problem can be formulated as:

$$\text{(70.57)} \qquad \begin{array}{lll} \text{maximize} & \displaystyle\sum_{P \in \mathcal{P}} z_P & \\ \text{subject to} & \text{(i)} \quad z_P \geq 0 & (P \in \mathcal{P}). \\ & \text{(ii)} \quad \displaystyle\sum_{P \in \mathcal{P}} z_P \chi^P(a) \leq c(a) & (a \in A). \end{array}$$

This is a linear programming problem with an exponential number of variables. Ford and Fulkerson [1958a] showed that this large number of variables can be avoided when solving the problem with the simplex method. The variables can be handled implicitly by using a *column generation technique* as follows.

When solving (70.57) with the simplex method we first should add a slack variable z_a for each $a \in A$. Let M denote the $A \times \mathcal{P}$ matrix with the incidence vectors of all paths in $\mathcal{P}$ as its columns and let w be the vector in $\mathbb{R}^{\mathcal{P}} \times \mathbb{R}^E$ with $w_P := 1$ for $P \in \mathcal{P}$ and $w_a := 0$ for $a \in A$. Then (70.57) is equivalent to:

$$\text{(70.58)} \qquad \begin{array}{l} \text{maximize } w^{\mathsf{T}} z \\ \text{subject to } [M \;\; I] z = c, \\ \qquad\qquad\quad z \geq \mathbf{0}. \end{array}$$

If we solve (70.58) with the simplex method, each simplex tableau is completely determined by the set of variables in the current base. So it is determined by subsets $\mathcal{P}'$ of $\mathcal{P}$ and A' of A, giving the indices of variables in the base. This is enough to know implicitly the whole tableau. Note that $|\mathcal{P}'| + |A'| = |A|$. So although the tableau is exponentially large, it can be represented in a concise way.

Let B be the matrix consisting of those columns of $[M \;\, I]$ corresponding to $\mathcal{P}'$ and A'. So the rows of B are indexed by A and the columns by $\mathcal{P}' \cup A'$. The basic solution corresponding to B is easily computed: the vector $B^{-1}c$ gives the values for z_P if $P \in \mathcal{P}'$ and for z_a if $a \in A'$, while we set $z_P := 0$ if $P \notin \mathcal{P}'$ and $z_a := 0$ if $a \notin A'$. Initially, $B = I$, that is $\mathcal{P}' = \emptyset$ and $A' = A$, implying $z_P = 0$ for all $P \in \mathcal{P}$ and $z_a = c(a)$ for all $a \in A$.

Now we describe pivoting (that is, finding variables leaving and entering the base) and checking optimality. Interestingly, it turns out that this can be done by solving a set of shortest path problems.

First consider the dual variable corresponding to an arc a. It has value (in the current tableau):

(70.59) $$w_B^{\mathsf{T}} B^{-1} \chi^a - w_a = w_B^{\mathsf{T}} (B^{-1})_a,$$

where, as usual, w_B denotes the part of vector w corresponding to B (that is, corresponding to $\mathcal{P}'$ and A') and where χ^a denotes the ath unit base vector in $\mathbb{R}^A$ (which is the column corresponding to a in $[M \;\, I]$). Note that the columns of B^{-1} are indexed by A; then $(B^{-1})_a$ is the column corresponding to a. Note also that $w_a = 0$ by definition.

Similarly, the dual variable corresponding to a path P in $\mathcal{P}$ has value:

(70.60) $$w_B^{\mathsf{T}} B^{-1} \chi^P - w_P = \big(\sum_{a \in P} w_B^{\mathsf{T}} (B^{-1})_a\big) - 1.$$

In order to pivot, we should find a negative dual variable. To this end, we first check if (70.59) is negative for some arc a. If so, we choose such an arc a and take z_a as the variable entering the base. Selecting the variable leaving the base now belongs to the standard simplex routine. For that, we only have to consider that part of the tableau corresponding to $\mathcal{P}', A'$, and a. We select an element f in $\mathcal{P}' \cup A'$ for which the quotient $z_f/(B^{-1})_{f,a}$ has positive denominator and is as small as possible. Then z_f is the variable leaving the base.

Suppose next that (70.59) is nonnegative for each arc a. We consider $w_B^{\mathsf{T}}(B^{-1})_a$ as the length $l(a)$ of a. Then for any path P,

(70.61) $$\sum_{a \in P} w_B^{\mathsf{T}} (B^{-1})_a$$

is equal to the length $\sum_{a \in P} l(a)$ of P. Hence, finding a dual variable (70.60) of negative value is the same as finding a path in $\mathcal{P}$ of length less than 1.

Such a path can be found by applying a shortest path algorithm: for each $i = 1, \ldots, k$, we find a shortest $s_i - t_i$ path (with respect to l). If each of these shortest paths has length at least 1, we know that all dual variables have nonnegative value, and hence the current basic solution is optimum.

If we find some $s_i - t_i$ path P of length less than 1, we choose z_P as variable entering the base. Again selecting a variable leaving the base is standard: we select an element f in $\mathcal{P}' \cup A'$ for which the quotient $z_f/(B^{-1}\chi^P)_f$ has positive denominator and is as small as possible.

This describes pivoting. In order to avoid cycling and to guarantee termination, a lexicographic rule can be incorporated for selecting the variable leaving the base as usual. (This only requires ordering A.)

The length function l in the final tableau has the properties described in Theorem 70.2.

70.13e. Approximate max-flow min-cut theorems for multiflows

In general, the cut condition is not sufficient for the existence of a feasible multiflow. Leighton and Rao [1988,1999] gave an upper bound (only depending on the number of vertices) on the relative error in case each pair of vertices forms a net, with all demands equal.

Let $G = (V, E)$ and $H = (V, R)$ be a supply and a demand graph, and let $c : E \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$ be a capacity and a demand function. Let λ be the maximum value for which there exists a multiflow subject to c of demand $\lambda \cdot d$. By the cut condition,

$$\lambda \leq \mu := \min_U \frac{c(\delta_E(U))}{d(\delta_R(U))}, \tag{70.62}$$

where the minimum is taken over all subsets U of V with $d(\delta_R(U)) > 0$.

Leighton and Rao proved that if R is the collection of *all* pairs from V and d is constant, then $\mu/\lambda = O(\log n)$ where $n := |V|$. They also showed that $O(\log n)$ is best possible, and that a set U attaining the minimum in (70.62) up to a factor $O(\log n)$ can be found in polynomial time.

Klein, Agrawal, Ravi, and Rao [1990] (cf. Klein, Rao, Agrawal, and Ravi [1995]) showed that if H is any demand graph, then $\mu/\lambda = O(\log C \log D)$, where C and D denote the sum of the capacities and demands, respectively. This was improved to $O(\log n \log D)$ by Tragoudas [1996], to $O(\log |R| \log D)$ by Garg, Vazirani, and Yannakakis [1993a,1996], and to $O(\log^2 |R|)$ by Plotkin and Tardos [1993,1995]. These papers also give polynomial-time algorithms to find a subset U attaining the minimum (70.62) up to the corresponding factor.

For planar graphs, Klein, Plotkin, and Rao [1993] gave a bound of $O(\log D)$, improved to $O(\log |R|)$ by Plotkin and Tardos [1993,1995], and of $O(1)$ if R consists of all pairs of vertices.

More results on approximate multiflows are given by Raghavan and Thompson [1987], Klein, Stein, and Tardos [1990], Shahrokhi and Matula [1990], Leighton, Makedon, Plotkin, Stein, Tardos, and Tragoudas [1991,1995], Goldberg [1992], Klein, Plotkin, and Rao [1993], Leong, Shor, and Stein [1993], Tardos and Vazirani [1993], Awerbuch and Leighton [1994], Klein, Plotkin, Stein, and Tardos [1994], Kamath and Palmon [1995], Linial, London, and Rabinovich [1995], Radzik [1995,1997], Aumann and Rabani [1998], Garg and Könemann [1998], Fleischer [1999a,2000a], Guruswami, Khanna, Rajaraman, Shepherd, and Yannakakis [1999], Leighton and Rao [1999], Baveja and Srinivasan [2000], Srivastav and Stangier [2000], Cheriyan, Karloff, and Rabani [2001], Fleischer and Wayne [2002], Günlük [2002], Karakostas [2002], and Kolman and Scheideler [2002]. A survey is given by Shmoys [1997]. Approximation algorithms for Steiner and directed multicuts are given by Klein, Plotkin, Rao, and Tardos [1997].

For approximating minimum-cost multiflows, see Plotkin, Shmoys, and Tardos [1991,1995], Kamath, Palmon, and Plotkin [1995], Karger and Plotkin [1995], Grigoriadis and Khachiyan [1996b,1996a], Garg and Könemann [1998], Goldberg, Oldham, Plotkin, and Stein [1998], and Karakostas [2002].

The 'quickest multicommodity flow problem' was investigated by Fleischer and Skutella [2002].

For surveys on approximation algorithms, see Shmoys [1995] and the book by Vazirani [2001].

70.13f. Further notes

Ford and Fulkerson [1958a] designed a (non-polynomial-time) algorithm for the fractional multiflow problem, based on the simplex method, with column generation — see Section 70.13d. Jewell [1958,1966] described a primal-dual simplex method, Sakarovitch [1966] gave a labeling algorithm solving a sequence of one-commodity flow problems after allocating the total capacity of each arc to each net, and Saigal [1967] developed an algorithm based on an arc-circuit formulation, using a column generation technique to handle the circuits. Dantzig-Wolfe decomposition was applied to multiflow problems by Chen and DeWald [1974]. Kapoor and Vaidya [1986,1996] and Kamath and Palmon [1995] study the complexity of applying interior point algorithms to multiflows.

Grinold [1968,1969] described a primal-dual algorithm for the maximum-value multiflow problem, based on allocating capacities to commodities and iteratively adapt the allocation. A simplex-based algorithm for minimum-cost and maximum-value multiflow problems was given by Hartman and Lasdon [1972]. Also Tomlin [1966], Wollmer [1972], Dragan [1974], and Nagamochi, Fukushima, and Ibaraki [1990] studied minimum-cost multiflows. A 'partitioning' algorithm for the multiflow problem was given by Grigoriadis and White [1972]. Related work was done by Kennington [1977], Farvolden, Powell, and Lustig [1993], and Hadjiat, Maurras, and Vaxes [2000]. Jarvis [1969] noticed the equivalence of vertex-arc and arc-chain formulations of the multiflow problem.

Bellmore, Greenberg, and Jarvis [1970] and Jarvis and Tindall [1972] described algorithms to find a minimum-capacity set disconnecting all nets in a directed multiflow problem.

Swoveland [1973] studied a generalization of the multiflow problem, where upper bounds can be prescribed for the sum of the flows of subsets of the nets on arcs. Ferland [1974] and Klessig [1974] studied nonlinear costs.

Computational work on multiflows is reported by Minoux [1975], Ulrich [1975], Helgason and Kennington [1977a], Kennington [1977,1978] (also minimum-cost), Kennington and Shalaby [1977], Ali, Helgason, Kennington, and Lall [1980], Kennington and Helgason [1980], Ali, Barnett, Farhangian, Kennington, Patty, Shetty, McCarl, and Wong [1984], Saviozzi [1986], Boland and Mees [1990], Nagamochi, Fukushima, and Ibaraki [1990], Barnhart [1993], Leong, Shor, and Stein [1993], Bienstock and Günlük [1995], Barnhart, Hane, and Vance [1996], Castro and Nabona [1996], Barnhart, Hane, and Vance [1997], McBride and Mamer [1997], McBride [1998], and Frangioni and Gallo [1999].

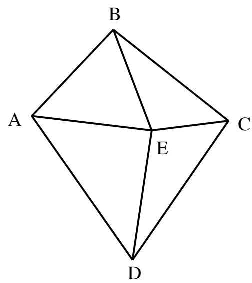
Surveys on multiflows were given by Hu [1969], Frank and Frisch [1971], Assad [1978], Kennington [1978], Phillips and Garcia-Diaz [1981], Gondran and Minoux [1984], Bazaraa, Jarvis, and Sherali [1990], Ahuja, Magnanti, and Orlin [1993], and Korte and Vygen [2000], on disjoint paths by Frank [1990e,1993a,1995], and on maximum-value multiflows by Karzanov [1991]. A bibliography on network optimization, including multicommodity flows, was compiled by Golden and Magnanti [1977].

70.13g. Historical notes on multicommodity flows

We review a few papers on multicommodity flows that are of historical interest.

In his monograph *Mathematical Methods of Organizing and Planning Production*, Kantorovich [1939] introduced linear programming methods for the multicommodity flow problem, giving as example the problem of a railroad network on which several connections have to be made simultaneously:

> Let us mention still another problem of different character which, although it does not lead directly to questions A, B, and C, can still be solved by our methods. That is the choice of transportation routes.



> Let there be several points A, B, C, D, E (Fig. 1) which are connected to one another by a railroad network. It is possible to make the shipments from B to D by the shortest route BED, but it is also possible to use other routes as well: namely BCD, BAD. Let there also be given a schedule of freight shipments; that is, it is necessary to ship from A to B a certain number of carloads, from D to C a certain number, and so on. The problem consists of the following. There is given a maximum capacity for each route under the given conditions (it can of course change under new methods of operation in transportation). It is necessary to distribute the freight flows among the different routes in such a way as to complete the necessary shipments with a minimum expenditure of fuel, under the condition of minimizing the empty runs of freight cars and taking account of the maximum capacities of the routes. As was already shown, this problem can also be solved by our methods.

A problem analogous to the multicommodity flow problem, the multi-index transportation problem, was considered by Motzkin [1952] and Schell [1955].

It was noted by Ford and Fulkerson [1954,1956b] that the max-flow min-cut theorem does not extend to maximum multiflows:

> It is worth pointing out that the minimal cut theorem is not true for networks with several sources and corresponding sinks, where shipment is restricted to be from a source to its sink.

Ford and Fulkerson give the example of the graph $K_{1,3}$, with nets all pairs of vertices of degree 1.

Robacker [1956a] observed that the following 'decomposition theorem' applies: for a graph $G = (V, E)$, nets $\{s_1, t_1\}, \dots, \{s_k, t_k\}$, and a capacity function $c : E \to \mathbb{R}_+$, the maximum total value of a multiflow subject to c is equal to

(70.63) $$\max_{c_1,\ldots,c_k} \sum_{i=1}^{k} \min_{C\in\mathcal{C}_i} c_i(C).$$

Here the maximum ranges over all k-tuples of vectors $c_1, \ldots, c_k$ in $\mathbb{R}_+^E$ with $c_1 + \cdots + c_k = c$. Moreover, $\mathcal{C}_i$ denotes the set of all $s_i - t_i$ cuts and $c_i(C)$ denotes the capacity of cut C with respect to the capacity function c_i.

So the theorem decomposes the maximum multicommodity flow problem into k maximum single-commodity flow problems. The problem is reduced to finding the optimum decomposition of the capacity function c into k functions $c_1, \ldots, c_k$. Robacker [1956a] remarked:

> At present there are no computational techniques other than those of linear programming for determining maximal flow through multicommodity networks. It is hoped, however, that the decomposition theorem may lead to new methods as did the minimum-cut, maximum-flow theorem for single-commodity networks.

Kalaba and Juncosa [1956] described applications of the multicommodity flow problem to telecommunication networks. In particular they mention:

> In a system such as the Western Union System, which has some 15 regional switching centers all connected to each other, an optimal routing problem of this type would have about 450 conditions and involve around 3000 variables. If solved using the simplex method in its most general form, this would be at the threshhold of the capacity of modern large-scale computers and would require several hours for solution.

They express the expectation that developments in computer technology and possible extensions of the combinatorial methods for one-commodity flows, will improve the situation greatly.

It turned out, however, that the combinatorial techniques that made the single-commodity flow problem so tractable, do not extend to multicommodity flows. Ford and Fulkerson [1958a] suggested a variant of the simplex method based on a column-generation technique, where each simplex step consists of determining a shortest path. Although they did not carry out computations, they expected that their method is more practicable than the direct simplex method, at least in space required. A primal-dual algorithm for multiflows was designed by Jewell [1958] (cf. Jewell [1966]).

Hu [1963] gave a combinatorial algorithm for the 2-commodity flow problem, but doubted whether it could be extended to general multicommodity flows:

> Although the algorithm for constructing maximum bi-flow is very simple, it is unlikely that similar techniques can be developed for constructing multicommodity flows. The linear programming approach used by Ford and Fulkerson to construct maximum multicommodity flows in a network is the only tool now available.

For remarks on the early history of multicommodity flows, see Jewell [1966].

Chapter 71

Two commodities

The integer 2-commodity flow problem is NP-complete, even if all capacities are 1 (Even, Itai, and Shamir [1975,1976]). Equivalently, the edge-disjoint paths problem in undirected graphs is NP-complete, even if the nets form two parallel classes.
However, if we add the Euler condition, the problem has a good characterization and can be solved in polynomial time. It is a generalization of Hu's 2-commodity flow theorem, stating that the cut condition implies the existence of a half-integer multiflow (for integer capacities and demands). This and related results form the topic of this chapter.
Except if stated otherwise, throughout this chapter $G = (V, E)$ and $H = (T, R)$ denote the supply and demand graph, in the sense of Chapter 70. The pairs in R are called the *nets*. If $s_1, t_1, \ldots, s_k, t_k$ are given, then $R := \{s_1t_1, \ldots, s_kt_k\}$. In fact, often in this chapter, $k = 2$, so $R = \{s_1t_1, s_2t_2\}$. If demands $d_1, \ldots, d_k$ are given, then $d(s_it_i) = d_i$. We denote $G+H = (V, E \cup R)$, where the disjoint union of E and R is taken, respecting multiplicities.

71.1. The Rothschild-Whinston theorem and Hu's 2-commodity flow theorem

It is a basic theorem of Hu [1963], that for 2-commodity flow problems in undirected graphs, the cut condition implies the existence of a feasible 2-commodity flow. Recall that the cut condition (in the undirected case) states that

(71.1) $$c(\delta_E(U)) \geq d(\delta_R(U))$$

for each $U \subseteq V$. This theorem, 'Hu's 2-commodity flow theorem', will be shown below as Corollary 71.1b.

Hu also showed that if moreover all capacities are integer, there is a half-integer 2-commodity flow. Generally, an integer multiflow need not exist, as is shown by Figure 70.3. In fact, the undirected integer 2-commodity flow problem is NP-complete (Even, Itai, and Shamir [1975,1976]).

Rothschild and Whinston [1966a] extended Hu's theorem by showing that adding the Euler condition guarantees the existence of an integer 2-commodity flow. We recall that the Euler condition states that

(71.2) $c(\delta_E(v)) + d(\delta_R(v))$ is even for each $v \in V$.

Theorem 71.1 (Rothschild-Whinston theorem)**.** *Let $G = (V, E)$ be a graph, let $\{s_1, t_1\}$ and $\{s_2, t_2\}$ be pairs of vertices of G, and let $c : E \to \mathbb{Z}_+$ and $d_1, d_2 \in \mathbb{Z}_+$ satisfy the Euler condition. Then there exists an integer 2-commodity flow subject to c and with value d_1, d_2 if and only if the cut condition is satisfied.*

Proof. Necessity being trivial, we show sufficiency. Suppose that the cut condition holds. Orient the edges of G arbitrarily, yielding the digraph $D = (V, A)$. For any $a \in A$, we denote by $c(a)$ the capacity of the underlying undirected edge. For $i = 1, 2$, define $p_i : V \to \mathbb{Z}$ by

(71.3) $p_i := d_i \cdot (\chi^{t_i} - \chi^{s_i})$.

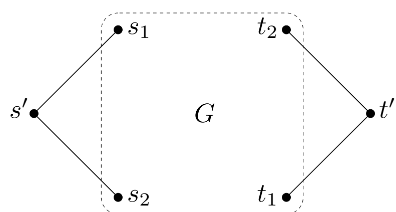


Figure 71.1

Extend G by two new vertices, s' and t', and new edges $s's_1$ and t_1t', each of capacity d_1, and new edges $s's_2$ and t_2t', each of capacity d_2 (Figure 71.1). This gives the graph G'.

By the max-flow min-cut theorem, G' contains an integer $s' - t'$ flow g of value $d_1 + d_2$, since by the cut condition the minimum capacity of an $s' - t'$ cut in G' is equal to $d_1 + d_2$. By the Euler condition we can assume that $g(e) \equiv c(e) \pmod 2$ for each $e \in E$: the edges e with $g(e) \not\equiv c(e) \pmod 2$ form an Eulerian graph; that is, each vertex is incident with an even number of such edges. Hence we can add a unit flow along a circuit, so as to decrease the number of such edges e.

Now in D, g gives a function $g' : A \to \mathbb{Z}$ satisfying

(71.4) $g'(a) \equiv c(a) \pmod 2$ and $|g'(a)| \leq c(a)$ for each $a \in A$, and $\text{excess}_{g'} = p_1 + p_2$.

(Here $\text{excess}_{g'}(v) := g'(\delta^{\text{in}}(v)) - g'(\delta^{\text{out}}(v))$ for $v \in V$.)

Similarly, by extending G by two new vertices, s'' and t'', and new edges $s''s_1$ and t_1t'', each of capacity d_1, and $s''t_2$ and s_2t'', each of capacity d_2 (Figure 71.2), we obtain a function $g'' : A \to \mathbb{Z}$ satisfying

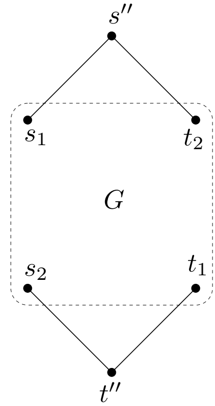

Figure 71.2

(71.5) $g''(a) \equiv c(a) \pmod 2$ and $|g''(a)| \leq c(a)$ for each $a \in A$, and $\text{excess}_{g''} = p_1 - p_2$.

Now define $f_1 := \frac{1}{2}(g' + g'')$ and $f_2 := \frac{1}{2}(g' - g'')$. Then f_1 and f_2 form a 2-commodity flow as required. Indeed, since $g' \equiv c \equiv g'' \pmod 2$, we know that f_1 and f_2 are integer. Moreover, $|f_1(a)| + |f_2(a)| = \frac{1}{2}(|g'(a)| + |g''(a)|) \leq c(a)$ for each $a \in A$. Finally, $\text{excess}_{f_i} = p_i$ for $i = 1, 2$, as follows directly from (71.4) and (71.5). ∎

This method of proof was given by Rothschild and Whinston [1966a] (similar proofs were given by Sakarovitch [1973] and Seymour [1978]).

A combinatorial form of Theorem 71.1 is:

Corollary 71.1a. *Let $G = (V, E)$ be a graph, let $s_1, t_1, s_2, t_2 \in V$, and let $d_1, d_2 \in \mathbb{Z}_+$, such that each vertex $v \neq s_1, t_1, s_2, t_2$ has even degree, while $\deg_G(s_i) \equiv \deg_G(t_i) \equiv d_i \pmod 2$ for $i = 1, 2$. Then there exist d_1 $s_1 - t_1$ paths and d_2 $s_2 - t_2$ paths, all edge-disjoint if and only if the cut condition* (70.21) *is satisfied.*

Proof. Directly from Theorem 71.1 by taking all capacities equal to 1. ∎

Conversely, Theorem 71.1 follows from Corollary 71.1a by replacing each edge e by $c(e)$ parallel edges.

Theorem 71.1 also implies a half-integer 2-commodity flow theorem, given by Hu [1963][15]:

Corollary 71.1b (Hu's 2-commodity flow theorem)**.** *Let $G = (V, E)$ be a graph, let s_1, t_1 and s_2, t_2 be pairs of vertices of G, let $c : E \to \mathbb{R}_+$, and*

[15] Hakimi [1962b] gave an erroneous proof of this theorem.

let $d_1, d_2 \in \mathbb{R}_+$. Then there exists a 2-commodity flow subject to c and with value d_1, d_2 if and only if the cut condition is satisfied. If all capacities and demands are integer, then we can take the flow half-integer.

Proof. By continuity and compactness, we can assume that c and the d_i are rational-valued, and hence, by scaling, even-integer-valued. So the Euler condition holds. Let the cut condition be satisfied. Then Theorem 71.1 gives the existence of a 2-commodity flow.

If c and the d_i are integer-valued, multiplying them by 2 and applying Theorem 71.1 gives an integer 2-commodity flow, and hence a half-integer multiflow for the original c and d_i. ∎

Notes. The proof of Theorem 71.1 yields a strongly polynomial-time algorithm to find a feasible integer 2-commodity flow if the Euler condition holds, of the same time order as that of finding a maximum one-commodity integer flow. It implies a strongly polynomial-time algorithm to find a half-integer 2-commodity flow, for integer capacities and demands.

Also Cherkasskiĭ [1973] gave a strongly polynomial-time ($O(n^2m)$) algorithm to find a feasible half-integer 2-commodity flow. Hu [1963] gave a combinatorial algorithm, which Itai [1978] showed to have a strongly polynomial-time implementation ($O(n^3)$). A similar algorithm was described by Arinal [1969].

71.1a. Nash-Williams' proof of the Rothschild-Whinston theorem

An alternative simple proof of the Rothschild-Whinston theorem was given by C.St.J.A. Nash-Williams (cf. Lovász [1979a] p. 289). We give the proof for the equivalent Corollary 71.1a. As necessity is easy, we show sufficiency.

By Menger's theorem (undirected version), G has d_1+d_2 edge-disjoint $\{s_1, s_2\}-\{t_1, t_2\}$ paths such that d_i of them start at s_i, and d_i of them end at t_i, for $i = 1, 2$. (But the paths starting at s_1 may end at t_2, and those starting at s_2 may end at t_1.) Hence G has an orientation $D = (V, A)$ with $(V, A \cup B)$ Eulerian, where B consists of d_i parallel arcs from t_i to s_i, for $i = 1, 2$.

Then Menger's theorem (directed version) implies that D has d_1 arc-disjoint directed $s_1 - t_1$ paths. Indeed, consider any $U \subseteq V$ with $s_1 \in U$, $t_1 \notin U$. We show $d_A^{\text{out}}(U) \geq d_1$. As $(V, A \cup B)$ is Eulerian, we have

$$(71.6) \qquad d_A^{\text{out}}(U) + d_B^{\text{out}}(U) = d_{A\cup B}^{\text{out}}(U) = d_{A\cup B}^{\text{in}}(U) = d_A^{\text{in}}(U) + d_B^{\text{in}}(U).$$

If $d_B^{\text{out}}(U) = 0$, this gives $d_A^{\text{out}}(U) \geq d_B^{\text{in}}(U) \geq d_1$. If $d_B^{\text{out}}(U) > 0$, then $t_2 \in U$, $s_2 \notin U$, hence $d_B^{\text{in}}(U) = d_1$ and $d_B^{\text{out}}(U) = d_2$. So

$$(71.7) \qquad d_A^{\text{out}}(U) = \tfrac{1}{2}(d_A^{\text{out}}(U) + d_A^{\text{in}}(U) + d_1 - d_2) = \tfrac{1}{2}(d_E(U) + d_1 - d_2) \geq d_1,$$

since $d_E(U) \geq d_1 + d_2$.

So D contains d_1 arc-disjoint $s_1 - t_1$ paths. Now delete from $(V, A \cup B)$ all arcs occurring in these paths, and delete the d_1 parallel arcs from t_1 to s_1. We are left with an Eulerian digraph, and hence the d_2 parallel arcs from t_2 to s_2 belong to d_2 arc-disjoint directed circuits. This gives the d_2 paths from s_2 to t_2 as required.

71.2. Consequences

E.A. Dinits (cf. Adel'son-Vel'skiĭ, Dinits, and Karzanov [1975]) observed that Hu's 2-commodity flow theorem and the Rothschild-Whinston theorem imply:

Corollary 71.1c. *Let $G = (V, E)$ be an undirected graph and let $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$ be pairs of vertices, such that there exist a two vertices intersecting each $\{s_i, t_i\}$. Let $c : E \to \mathbb{R}_+$ and $d_1, \ldots, d_k \in \mathbb{R}_+$. Then the cut condition implies the existence of a feasible multiflow. If c and the d_i are integer, there exists a half-integer multiflow. If moreover the Euler condition holds, there exists an integer multiflow.*

Proof. We can assume that $s_i = s$ for $i = 1, \ldots, l$, and that $t_i = t'$ for $i = l+1, \ldots, k$. Let t and s' be two new vertices. For each $i = 1, \ldots, l$, add a new edge connecting t_i and t, of capacity d_i. For each $i = l+1, \ldots, k$, add a new edge connecting s' and s_i, of capacity d_i. This makes the graph H. Define $d := d_1 + \cdots + d_l$ and $d' := d_{l+1} + \cdots + d_k$.

Then the cut condition for G implies that each cut $\delta_H(U)$ in H has capacity at least $d + d'$ if it is both $s - t$ and $s' - t'$ separating; at least d if it separates s and t; and at least d' if it separates s' and t'. Hence, by Hu's 2-commodity flow theorem, H has a feasible 2-commodity flow. Restriction to G gives a feasible multiflow.

The last two statement of this corollary follow similarly. ∎

Another consequence of Theorem 71.1 is what Hu called the *max-biflow min-cut theorem*[16]:

Corollary 71.1d (max-biflow min-cut theorem)**.** *Let $G = (V, E)$ be a graph, let $\{s_1, t_1\}$ and $\{s_2, t_2\}$ be pairs of vertices, and let $c : E \to \mathbb{R}_+$. Then the maximum total value M of a 2-commodity flow subject to c is equal to the minimum capacity m of a cut which is both $s_1 - t_1$ and $s_2 - t_2$ separating. If c is integer, the maximum is attained by a half-integer multiflow. If c is integer and $c(\delta(v))$ is even for each vertex $v \neq s_1, t_1, s_2, t_2$, the maximum is attained by an integer multiflow.*

Proof. By continuity, compactness, and scaling, we can assume that c is integer and that $c(\delta(v))$ is even for each $v \neq s_1, t_1, s_2, t_2$. By replacing edges by parallel edges, we can assume that $c(e) = 1$ for each $e \in E$. So M is equal to the maximum number of edge-disjoint paths, each connecting either s_1 and t_1, or s_2 and t_2. As trivially $M \leq m$, it suffices to prove $M \geq m$. We can assume that $m > 0$.

[16] due to Hu [1963] and (the last statement) to Rajagopalan [1994] (who also showed a hole in the proof by Sakarovitch [1973] of this); it sharpens a result of Rothschild and Whinston [1966b], who required that $c(\delta(v))$ is even for *all* vertices v.

First assume that $\deg_G(s_1) \equiv \deg_G(t_1) \pmod 2$ and (hence) $\deg_G(s_2) \equiv \deg_G(t_2) \pmod 2$. For $i = 1, 2$, let m_i be the minimum size of an $s_i - t_i$ cut. We show that

(71.8) there exists $d_1, d_2 \in \mathbb{Z}_+$ such that $d_1 \leq m_1$, $d_2 \leq m_2$, $d_1 + d_2 = m$, $d_1 \equiv \deg_G(s_1) \pmod 2$, and $d_2 \equiv \deg_G(s_2) \pmod 2$.

To see this, note that $m \leq m_1 + m_2$ (since the union of an $s_1 - t_1$ cut and an $s_2 - t_2$ cut separates both s_1 and t_1, and s_2 and t_2), $m_1 \leq m$, and $m \equiv \deg_G(s_1) + \deg_G(s_2) \pmod 2$. As $m > 0$, by symmetry we may assume that $m_2 > 0$. If $m_1 \equiv \deg_G(s_1) \pmod 2$, then we can take $d_1 := m_1$ and $d_2 := m - m_1$. If $m_1 \not\equiv \deg_G(s_1) \pmod 2$, then we can take $d_1 := m_1 - 1$ and $d_2 := m - m_1 + 1$. Indeed, as $m_1 \not\equiv \deg_G(s_1) \pmod 2$, any minimum-size $s_1 - t_1$ cut also separates s_2 and t_2. So $m = m_1$. Hence $d_1 \geq 0$ (as $m > 0$) and $d_2 = 1 \leq m_2$ (as $m_2 > 0$).

This shows (71.8). By Corollary 71.1a, there exist d_1 $s_1 - t_1$ paths and d_2 $s_2 - t_2$ paths, any two of which are edge-disjoint. So $M \geq d_1 + d_2 = m$.

Next assume that $\deg_G(s_1) \not\equiv \deg_G(t_1) \pmod 2$ and (hence) $\deg_G(s_2) \not\equiv \deg_G(t_2) \pmod 2$. By symmetry, we may assume that m is attained by a cut with s_1, s_2 at one side and t_1, t_2 at the other side. So the size of any cut with s_1, t_2 at one side and t_1, s_2 at the other side, has parity different from that of m; hence its size is at least $m+1$. Therefore, adding a new edge connecting s_2 and t_1 increases the minimum m by 1. Moreover, the maximum M increases by at most 1. In the new situation, the degrees of s_1 and t_1 have the same parity, and similarly for s_2 and t_2. Hence the first part of this proof applies, showing $M \geq m$. ∎

(An alternative proof was given by Lovász [1976b].)

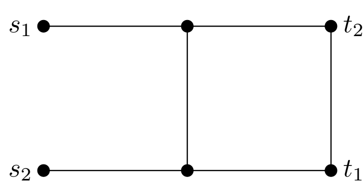

Figure 71.3
The maximum total value of a 2-commodity flow (subject to capacity **1**) is equal to 2, but the maximum total value of an integer 2-commodity flow is equal to 1.

The graph in Figure 71.3 shows that in the max-biflow min-cut theorem (Corollary 71.1d) we cannot delete the parity conditions (example of Rothschild and Whinston [1966b]). This example is critical, as is shown by the following result, which is a special case of a general hypergraph theorem of Seymour [1977b] (Theorem 80.1).

Theorem 71.2. *Let $G = (V, E)$ be a graph and $s_1, t_1, s_2, t_2 \in V$. Then for each capacity function $c : E \to \mathbb{Z}_+$, the maximum total value of an integer 2-commodity flow is equal to the minimum capacity of a cut separating both s_1 and t_1, and s_2 and t_2, if and only if G has no subgraph contractible to the graph of Figure 71.3, up to exchanging s_1 and t_1, and s_2 and t_2.*

Here we assume that the subgraph contains the s_i and t_i, and that these vertices are contracted to the vertices indicated by s_i and t_i in the figure. For a proof, we refer to Section 80.5a.

A similar result for feasibility can be derived (Seymour [1981a]):

(71.9) Let $G = (V, E)$ be a graph and $s_1, t_1, s_2, t_2 \in V$. Then for each capacity function $c : E \to \mathbb{Z}_+$ and each demands $d_1, d_2 \in \mathbb{Z}_+$, the cut condition implies the existence of an integer multiflow if and only if the graph of Figure 70.3 is not a minor of G.

We derive this result from Theorem 71.2. By taking $c(e)$ large one can see that the property described is closed under contractions of edges. As Figure 70.3 satisfies the cut condition but has no integer multiflow (for $c = \mathbf{1}$, $d = \mathbf{1}$), we have necessity of the condition in (71.9).

To derive sufficiency from Theorem 71.2, let G have no subgraph contractible to Figure 70.3 and let $c : E \to \mathbb{Z}_+$ and $d_1, d_2 \in \mathbb{Z}_+$ satisfy the cut condition. Let s'_1 and s'_2 be two new vertices, and let $s'_1 s_1$ and $s'_2 s_2$ be two new edges, of capacity d_1 and d_2 respectively. Then the extended graph G' has no subgraph contractible to the graph of Figure 71.3, with s_i replaced by s'_i $(i = 1, 2)$, up to exchanging s'_1 and t_1, and s'_2 and t_2. Also, the minimum capacity of a cut in G' separating both s'_1 and t_1, and s'_2 and t_2, is equal to $d_1 + d_2$. Hence by Theorem 71.2, G' has an integer multiflow of total value $d_1 + d_2$. Restricted to G this gives a multiflow satisfying d_1, d_2.

Notes. For the case where $G + H$ is planar, Lomonosov [1983] characterized for *fixed* integer capacity function c, when the maximum and minimum in Theorem 71.2 are equal. He also showed that if $G + H$ is planar, the maximum and minimum differ by at most 1.

71.3. 2-commodity cut packing

By Theorem 70.5, Hu's 2-commodity flow theorem implies that if $G = (V, E)$ is an undirected graph, $s_1, t_1, s_2, t_2 \in V$, and $l : E \to \mathbb{R}_+$, then there exist $\lambda_U \geq 0$ for $U \subseteq V$ such that

(71.10) $$\sum_U \lambda_U \chi^{\delta_E(U)} \leq l$$

and

(71.11) $$\mathrm{dist}_l(s_i, t_i) = \sum_U \lambda_U \chi^{\delta_R(U)}(s_i t_i),$$

for $i = 1, 2$, where $R := \{s_1t_1, s_2t_2\}$. (Here $\text{dist}_l(s,t)$ is the distance of s and t, taking l as length function.)

We shall see that if l is integer, we can take the λ_U half-integer. More precisely, and more strongly:

(71.12) if l is integer such that each circuit in G has even length, then we can take the λ_U integer.

This was proved by Seymour [1978]. Equivalently (by replacing each edge e by a path of length $l(e)$; $\text{dist}_G(s,t)$ denotes the distance of s and t in G (for length function $\mathbf{1}$)):

Theorem 71.3. *Let $G = (V,E)$ be a bipartite graph and let $s_1, t_1, s_2, t_2 \in V$. Then there exist disjoint cuts such that s_i and t_i are separated by $\text{dist}_G(s_i,t_i)$ of these cuts, for $i = 1, 2$.*

Proof. We may assume that G is connected. Denote $d(u,v) := \text{dist}_G(u,v)$ for $u, v \in V$. Define for each vertex v:

(71.13)
$$\varphi(v) := \tfrac{1}{2}(d(s_1,v) + d(s_2,v) - d(s_1,s_2)),$$
$$\psi(v) := \tfrac{1}{2}(d(s_1,v) - d(s_2,v) + d(s_1,s_2)).$$

These numbers are nonnegative and integer, by the triangle inequality and by the fact that each circuit in G has even length.

If u and v are adjacent vertices of G, then either $\varphi(u) = \varphi(v)$ and $|\psi(v) - \psi(u)| = 1$, or $\psi(u) = \psi(v)$ and $|\varphi(v) - \varphi(u)| = 1$, since $d(s_1,v) - d(s_1,u) = \pm 1$ and $d(s_2,v) - d(s_2,u) = \pm 1$. Let A_i be the set of edges uv with $\varphi(v) = i-1$ and $\varphi(u) = i$. Let B_i be the set of edges uv with $\psi(v) = i-1$ and $\psi(u) = i$. So the sets $A_1, A_2, \ldots, B_1, B_2, \ldots$ are cuts partitioning E.

Now $\varphi(s_1) = \psi(s_1) = 0$ and $\varphi(t_1) + \psi(t_1) = d(s_1,t_1)$. So there exist $d(s_1,t_1)$ cuts among $A_1, A_2, \ldots, B_1, B_2, \ldots$ that separate s_1 and t_1.

Moreover

(71.14)
$$\begin{aligned}&|\varphi(t_2) - \varphi(s_2)| + |\psi(t_2) - \psi(s_2)| = \\ &\tfrac{1}{2}|d(s_1,t_2) + d(s_2,t_2) - d(s_1,s_2)| + \tfrac{1}{2}|d(s_1,t_2) - d(s_2,t_2) - d(s_1,s_2)| \\ &= d(s_2,t_2).\end{aligned}$$

This implies that there exist $d(s_2,t_2)$ cuts among $A_1, A_2, \ldots, B_1, B_2, \ldots$ that separate s_2 and t_2. ∎

A consequence of Theorem 71.3 is a min-max relation for the maximum number of disjoint cuts that are both $s_1 - t_1$ and $s_2 - t_2$ separating, in a bipartite graph (Seymour [1978]):

Corollary 71.3a. *Let $G = (V,E)$ be a bipartite graph and let $s_1, t_1, s_2, t_2 \in V$. Then the maximum number of disjoint cuts each separating both s_1 and t_1, and s_2 and t_2, is equal to the minimum of $\text{dist}_G(s_1,t_1)$ and $\text{dist}_G(s_2,t_2)$.*

Proof. We may assume that G is connected. Let $d(u,v) := \text{dist}_G(u,v)$ for $u,v \in V$. Let $k := \min\{d(s_1,t_1), d(s_2,t_2)\}$. Let $C_1,\ldots,C_t$ be the cuts described in Theorem 71.3. At least k of these cuts separate s_1 and t_1, and at least k of these cuts separate s_2 and t_2. If C_i separates s_1 and t_1 and C_j separates s_2 and t_2, then $C_i \cup C_j$ contains a cut separating both s_1 and t_1, and s_2 and t_2. Thus by properly combining the C_i, we obtain k disjoint cuts as required.

(To see this, we can assume that $C_1,\ldots,C_k$ separate s_1 and t_1, and that $C_{l+1},\ldots,C_{l+k}$ separate s_2 and t_2, where $0 \leq l \leq k$. Then each of the (disjoint) sets $C_1 \cup C_{k+1},\ldots,C_l \cup C_{l+k}, C_{l+1},\ldots,C_k$ contains a cut separating both s_1 and t_1, and s_2 and t_2.) ∎

Let $G=(V,E)$ be a graph and let $s_1,t_1,s_2,t_2 \in V$. Let $\mathcal{C}$ be the collection of all cuts that are both s_1-t_1 and s_2-t_2 separating. Consider a length function $l : E \to \mathbb{R}_+$. Corollary 70.6a applied to the max-biflow min-cut theorem gives:

(71.15) $\min\{\text{dist}_l(s_1,t_1), \text{dist}_l(s_2,t_2)\}$ is equal to the maximum value of $\sum_{C\in\mathcal{C}} y(C)$, where $y : \mathcal{C} \to \mathbb{R}_+$ is such that $\sum_{C\in\mathcal{C}} y(C)\chi^C \leq l$.

Then Corollary 71.3a implies (Seymour [1978], Pevzner [1979b]):

Corollary 71.3b. *If l is integer-valued, we can take y half-integer valued.*

Proof. Replace each edge e by a path of length $2l(e)$. This makes the bipartite graph H. Applying Corollary 71.3a to H does the rest. ∎

Bipartiteness is necessary in Corollary 71.3a, since otherwise the graph in Figure 71.4 (Seymour [1977b], cf. Hu [1973]) would yield a contradiction. (This answers a question of Fulkerson [1971a].)

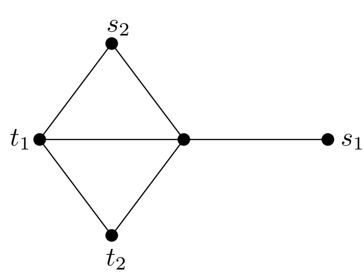

Figure 71.4
The minimum of the distances of s_1 and t_1 and of s_2 and t_2 is equal to 2, but there exist no two disjoint cuts each separating both s_1 and t_1, and s_2 and t_2.

From a more general hypergraph result of Seymour [1977b] (Theorem 80.1), it follows that Figure 71.4 is critical for the existence of an integer-valued packing of cuts:

Theorem 71.4. *Let $G = (V, E)$ be a graph and let $s_1, t_1, s_2, t_2 \in V$. Then for each $l : E \to \mathbb{Z}_+$, the maximum in* (71.15) *is attained by an integer-valued y if and only if G has no subgraph contractible to the graph in Figure* 71.4*, up to permuting indices and permuting s_1 and t_1.*

Again, we assume that the subgraph contains the s_i and t_i, and that these vertices are contracted to the vertices indicated by s_i and t_i in the figure. For a proof, we refer to Section 80.5a.

Notes. Seymour [1981a] showed the following related result: let $G = (V, E)$ be a bipartite graph, and choose $s_1, t_1, s_2, t_2 \in V$, with s_1, s_2 in one colour class and t_1, t_2 in the other. Choose odd integers $d_1 \leq \text{dist}_G(s_1, t_1)$ and $d_2 \leq \text{dist}_G(s_2, t_2)$ such that $d_1 + d_2 \leq \text{dist}_G(s_1, s_2) + \text{dist}_G(t_1, t_2)$ and $d_1 + d_2 \leq \text{dist}_G(s_1, t_2) + \text{dist}_G(t_1, s_2)$. Then there exist disjoint cuts, d_1 of which separate s_1 and t_1 and not s_2 and t_2, and d_2 of which separate s_2 and t_2 and not s_1 and t_1.

Let $\mathcal{S}$ be a collection of nonempty proper subsets of a finite set T. Let $G = (V, E)$ be a graph with $V \supseteq T$. Let $\mathcal{A}$ be the collection of subsets U of V with $U \cap T \in \mathcal{S}$.

Consider any length function $l : E \to \mathbb{R}_+$ and any $d : \mathcal{S} \to \mathbb{R}_+$. The multicut analogue of the multiflow problem asks for a function $y : \mathcal{A} \to \mathbb{R}_+$ such that

(71.16) $$\sum_{U \in \mathcal{A}} y(U) \chi^{\delta_E(U)} \leq l$$

and such that

(71.17) $$\sum (y(U) \mid U \in \mathcal{A}, U \cap T = X) = d(X)$$

for each $X \in \mathcal{S}$. A necessary condition for the existence of y is that

(71.18) $$\text{dist}_l(s, t) \geq \sum (d(X) \mid X \in \mathcal{S}, X \text{ splits } s, t)$$

for all distinct $s, t \in T$. (Here X *splits* s, t if X contains precisely one of s, t.) Karzanov [1984] showed that this condition is sufficient for each graph G and each l if and only if $\mathcal{S}$ contains no three pairwise crossing sets. If moreover l and d are integer, there is a half-integer y. If moreover $l(C)$ is even for each circuit C and both sides of (71.18) have the same parity for all s, t, then there is an integer y. Karzanov [1984] also gave a polynomial-time greedy-type algorithm to find y.

As for the corresponding maximization problem, consider any length function $l : E \to \mathbb{R}_+$ and the problem

(71.19) $$\min\{l^{\mathsf{T}} x \mid x \in \mathbb{R}_+^E : x(\delta_E(U)) \geq 1 \text{ for each } U \in \mathcal{A}\}.$$

By linear programming duality, this minimum is equal to the maximum value of

(71.20) $$\sum_{U \in \mathcal{A}} y(U),$$

where $y : \mathcal{A} \to \mathbb{R}_+$ satisfies (71.16). Karzanov [1984] showed the following. Let $\mathcal{S}$ have the following property: for any three pairwise crossing sets A_1, A_2, A_3 in $\mathcal{S}$, there exist $\gamma_1, \gamma_2, \gamma_3 \geq 0$ and $z : \mathcal{S} \to \mathbb{R}_+$ such that

(71.21) $$\sum_{i=1}^{3} \gamma_i \leq \sum_{U \in \mathcal{S}} z_U \text{ and } \sum_{i=1}^{3} \gamma_i \chi^{\delta_R(A_i)} > \sum_{U \in \mathcal{S}} z_U \chi^{\delta_R(U)},$$

where $R := \{st \mid s, t \in T, s \neq t\}$. Then the maximum value of (71.20) is equal to the minimum value of

(71.22) $$\sum_{r \in R} \beta(r) \mathrm{dist}_l(r),$$

where $\beta : R \to \mathbb{R}_+$ satisfies $\beta(\delta_R(U)) \geq 1$ for each $U \in \mathcal{S}$. (We write $\mathrm{dist}_l(r)$ for $\mathrm{dist}_l(s, t)$ if $r = st$.) This specifies the above $x : E \to \mathbb{R}_+$ as a function

(71.23) $$x = \sum_{r \in R} \beta(r) \chi^{P_r},$$

where P_r is a shortest r-path with respect to l, since

(71.24) $$l^{\mathsf{T}} x = \sum_{r \in R} \beta(r) l(P_r) \text{ and } x(\delta_E(U)) \geq \sum_{r \in \delta_R(U)} \beta(r) = \beta(\delta_R(U)) \geq 1$$

for each $U \in \mathcal{S}$. (An *r-path* is a path connecting the vertices in r.) Again this characterization is tight.

This has as special cases theorems on packing $s - t$ cuts (Theorem 6.1), 2-commodity cuts (Theorem 71.3), and T-cuts (Corollary 29.9a).

These cases are further characterized by the following result of Karzanov [1985a]. Let T be a finite set and let $\mathcal{S}$ be a collection of nonempty proper subsets of T such that (i) if $U \in \mathcal{S}$, then $T \setminus U \in \mathcal{S}$, (ii) for each $t \in T$ there is a $U \in \mathcal{S}$ with $t \in U$ and $U \setminus \{t\} \notin \mathcal{S}$, (iii) for all distinct $s, t \in T$ there is a $U \in \mathcal{S}$ separating s and t. Let G be the complete graph on vertex set V with $V \supset T$ and $|V| \geq |T| + 2$. Then minimum (71.19) is attained by an integer optimum solution x for each $l : E \to \mathbb{R}_+$ if and only if:

(71.25)
(i) there exist $s, t \in T$ such that each set in $\mathcal{S}$ contains exactly one of s and t, and such that the collection of sets in $\mathcal{S}$ containing s, is closed under unions and intersections,
or (ii) $T = \{s_1, t_1, s_2, t_2\}$ and $\mathcal{S} = \{\{s_1, s_2\}, \{s_1, t_2\}, \{t_1, s_2\}, \{t_1, t_2\}\}$,
or (iii) $\mathcal{S}$ is equal to the collection of odd-size subsets of T, where $|T|$ is even.

71.4. Further results and notes

71.4a. Two disjoint paths in undirected graphs

The polynomial-time solvability of the 2 vertex-disjoint paths problem in undirected graphs was shown by Seymour [1980b], Shiloach [1980b], and Thomassen [1980]. As was observed by Seymour [1980b], this can be derived from the following characterization of Seymour [1980b] and Thomassen [1980] (as usual, $N(K)$ denotes the set of vertices not in K adjacent to at least one vertex in K):

Theorem 71.5. *Let $G = (V, E)$ be a graph and let s_1, t_1, s_2, t_2 be distinct vertices. Then G has disjoint paths P_1 and P_2, where P_i connects s_i and t_i ($i = 1, 2$), if and only if there is no subset U of V such that:*

(71.26) (i) $s_1, t_1, s_2, t_2 \in U$,
(ii) $|N(K)| \leq 3$ *for each component* K *of* $G - U$;
(iii) *the graph* H *obtained from* $G[U]$ *by adding, for each component* K *of* $G - U$ *and each distinct* $u, v \in N(K)$, *an edge connecting* u *and* v, *is planar, with* s_1, s_2, t_1, t_2 *in this order cyclically on the outer boundary of* H.

In fact, condition (ii) is superfluous. (Theorem 71.5 was proved for 4-connected graphs by Jung [1970], generalizing Watkins [1968] who proved it for 4-connected graph containing a subdivision of K_5.)

The polynomial-time solvability of the 2 vertex-disjoint paths problem can be derived by observing that we can reduce the problem if there is a $K \subseteq V \setminus \{s_1, t_1, s_2, t_2\}$ with $|N(K)| \leq 3$ (remove K and add edges as in (71.26)(iii)). So we can assume that no such K exists. Hence, by the characterization, if no paths as required exist, the graph should be planar with the terminals in the cyclic order s_1, s_2, t_1, t_2 along the outer boundary — this can be tested in polynomial time. (Khuller, Mitchell, and Vazirani [1992] gave a parallel implementation.)

A related result for the 2 edge-disjoint paths problem was given by Dinits and Karzanov [1979] and Seymour [1980b]:

(71.27) Let $G = (V, E)$ be a connected graph and let $s_1, t_1, s_2, t_2 \in V$. Then G has edge-disjoint paths P_1 and P_2, where P_i connects s_i and t_i $(i = 1, 2)$ if and only if the cut condition holds and there is no $F \subseteq E$ such that the graph G/F, obtained from G by contracting all edges in F, is connected and planar and has maximum degree ≤ 3, while s_1, s_2, t_1, t_2 are distinct, all have degree at most 2, and occur in this order around the outer boundary of G/F.

This implies in particular that if G is 3-edge-connected, then the 2 edge-disjoint paths problem has a solution, for any choice of two nets.

71.4b. A directed 2-commodity flow theorem

Frank [1989] observed that a directed version of the 2-commodity flow theorem holds:

Theorem 71.6. *Let* $D = (V, A)$ *be as digraph, and let* R *consist of two parallel classes of arcs, with* $(V, A \cup R^{-1})$ *Eulerian. Then the cut condition is necessary and sufficient for the solvability of the arc-disjoint paths problem.*

Proof. Let R consist of k_i parallel arcs from s_i to t_i, for $i = 1, 2$. With Menger's theorem, the cut condition implies that there exist k_1 arc-disjoint $s_1 - t_1$ paths in D. After deleting the arcs of these paths from D, the remainder has k_2 arc-disjoint $s_2 - t_2$ paths, as adding k_2 parallel $t_2 - s_2$ arcs makes the remainder Eulerian. ∎

This proof also gives a polynomial-time algorithm. We should note that in the directed case, Eulericity is rather prohibitive: unlike in the undirected case we cannot make a digraph Eulerian by some simple doubling argument.

Frank, Ibaraki, and Nagamochi [1995,1998] gave a characterization and polynomial-time algorithm for the problem: given an Eulerian digraph $D = (V, A)$ and

$s_1, t_1, s_2, t_2 \in V$, find two arc-disjoint directed paths P_1 and P_2, where P_i connects s_i and t_i, in one way or the other ($i = 1, 2$). The characterization is analogous to Theorem 71.5.

It implies a characterization and algorithm of Ibaraki and Poljak [1991] for the 3 arc-disjoint paths problem if the Euler condition holds. For let $D = (V, A)$ be a digraph, and let $s_1, t_1, \ldots, s_3, t_3 \in V$, such that for $R := \{(s_1, t_1), (s_2, t_2), (s_3, t_3)\}$, the digraph $(V, A \cup R^{-1})$ is Eulerian. Extend D by four new vertices x_1, y_1, x_2, y_2 and arcs (t_1, x_2), (x_2, s_2), (t_3, y_1), (y_1, s_1), (t_2, y_2), (y_2, x_1), (x_1, s_3). Then the new digraph is Eulerian. Moreover, it has arc-disjoint directed $x_i - y_i$ paths (for $i = 1, 2$) if and only if D has arc-disjoint $s_i - t_i$ paths (for $i = 1, 2, 3$).

71.4c. Kleitman, Martin-Löf, Rothschild, and Whinston's theorem

Let G be an undirected graph. Suppose that we have four disjoint sets S_1, T_1, S_2, T_2 of vertices, and that we want to know the maximum number of edge-disjoint paths, each connecting either S_1 and T_1, or S_2 and T_2. Generally it is *not true* that the maximum number of such paths is equal to the minimum number of edges intersecting each such path. This even is not the case if the graph is Eulerian, as is shown by the graph in Figure 71.5 (cf. Rothschild and Whinston [1966b]). (One

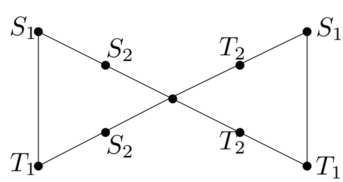

Figure 71.5
The maximum number of edge-disjoint paths each connecting vertices labeled S_i and T_i for some i, is equal to 4, whereas the minimum size of an edge set intersecting each such path is equal to 5. Note that the graph is Eulerian.

could think of a proof method based on adding 4 new vertices s_1, t_1, s_2, t_2, adjacent, by a large number of parallel edges, to all vertices in S_1, T_1, S_2, T_2 respectively, and then applying Corollary 71.1d. But this procedure can create new paths, for instance, from S_1 to T_1 via s_2.)

However, if S_1, T_1, S_2, T_2 partition the vertex set, such a generalization holds, as was shown by Kleitman, Martin-Löf, Rothschild, and Whinston [1970]. In fact, they showed a more general result, that can be proved with the help of the following theorem equivalent to (the edge-disjoint undirected version of) Menger's theorem (which is the special case where A and B are stars).

If $G = (V, E)$ a graph and $A, B \subseteq E$, we say that a path *connects* A and B if it traverses at least one edge in A and at least one edge in B.

Theorem 71.7. *Let $G = (V, E)$ be a graph and let $A, B \subseteq E$. Then the maximum number of edge-disjoint paths each connecting A and B is equal to the minimum number of edges intersecting each such path.*

Proof. We can assume that $A \cap B = \emptyset$, since deleting any edge in $A \cap B$ reduces both optima by 1.

Construct a new graph H as follows. Add two new vertices s and t. For each edge $e \in A \cup B$, put a new vertex v_e on e, and connect it to s if $e \in A$ and to t if $e \in B$.

We apply Menger's theorem to the $s-t$ paths in H. Let $Q_1, \ldots, Q_k$ be a maximum number of edge-disjoint $s-t$ paths in H. Consider any of these paths Q_j. We can assume that the second vertex, v_a say, and the one but last vertex, v_b say, of Q_j are the only two vertices on Q_j that belong to $\{v_e \mid e \in A \cup B\}$ (otherwise we can shortcut Q_j, since each vertex v_e has degree 3). Replacing the first two edges of Q_j by edge a of G, and the last two edges of Q_j by edge b of G, we obtain a path P_j in G connecting A and B.

This gives k edge-disjoint paths in G each connecting A and B. By Menger's theorem, there exists a set D of k edges of H intersecting each $s-t$ path. For $e \in A \cup B$, replacing (in D) any edge sv_e and any of the split-offs of e, by e, we obtain a set C of at most k edges in G that intersects each path connecting A and B. Indeed, consider any path P in G connecting A and B. We can assume that it intersects A and B only at its ends. So we can transform P to an $s-t$ path Q in H, by deviating the end edges towards s and t. Then Q intersects D, implying that P intersects C. This shows the theorem. ∎

This implies the theorem of Kleitman, Martin-Löf, Rothschild, and Whinston [1970]:

Corollary 71.7a. *Let $G = (V, E)$ be a graph, let $S_1, T_1, \ldots, S_k, T_k$ be subsets of V, with $S_i \cap T_i = \emptyset$ for $i = 1, \ldots, k$, and define $U_i := V - S_i - T_i$ for $i = 1, \ldots, k$. If $U_1, \ldots, U_k$ are disjoint, then the maximum number of edge-disjoint paths among $\{P \mid \exists i : P \text{ is an } S_i - T_i \text{ path}\}$ is equal to the minimum number of edges intersecting each such path.*

Proof. We can assume that the U_i partition V, since we can add an extra pair S_0, T_0 with $S_0 := V - U_1 - \cdots - U_k$ and $T_0 := \emptyset$. We can also assume that, for any i, no edge connects S_i and T_i, since deleting it reduces both optima by 1.

Let R be the set of edges connecting distinct sets among $U_1, \ldots, U_k$. Then for each i, any inclusionwise minimal $S_i - T_i$ path has its end edges in R and has no other edges in R (since all internal vertices belong to U_i). Let A be the set of edges e in R such that e is disjoint from an even number of $S_1, \ldots, S_k$, and let $B := R - A$.

The sets A and B have the following property. Let P be a path with only its end edges in R. Then:

(71.28) P connects S_i and T_i for some i if and only if P connects A and B.

With Theorem 71.7, this immediately proves the present corollary.

To prove (71.28), let u and w be the first and last vertex of P, let I be the set of internal vertices of P, and let c and d be the first and last edge of P. Since only the end edges of P are in R, we know by definition of R that there exists an i such that each internal edge of P only meets U_i and such that $u, v \notin U_i$. In other words, $I \subseteq U_i$ and $u, w \in S_i \cup T_i$.

Consider any $j \neq i$. As $I \subseteq U_i$ and $U_i \cap U_j = \emptyset$, we know $I \subseteq S_j \cup T_j$. As no edge connects S_j and T_j, either $I \subseteq S_j$ and $u, w \in U_j \cup S_j$, or $I \subseteq T_j$ and $u, w \in U_j \cup T_j$. So $c \cap S_j = \emptyset$ if and only if $d \cap S_j = \emptyset$. Hence, by definition of A and B:

(71.29) P connects A and B $\iff$ precisely one of $c \cap S_i$ and $d \cap S_i$ is nonempty $\iff$ precisely one of u, w belongs to S_i, the other belongs to T_i $\iff$ P connects S_i and T_i.

So we have (71.28). ∎

The proof method directly gives an algorithmic reduction to the (one-commodity) disjoint paths problem. (Kleitman [1971] and Kant [1974] describe other methods.)

71.4d. Further notes

Itai and Zehavi [1984] showed that if $G = (V, E)$ is a graph and $s_1, t_1, s_2, t_2 \in V$ are such that for $i = 1, 2$, there exist k edge-disjoint $s_i - t_i$ paths, then for each choice of d_1, d_2 with $d_1 + d_2 = k$, there exist d_1' and d_2' with $d_1' + d_2' = k$, $d_1 \leq d_1' \leq d_1 + 1$, and a collection of edge-disjoint paths such that d_i' of them connect s_i and t_i $(i = 1, 2)$.

The integer 2-commodity flow problem is solvable in polynomial time if $G + H$ is planar — see Section 74.2b.

Rebman [1974] studied a generalization of totally unimodular matrices appropriate for 2-commodity flows.

Chapter 72

Three or more commodities

Hu's 2-commodity theorem concerns multiflows where the demand graph H consists of two edges — whatever the supply graph is. In this chapter we consider to which extent Hu's theorem can be generalized to other demand graphs. That is, we study for which graphs $H = (T, R)$ it is true that for *each* graph $G = (V, E)$ with $V \supseteq T$ and each capacity and demand functions the phenomena described in the previous chapter are maintained (sufficiency of the cut condition, existence of a half-integer multiflow, sufficiency of the Euler condition to obtain an integer multiflow).

Results of Papernov [1976], Lomonosov [1976,1985], and Seymour [1980c] give an answer to this question: the graphs H are those containing neither of the two graphs in Figure 72.1 below as a subgraph. These are exactly the graphs H that are the union of two stars or are equal to K_4 or C_5 (up to adding isolated vertices, loops, and parallel edges).

Except if stated otherwise, throughout this chapter $G = (V, E)$ and $H = (T, R)$ denote the supply and demand graph, in the sense of Chapter 70. The pairs in R are called the *nets*. If $s_1, t_1, \ldots, s_k, t_k$ are given, then $R := \{s_1t_1, \ldots, s_kt_k\}$. If demands $d_1, \ldots, d_k$ are given, then $d(s_it_i) = d_i$. We denote $G + H = (V, E \cup R)$, where the disjoint union of E and R is taken, respecting multiplicities.

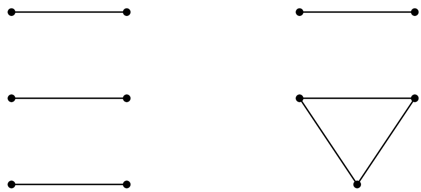
72.1. Demand graphs for which the cut condition is sufficient

Consider for any graph $H = (T, R)$ the following property:

(72.1) H has neither of the two graphs of Figure 72.1 as a subgraph.

Theorem 72.1. *Let $H = (T, R)$ be a simple graph without isolated vertices. Then H satisfies* (72.1) *if and only if $H = K_4$, or $H = C_5$, or H is the union of two stars.*

Proof. Sufficiency is direct. Necessity is shown by induction on $|R|$. If all degrees of H are at most 2, the theorem is easy. Assume now that H has a vertex u of degree at least 3. For any edge $e = uw$ incident with u, if $H - e$ is K_4 or C_5 (after deleting any isolated vertex), then H contains one of the



(a) (b)

Figure 72.1

graphs in Figure 72.1. So $H - e \neq K_4$ and $H - e \neq C_5$. Hence, by induction, there exist two vertices s, t such that each edge of $H - e$ intersects $\{s, t\}$. If $u \in \{s, t\}$, then H is the union of two stars. So we can assume that $u \notin \{s, t\}$. Hence each neighbour v of u with $v \neq w$ belongs to $\{s, t\}$. So u has degree 3, and each edge f of H not incident with u connects two neighbours of u (as any neighbour of u can serve as w). So $H = K_4$. ∎

The following theorem extends Theorem 71.1 and Corollary 71.1c, and was proved by Lomonosov [1976,1985] and Seymour [1980c] for $H = K_4$, and by Lomonosov [1976,1985] for $H = C_5$. The proof below is inspired by the direct proof given by Frank [1990e]. (Here $G + H$ is the graph $(V, E \cup R)$, taking multiplicities of edges into account.)

Theorem 72.2. *Let $G = (V, E)$ and $H = (T, R)$ be supply and demand graphs, with $T \subseteq V$. Let $H = (T, R)$ satisfy* (72.1)*, with $G + H$ Eulerian. Then there exist edge-disjoint paths P_r (for $r \in R$) such that P_r connects the vertices in r if and only if the cut condition holds.*

Proof. Necessity being easy, we show sufficiency. Let G, H form a counterexample with $|E| + |R|$ minimal. Then G is connected. Also, there is no net $r \in R$ parallel to an edge $e \in E$, since otherwise deleting r and e would give a smaller counterexample.

Call a subset U of V *tight* if $d_E(U) = d_R(U)$.[17] By the minimality of the counterexample we have[18]

(72.2) for each pair of edges e and f incident with a vertex v there is a tight set splitting both e and f.

Otherwise we can replace $e = uv$ and $f = wv$ by a new edge uw to obtain a smaller counterexample.

Another observation is:[19]

[17] As usual, $d_E(U) = |\delta_E(U)|$ and $d_R(U) = |\delta_R(U)|$.

[18] A set X *splits* a pair uv if X contains exactly one of u and v.

[19] $F[X, Y]$ denotes the set of pairs xy in F with $x \in X$ and $y \in Y$.

(72.3) for each tight set X and each $v \in V \setminus X$ we have $|E[X,v]| - |R[X,v]| \leq \frac{1}{2}(\deg_E(v) - \deg_R(v))$,

since, setting $X' := X \cup \{v\}$ we have $d_E(X') = d_E(X) + \deg_E(v) - 2|E[X,v]|$ and $d_R(X') = d_R(X) + \deg_R(v) - 2|R[X,v]|$. Then $d_E(X) = d_R(X)$ and $d_E(X') \geq d_R(X')$ give (72.3).

The following is also useful to observe:

(72.4) if X and Y are tight, and no net connects $X \setminus Y$ and $Y \setminus X$, then $X \cap Y$ and $X \cup Y$ are tight again, and no edge connects $X \setminus Y$ and $Y \setminus X$.

To see this, consider:

(72.5)
$$\begin{aligned} & d_R(X) + d_R(Y) = d_E(X) + d_E(Y) \\ & = d_E(X \cap Y) + d_E(X \cup Y) + 2|E[X \setminus Y, Y \setminus X]| \\ & \geq d_E(X \cap Y) + d_E(X \cup Y) \geq d_R(X \cap Y) + d_R(X \cup Y) \\ & = d_R(X) + d_R(Y). \end{aligned}$$

So we have equality throughout, proving (72.4).

This implies:

(72.6) let B be a set of vertices intersecting all nets, and let X and Y be tight sets with $X \cap B = Y \cap B$. Then $X \cap Y$ and $X \cup Y$ are tight.

Otherwise, by (72.4) there is a net connecting $X \setminus Y$ and $Y \setminus X$, and hence not intersecting B, a contradiction.

We next show that for each terminal t:[20]

(72.7) $\deg_E(t) = \deg_R(t)$.

Assume $\deg_E(t) > \deg_R(t)$. Let $\mathcal{X}$ be the collection of inclusionwise maximal tight subsets of $V \setminus \{t\}$. For each edge or net p, let $\mathcal{X}_p$ denote the set of $U \in \mathcal{X}$ splitting p.

We have $|\mathcal{X}_e| \geq 2$ for each edge $e \in \delta_E(t)$, since by (72.2), each pair of edges incident with t is split by some $U \in \mathcal{X}$, and since no tight set X splits all edges incident with t simultaneously, as it would imply

(72.8)
$$\begin{aligned} & d_E(X \cup \{t\}) = d_E(X) - \deg_E(t) = d_R(X) - \deg_E(t) \\ & < d_R(X) - \deg_R(t) \leq d_R(X \cup \{t\}). \end{aligned}$$

Also we have $|\mathcal{X}_r| \leq 2$ for each $r \in \delta_R(t)$, and we have $|\mathcal{X}| \leq 4$. Indeed, let $r = st$. By (72.1), there exists a vertex u such that each net intersects $B := \{s, t, u\}$. Therefore, by (72.6), any two sets in $\mathcal{X}$ have a different intersection with B (as otherwise their union is tight, contradicting their maximality). As no set in $\mathcal{X}$ contains t, we have the required inequalities.

This gives with (72.3):

[20] A *terminal* is a vertex covered by at least one net.

$$
\begin{aligned}
(72.9) \qquad 2(\deg_E(t)-\deg_R(t)) &\leq \sum_{e\in\delta_E(t)} |\mathcal{X}_e| - \sum_{r\in\delta_R(t)} |\mathcal{X}_r| \\
&= \sum_{U\in\mathcal{X}} (|E[U,t]| - |R[U,t]|) \leq \tfrac{1}{2}|\mathcal{X}|(\deg_E(t)-\deg_R(t)) \\
&\leq 2(\deg_E(t)-\deg_R(t)).
\end{aligned}
$$

Hence equality holds throughout in (72.9). So $|\mathcal{X}| = 4$, $|\mathcal{X}_e| = 2$ for each $e \in \delta_E(t)$, and $|\mathcal{X}_r| = 2$ for each $r \in \delta_R(t)$. Hence the $\mathcal{X}_e$ form a graph on the vertex set $\mathcal{X}$, such that any two of its edges intersect (by (72.2)), but no vertex is in all edges (since no tight set splits all edges in $\delta_E(t)$). So there is a $U \in \mathcal{X}$ contained in no $\mathcal{X}_e$; that is, $E[U,t] = \emptyset$. Since we have equality in (72.3) (as we have equality throughout in (72.9)), it follows that $\deg_E(t) - \deg_R(t) = 0$, that is, we have (72.7).

(72.7) implies that

(72.10) no two terminals s and t are adjacent,

since otherwise $d_E(\{s,t\}) < \deg_E(s) + \deg_E(t) = \deg_R(s) + \deg_R(t) = d_R(\{s,t\})$, contradicting the cut condition.

Now choose $st \in R$. By (72.1), there is a vertex $u \notin \{s,t\}$ such that each commodity disjoint from st intersects u. We can assume that u is a terminal, as otherwise s and t are the only terminals, in which case the theorem follows from Menger's theorem. Since, by (72.7), $V \setminus \{u\}$ is tight, there exists a tight subset Z which is inclusionwise minimal under the conditions that $s,t \in Z$ and $u \notin Z$.

Then s has a neighbour $v \in Z$. Otherwise we have

(72.11) $d_E(Z) = \deg_E(s) + d_E(Z\setminus\{s\}) \geq \deg_R(s) + d_R(Z\setminus\{s\}) > d_R(Z)$

(as $s,t \in Z$), contradicting the tightness of Z.

Let $\mathcal{Y}$ be the collection of all inclusionwise maximal tight subsets of $V\setminus\{v\}$ containing s. By (72.10), v is not a terminal. Hence, by (72.3), $|E[Y,v]| \leq \frac{1}{2}\deg_E(v)$ for each $Y \in \mathcal{Y}$. Therefore, since (by (72.2)) each edge incident with v is split by at least one $Y \in \mathcal{Y}$, we have $|\mathcal{Y}| \geq 3$.

Then by (72.6), the sets in $\mathcal{Y}$ all have different intersections with $\{t,u\}$. (By definition, each set in $\mathcal{Y}$ contains s.) Moreover, $Y \cap \{t,u\} \neq \{t\}$ for each $Y \in \mathcal{Y}$, since otherwise also $Y \cap Z$ is tight (by (72.6), as $Z \cap \{t,u\} = \{t\}$), contradicting the minimality of Z (note that $v \notin Y \cap Z$).

So $|\mathcal{Y}| = 3$ and the sets in $\mathcal{Y}$ intersect $\{t,u\}$ in $\emptyset$, $\{u\}$, and $\{t,u\}$ — denote these sets by S, U, and W, respectively (cf. Figure 72.2).

By the maximality of S, U, and W, $S \cup U$ and $U \cup W$ are not tight. Hence, by (72.4), there is a net γ connecting $S \setminus U$ and $U \setminus S$, and a net δ connecting $W \setminus U$ and $U \setminus W$. Then γ and δ intersect $\{s,t,u\}$. As $s,t \notin \gamma$ (since $s,t \in S \cap U$) and $u \notin S \setminus U$, we know $\gamma = uw$ for some $w \in S \setminus U$. As $s,u \notin \delta$ (since $s \in S \cap W$ and $u \notin S \cup W$) and $t \notin U \setminus W$, we know $\delta = tx$ for some $x \in U \setminus W$. As st and tx are disjoint from uw, each net disjoint from uw contains t.

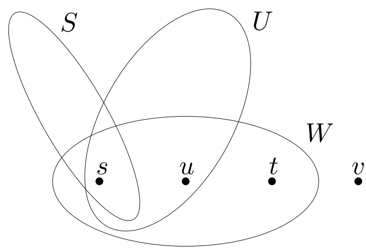


Figure 72.2

However, as edge sv connects $W \cap S$ and $V \setminus (W \cup S)$, by (72.4) (applied to $X := W$ and $Y := V \setminus S$), there is a net sa connecting these two sets. Then $a \neq u, w, t$, and therefore sa is disjoint from u, w, t, a contradiction. ∎

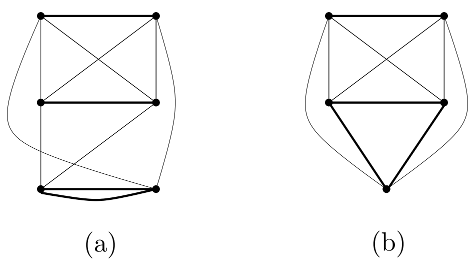

Figure 72.3
Examples where the cut and Euler conditions hold, but no fractional multiflow exists. The heavy lines are the nets and the other lines the edges. All capacities and demands are equal to 1.

Theorem 72.2 also holds if H consists of three disjoint edges — see Theorem 72.3. The examples in Figure 72.3 (from Papernov [1976]) show that the condition on the demand graph H in Theorem 72.2 is close to tight. This is made more precise in the following characterization implied by Theorem 72.2 (the equivalence (i)⇔(iv)⇔(v) is due to Papernov [1976], the other equivalences to Lomonosov [1976,1985] and (for K_4) to Seymour [1980c]):

Corollary 72.2a. *For each simple graph $H = (T, R)$ without isolated vertices, the following are equivalent:*

(72.12) (i) *for each graph $G = (V, E)$ with $V \supseteq T$, and each $c : E \to \mathbb{R}_+$ and $d : R \to \mathbb{R}_+$, the cut condition implies the existence of a fractional multiflow;*

(ii) *for each graph* $G = (V, E)$ *with* $V \supseteq T$*, and each* $c : E \to \mathbb{Z}_+$ *and* $d : R \to \mathbb{Z}_+$*, the cut condition implies the existence of a half-integer multiflow;*

(iii) *for each graph* $G = (V, E)$ *with* $V \supseteq T$*, and each* $c : E \to \mathbb{Z}_+$ *and* $d : R \to \mathbb{Z}_+$*, the cut and Euler conditions imply the existence of an integer multiflow;*

(iv) H *contains none of the graphs in Figure* 72.1 *as subgraph;*

(v) $H = K_4$*, or* $H = C_5$*, or* H *is the union of two stars.*

Proof. The equivalence (iv)$\Leftrightarrow$(v) was shown in Theorem 72.1. The implications (iii)$\Rightarrow$(ii)$\Rightarrow$(i) are general multiflow theory, while (i)$\Rightarrow$(iv) follows from the examples of Figure 72.3. The implication (iv)$\Rightarrow$(iii) follows from Theorem 72.2, by replacing each edge of G by $c(e)$ parallel edges and each edge of H by $d(e)$ parallel edges. ∎

Karzanov [1979b] gave a strongly polynomial-time algorithm finding a half-integer multiflow as required if H satisfies (72.12)(iv) (or finding a cut violating the cut condition).

72.2. Three commodities

An important case excluded by the theorems in the previous sections is that of a demand graph consisting of three disjoint edges, with $d = \mathbf{1}$.

Theorem 72.3. *Let* $G = (V, E)$ *and* $H = (T, R)$ *be graphs, with* $T \subseteq V$*, such that* $G + H$ *is Eulerian and such that* R *consist of three disjoint edges. Then there exist edge-disjoint paths* P_r *(for* $r \in R$*) such that* P_r *connects the vertices in* r *if and only if the cut condition holds.*

Proof. Let $R = \{r_1, r_2, r_3\}$. Let G be a counterexample with a minimum number of edges. Then G is connected, and each vertex of G has degree at least two. Call $U \subseteq V$ *tight* if $d_E(U) = d_R(U)$. Also:

(72.13) $d_R(U) = 3$ for each tight nonempty proper subset U of V.

To see this, let U be a counterexample with $d_E(U)$ smallest. Then $G[U]$ and $G - U$ are connected. (Otherwise we could replace U by one of the components K of $G[U]$ or $G - U$, while $d_E(K) < d_E(U)$.) Also, $d_R(U) = d_E(U) \geq 1$ as G is connected. So we can assume that $r_1 \in \delta_R(U)$ and that $V \setminus U$ spans r_2. Contract U to obtain graph G/U. As the cut condition remains to hold, and as G/U is smaller than G (since $|U| \geq 2$, as $d_E(v) \geq 2 > d_R(v)$ for each $v \in V$), G/U contains edge-disjoint paths Q_1 and Q_2 where Q_i connects (the contractions of) the vertices in r_i ($i = 1, 2$). As $G[U]$ is connected, $G[U]$ contains a path connecting the vertex in $r_1 \cap U$ and the end of the edge in $\delta_E(U)$ that is traversed by Q_1. It follows that G contains two edge-disjoint paths P_1 and P_2 where P_i connects the vertices in r_i ($i = 1, 2$). Removing the edges of P_1 and P_2 from G, we are left with a graph with exactly two vertices of odd degree, namely the vertices in the pair r_3. Hence this graph contains a path P_3 connecting the vertices in r_3. Then P_1, P_2, and P_3 are as required. This is a contradiction, proving (72.13).

Consider now any $r = st \in R$ and any edge tu of G incident with t. Let $R' := (R \setminus \{st\}) \cup \{su\}$. Let $G' = (V, E')$ be the graph obtained from G by deleting edge tu. If the cut condition holds for G', R', we obtain (by induction) three paths in G' that directly yields paths as required in G. So we can assume that there is a subset U of V with $d_{R'}(U) > d_{E'}(U)$ and $t \notin U$. As $G' + H'$ is Eulerian, we know $d_{R'}(U) \geq d_{E'}(U) + 2$. Then

$$(72.14) \qquad d_R(U) \geq d_{R'}(U) - 1 \geq d_{E'}(U) + 1 \geq d_E(U) \geq d_R(U).$$

So we have equality throughout, and hence $d_E(U) = d_R(U)$, and $s \notin U$, $u \in U$ (otherwise $d_{R'}(U) \geq d_R(U)$). So $d_R(U) \leq 2$, contradicting (72.13). ∎

With Theorem 72.2, this implies the following characterization:

Corollary 72.3a. *For any loopless graph $H = (T, R)$ without isolated vertices, the following are equivalent:*

(72.15)
(i) *for each graph $G = (V, E)$ with $V \supseteq T$ satisfying the cut and Euler condition (with respect to H), the edge-disjoint paths problem has a solution;*
(ii) *T has two vertices intersecting all pairs in R, or $|T| \leq 4$, or H is C_5 with parallel edges added, or R consists of three disjoint edges;*
(iii) *H has no subgraph equal to* , , , , *or* .

Proof. The implication (iii)⇒(ii) follows from Theorem 72.1. The implication (ii)⇒(i) follows from Theorems 72.2 and 72.3. The implication (i)⇒(iii) follows from the examples in Figure 72.3, since from each of graphs given in (iii) we can obtain  or , by identifying some vertices. Then from the examples in Figure 72.3 we can obtain examples for the graphs in (iii) by adding two parallel edges between any pair of identified vertices. ∎

Notes. For $|R| = 3$, Okamura [1984a] showed that the cut condition implies the existence of a half-integer solution for the edge-disjoint paths problem. (This seems not to follow from Theorem 72.3. On the other hand, having Okamura's result, to prove Theorem 72.3 it suffices to show that if the Euler condition holds and a half-integer solution exists, there is an integer solution.)

This implies the following characterization, extending Corollary 72.3a.

Theorem 72.4. *For any loopless graph $H = (T, R)$ without isolated vertices, the following are equivalent:*

(72.16)
(i) *for each graph $G = (V, E)$ with $V \supseteq T$ satisfying the cut condition, the edge-disjoint paths problem has a fractional solution;*

(ii) *for each graph $G = (V, E)$ with $V \supseteq T$ satisfying the cut condition, the edge-disjoint paths problem has a half-integer solution;*
(iii) *for each graph $G = (V, E)$ with $V \supseteq T$ satisfying the cut and Euler condition, the edge-disjoint paths problem has a solution;*
(iv) *T has two vertices intersecting all pairs in R, or $|T| \leq 4$, or H is C_5 with parallel edges added, or R consists of three disjoint pairs;*
(v) *H has no subgraph equal to* , , , , *or* .

Figure 70.4 shows that there is no integer p such that if a 3-commodity problem, with integer capacities and demands, has a fractional solution, then it has a $1/p$-integer solution. More precisely, for each integer $k \geq 2$, there is a graph $G = (V, E)$ and a collection R of three disjoint pairs from V, such that for $c : E \to \mathbb{Z}_+$ defined by $c(e) = 1$ for each edge e and $d : R \to \mathbb{Z}_+$ with values $1, 2k, 2k$ respectively, there is a fractional multiflow, but each feasible solution has some of its values equal to $1/2k$.

By doubling capacities and demands, one obtains an example of a 3-commodity flow problem satisfying the Euler condition, where a fractional but no half-integer multiflow exists. A variant of the example gives a 3-commodity flow problem satisfying the Euler condition, where a half-integer but no integer solution exists.

M. Middendorf and F. Pfeiffer (cf. Pfeiffer [1990]) showed that it is NP-complete to decide if the edge-disjoint paths problem has a half-integer solution, even if the nets consist of three disjoint parallel classes of edges. This implies a result of Vygen [1995] that it is NP-complete to decide if the edge-disjoint paths problem has a solution, even if the nets consist of three disjoint parallel classes of edges and the Euler condition holds.

Let H_6 be the graph obtained from $K_{3,3}$ by adding in each of the two colour class one new edge (cf. Figure 72.3(a)). Seymour [1981a] showed for each graph $G = (V, E)$:

(72.17) G has no H_6 minor if and only if for each $R \subseteq E$ with $|R| \leq 3$ and each $c : E \setminus R \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$ satisfying the Euler condition, the cut condition implies the existence of an integer multiflow (where $(V, E \setminus R)$ is the supply graph).

The proof is by showing that each 3-connected graph without H_6 minor is K_5 or has no K_5 minor, and hence can be decomposed into planar graphs and copies of V_8 (Wagner's theorem (Theorem 3.3)).

72.2a. The $K_{2,3}$-metric condition

Karzanov [1987a] showed that a strengthened form of the cut condition, the '$K_{2,3}$-metric condition', is sufficient for having a fractional multiflow for a class of demand graphs larger than described in Section 72.1.

This is described as follows. Let Γ be a graph and let V be a finite set. A metric μ on V is called a *Γ-metric* if there is a function $\phi : V \to V\Gamma$ with

(72.18) $\mu(u, v) = \mathrm{dist}_\Gamma(\phi(u), \phi(v))$

for all $u, v \in V$. (Here $\mathrm{dist}_\Gamma(x, y)$ denotes the distance of x and y in Γ.)

Γ-metrics give rise to the following necessary condition, the *Γ-metric condition*, for the existence of a feasible fractional multiflow:

(72.19) $$\sum_{r=st\in R} d(r)\mu(s,t) \leq \sum_{e=uv\in E} c(e)\mu(u,v) \text{ for each } \Gamma\text{-metric } \mu \text{ on } V.$$

This is a specialization of condition (70.11). Since each cut gives a K_2-metric, and hence a $K_{2,3}$-metric, condition (72.19) includes the cut condition.

Karzanov [1987a] showed:

Theorem 72.5. *Let $G = (V, E)$ be a graph and let $H = (T, R)$ be a complete graph with $|T| = 5$ and $T \subseteq V$. Let $c : E \to \mathbb{R}_+$ and $d : R \to \mathbb{R}_+$. Then there exists a fractional multiflow if and only if the $K_{2,3}$-metric condition holds. If moreover c and d are integer, there is a half-integer multiflow. If moreover the Euler condition holds, there is an integer multiflow.*

Theorem 72.5 implies the following characterization:

Corollary 72.5a. *For each simple graph $H = (T, R)$ without isolated vertices, the following are equivalent:*

(72.20)
- (i) *for each graph $G = (V, E)$ with $V \supseteq T$, and each $c : E \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$, the existence of a fractional solution implies the existence of a half-integer solution;*
- (ii) *for each graph $G = (V, E)$ with $V \supseteq T$, and each $c : E \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$, the Euler condition and the existence of a fractional solution imply the existence of an integer solution;*
- (iii) *H has no three disjoint edges and no two disjoint triangles;*
- (iv) *$|VH| = 5$, or H is the union of a triangle and a star, or H is the union of two stars.*

That (72.20)(iv) implies (72.20)(i) follows from Theorem 72.5, as we can replace a star with center s by an edge sw, where w is a new vertex, with the construction of Dinits given in the proof of Corollary 71.1c. Conversely, (72.20)(i) implies (72.20)(iii). It requires giving a counterexample if H consists of three disjoint edges, and one if H consists of two disjoint triangles. If H consists of three disjoint edges, a counterexample was given in Figure 70.4. If H consists of two disjoint triangles, a counterexample follows (by doubling all capacities and demands) from Figure 72.4 (A.V. Karzanov, personal communication 2000), where c and d are integer, and where a quarter-integer, but no half-integer solution exists.

Karzanov [1991] conjectures that if R consists of two disjoint triangles and c and d are integer and satisfy the Euler condition, then the existence of a fractional solution implies the existence of a half-integer solution[21]. This would imply that for each fixed graph $H = (T, R)$ the following equivalences holds:

(72.21) (?) there is an integer k such that for each graph $G = (V, E)$ with $V \supseteq T$ and each $c : E \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$, if there is a feasible multiflow, then there exists a $\frac{1}{k}$-integer multiflow
$\Longleftrightarrow$ for each graph $G = (V, E)$ with $V \supseteq T$ and each $c : E \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$, if there is a feasible multiflow, then there exists a $\frac{1}{4}$-integer multiflow
$\Longleftrightarrow$ H has no three disjoint edges. (?)

[21] A proof of this was announced in Karzanov [1987a], but A.V. Karzanov communicated to me that the proof failed.

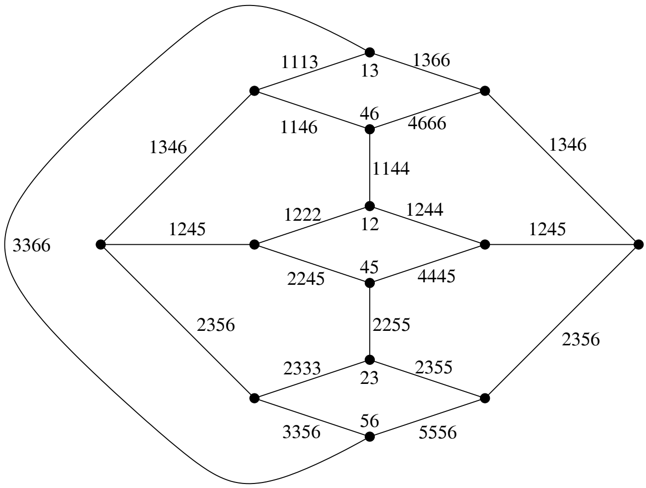

Figure 72.4

A quarter-integer multiflow exists, but no half-integer multiflow. The nets (indexed by $1, \ldots, 6$) are indicated by indices at vertices. All capacities and demands are 1. The quarter-integer multiflow is indicated by indices at the edges: k times index i at edge e means $f_i(e) = \frac{k}{4}$.

The nonexistence of a half-integer multiflow can be seen as follows. Give each of the (three) edges that connect terminals length 2, and any other edge length 1. Then the distance between the two terminals in any net is 4. Also, the sum of the lengths of the edges equals 24. So any flow f_i in a half-integer multiflow, can be decomposed as half of the sum of two flows following $s_i - t_i$ paths $P_{i,1}$ and $P_{i,2}$ of length 4. Moreover, on each edge, the capacity is fully used. Hence, each vertex v of degree 3 not being a terminal, is traversed by three paths $P_{i,j}$, each using a different pair of edges incident with v. One easily checks that this is not possible.

Karzanov [1998d] studied the existence of an integer multiflow if the nets form a disjoint union of a triangle and an edge.

72.2b. Six terminals

Okamura [1987] showed the following. Let $G = (V, E)$ and $H = (T, R)$ be a supply and a demand graph. If $|T| \leq 6$ and $k := |R|$ is odd, and if moreover G has k edge-disjoint $s - t$ paths, for each $st \in R$, then there exists a family $(P_r \mid r \in R)$ of edge-disjoint paths in G, where P_r connects the ends of r (for $r \in R$). (For $|T| \leq 5$ this was proved in Okamura [1984b].)

Okamura [1998] showed that if $|T| \leq 6$ and G is l-edge-connected, where

(72.22) $$l := \max_{U \subseteq V} d_R(U),$$

then the edge-disjoint paths problem has a half-integer solution (that is, for each $r \in R$ there exist paths P'_r and P''_r connecting the ends of r, such that each edge of G is in at most two of the paths P'_r, P''_r (over all $r \in R$)). She conjectures that here the condition $|T| \leq 6$ can be deleted.

72.3. Cut packing

By Theorem 70.5, Corollary 72.2a implies a fractional cut packing theorem. A stronger (integer) version of it was proved by Karzanov [1985b], which generalizes Theorem 71.3 (we follow the proof given in Schrijver [1991e]):

Theorem 72.6. *Let $G = (V, E)$ be a connected bipartite graph and let $H = (T, R)$ be a simple graph satisfying* (72.1)*, with $T \subseteq V$. Then G has disjoint cuts such that for each $st \in R$, $\mathrm{dist}_G(s, t)$ is equal to the number of these cuts separating s and t.*

Proof. Let $G = (V, E)$ be a counterexample with $|E|$ as small as possible. Define $d(u, v) := \mathrm{dist}_G(u, v)$ for $u, v \in V$. We first show:

(72.23) for each nonempty cut C there exist a pair $st \in R$ and an $s - t$ path P with $|EP \setminus C| \leq d(s, t) - 2$.

If not, contract all edges in C, giving graph G'. Then for all $st \in R$ we have

$$(72.24)\qquad d'(s', t') = \begin{cases} d(s, t) - 1 & \text{if } C \text{ separates } \{s, t\}, \\ d(s, t) & \text{if } C \text{ does not separate } \{s, t\}. \end{cases}$$

(Here and below, v' denotes the image of v in G, and d' denotes the distance function of G'.) As G is a smallest counterexample, G' has disjoint cuts $C_1, \ldots, C_t$ such that $d'(s', t')$ is equal to the number of cuts separating s' and t', for each $st \in R$. Together with C this gives, in the original graph G, cuts as required, by (72.24). This proves (72.23).

From (72.23) we derive:

(72.25) for all $u, w \in V$, there exists a pair $st \in R$ such that $\{s, t\} \cap \{u, w\} = \emptyset$ and such that
$$d(s, t) + d(u, w) \geq d(s, w) + d(u, t) \text{ and}$$
$$d(s, t) + d(u, w) \geq d(s, u) + d(w, t).$$

To prove this, let X be the set of vertices that are on at least one shortest $u - w$ path.

First, suppose that $X = V$. By (72.23), there exist $st \in R$ and an $s - t$ path P with $|EP \setminus \delta(u)| \leq d(s, t) - 2$. So P is a shortest $s - t$ path traversing u, and $u \neq s, t$. To see that $w \neq s, t$, suppose $w = t$, say. Then, as $d(u, w) = d(u, s) + d(s, w)$ (since $s \in X$),

$$\begin{aligned}(72.26)\qquad |EP \setminus \delta(u)| &= |EP| - 2 = d(s, u) + d(u, t) - 2 \\ &= d(s, u) + d(u, w) - 2 = 2d(s, u) + d(s, w) - 2 > d(s, w) - 2 \\ &= d(s, t) - 2,\end{aligned}$$

a contradiction. So $\{s,t\} \cap \{u,w\} = \emptyset$. Moreover,

(72.27) $$d(s,t) + d(u,w) = d(s,t) + d(u,s) + d(s,w) \geq d(s,w) + d(u,t).$$

One similarly shows the second inequality in (72.25).

Second, suppose that $X \neq V$. Let $C := \delta(X)$, and let G' be the graph obtained from G by contracting all edges in C. Then for each vertex x:

(72.28) $$d'(u',x') \geq d(u,x) - 1 \text{ and } d'(w',x') \geq d(w,x) - 1.$$

To see the first inequality, let P be a $u-x$ path in G with $|EP \setminus C| = d'(u',x')$. Choose P with $|EP \cap C|$ smallest. If the first inequality does not hold, then $|EP \cap C| \geq 2$. Then we can split P as $P'P''$ such that $|EP' \cap C| = 2$. Let P' connect u and v. As $|EP' \cap C| = 2$ and $u \in X$ we know $v \in X$. Since P' is not fully contained in X, we know that $|EP'| \geq d(u,v) + 2$. Let Q be a shortest $u-v$ path in G. Then $|EQ| = d(u,v) \leq |EP'| - 2$, and Q is fully contained in X. Let R be the concatenation QP''. Then $|ER \setminus C| \leq |EP \setminus C|$ and $|ER \cap C| = |EP \cap C| - 2$, contradicting the minimality of $|EP \cap C|$. This shows the first inequality in (72.28); the second inequality is proved similarly.

By (72.23), there exists $st \in R$ such that $d'(s',t') \leq d(s,t) - 2$. Then (72.28) implies $\{s,t\} \cap \{u,w\} = \emptyset$. Moreover, there exist a $v \in X$ and a shortest $s'-t'$ path in G' traversing v'. Hence

(72.29) $$\begin{aligned} d(s,t) + d(u,w) &\geq d'(s',t') + d(u,w) + 2 \\ &= d'(s',v') + d'(v',t') + d(u,v) + d(v,w) + 2 \\ &\geq d'(s',v') + d'(v',t') + d'(u',v') + d'(v',w') + 2 \\ &\geq d'(s',w') + d'(u',t') + 2 \geq d(s,w) + d(u,t). \end{aligned}$$

This gives the first inequality in (72.25); the second inequality is proved similarly.

(72.25) implies that for each pair $\{u,w\}$ of vertices of G there exists an $st \in R$ disjoint from $\{u,w\}$. So H is not the union of two stars, and hence $H = K_4$ or $H = C_5$ (up to isolated vertices, which we can ignore).

If $H = K_4$, let $T = \{r_1, r_2, r_3, r_4\}$. Then by (72.25):

(72.30) $$\begin{aligned} d(r_1,r_2) + d(r_3,r_4) &\geq d(r_1,r_3) + d(r_2,r_4) \geq d(r_1,r_4) + d(r_2,r_3) \\ &\geq d(r_1,r_2) + d(r_3,r_4). \end{aligned}$$

Hence we have equality throughout, that is

(72.31) $$d(t,u) + d(v,w) = d(t,v) + d(u,w) \text{ for all distinct } t,u,v,w \in T.$$

This implies that there exists a function $\phi : T \to \mathbb{R}_+$ such that $d(u,v) = \phi(u) + \phi(v)$ for each two distinct $u,v \in T$. (Indeed, let $\phi(v) := \frac{1}{2}(d(u,v) + d(v,w) - d(u,w))$ for arbitrary u,w with $v \neq u \neq w \neq v$. That this is independent of the choice of u,w follows from (72.31).)

Since all vertices are distinct, $d(u,v) > 0$ for all distinct $u,v \in T$, and so $\phi(v) > 0$ for at least one $v \in T$. By (72.23), there exist $st \in R$ and an $s-t$ path P such that $|EP \setminus \delta(v)| \leq d(s,t) - 2$. So P traverses v, and $|EP| = d(s,t) = \phi(s) + \phi(t)$. However,

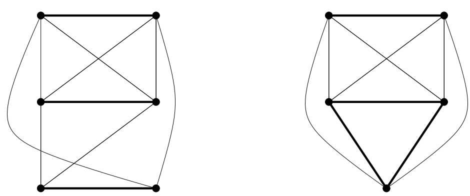
$$|EP| \geq d(s,v) + d(v,t) = \phi(s) + 2\phi(v) + \phi(t) > \phi(s) + \phi(t), \tag{72.32}$$

a contradiction.

If $H = C_5$, let $T = \{r_1, \ldots, r_5\}$ and $R = \{r_i r_{i+1} \mid i = 1, \ldots, 5\}$, taking indices mod 5. Applying (72.25) to $u := r_i$ and $w := r_{i+2}$, we obtain $st = r_{i+3}r_{i+4}$ (as it is the unique pair in R disjoint from $\{u, w\}$), and hence

$$\begin{aligned} d(r_i, r_{i+2}) + d(r_{i+3}, r_{i+4}) &\geq d(r_i, r_{i+3}) + d(r_{i+2}, r_{i+4}) \\ &\qquad (i = 1, \ldots, 5), \\ d(r_i, r_{i+2}) + d(r_{i+3}, r_{i+4}) &\geq d(r_i, r_{i+4}) + d(r_{i+2}, r_{i+3}) \\ &\qquad (i = 1, \ldots, 5). \end{aligned} \tag{72.33}$$

Adding up these ten inequalities, we obtain the same sum at both sides of the inequality sign. So we have equality in each of (72.33). This is equivalent to (72.31), and we obtain a contradiction in the same way as above. ∎



(a) (b)

Figure 72.5

The heavy lines are the edges of H, the other lines those of G. In both cases, G has no disjoint cuts such that for any edge r in H, the distance in G between the vertices in r is equal to the number of cuts separating them.

We cannot delete condition (72.1) in Theorem 72.6, as is shown by the examples given in Figure 72.5.

Notes. Karzanov [1985b] gave an $O(n^3)$ algorithm to find the cut packings of Theorem 72.6 (also for the weighted case). Theorem 72.2 can also be derived from Theorem 72.6, with the help of Theorems 70.5 and 70.7.

Karzanov [1990b] extended these cut packing results to packing $K_{2,3}$-metrics (cf. Section 72.2a):

(72.34) Let $G = (V, E)$ be a bipartite graph and let $T \subseteq V$ with $|T| = 5$. Then there exist $K_{2,3}$-metrics $\mu_1, \ldots, \mu_k$ such that $\mathrm{dist}_G(u, v) \geq \mu_1(u, v) + \cdots + \mu_k(u, v)$ for all $u, v \in V$, with equality if $u, v \in T$.

Chapter 73

T-paths

We now go over to the problem of finding a maximum number of disjoint paths whose ends are two different vertices in a given set T of vertices — the T-paths. (So the nets are all pairs of distinct vertices in T.) Fundamental theorems of Mader imply min-max relations for this.

73.1. Disjoint T-paths

Let $G = (V, E)$ be a graph and let $T \subseteq V$. A path is called an *T-path* if its ends are distinct vertices in T and no internal vertex belongs to T.

Mader [1978c] gave a min-max formula for the maximum number of internally vertex-disjoint T-paths. It generalizes the undirected, vertex-disjoint version of Menger's theorem (by taking $|T| = 2$) and the Tutte-Berge formula (by adding to each vertex v of a graph G a copy v' of v and an edge vv'; taking for T the set of new vertices, the maximum number of internally vertex-disjoint T-paths is equal to the matching number of G).

As in Schrijver [2001], we derive Mader's theorem from a theorem of Gallai [1961], which we derive (as Gallai did) from matching theory (the Tutte-Berge formula):

Theorem 73.1 (Gallai's disjoint T-paths theorem)**.** *Let $G = (V, E)$ be an undirected graph and let $T \subseteq V$. The maximum number of disjoint T-paths is equal to the minimum value of*

$$(73.1) \qquad |U| + \sum_K \lfloor \tfrac{1}{2}|K \cap T| \rfloor$$

taken over $U \subseteq V$, where K ranges over the components of $G - U$.

Proof. The maximum is at most the minimum, since for each $U \subseteq V$, each T-path intersects U or has its ends in $K \cap T$ for some component K of $G - U$.

To see equality, let μ be equal to the minimum value of (73.1). Let the graph $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ arise from G by adding a disjoint copy G' of $G - T$, and making the copy v' of each $v \in V \setminus T$ adjacent to v and to all neighbours of v in G. By the Tutte-Berge formula (Theorem 24.1), $\widetilde{G}$ has a matching M of size $\mu + |V \setminus T|$. To see this, we must prove that for any $\widetilde{U} \subseteq \widetilde{V}$:

$$|\widetilde{U}| + \sum_{\widetilde{K}} \lfloor \tfrac{1}{2} |\widetilde{K}| \rfloor \geq \mu + |V \setminus T|, \tag{73.2}$$

where $\widetilde{K}$ ranges over the components of $\widetilde{G} - \widetilde{U}$. Now if for some $v \in V \setminus T$ exactly one of v, v' belongs to $\widetilde{U}$, then we can delete it from $\widetilde{U}$, thereby not increasing the left-hand side of (73.2).

So we can assume that for each $v \in V \setminus T$, either $v, v' \in \widetilde{U}$ or $v, v' \notin \widetilde{U}$. Define $U := \widetilde{U} \cap V$. Then each component K of $G - U$ is equal to $\widetilde{K} \cap V$ for some component $\widetilde{K}$ of $\widetilde{G} - \widetilde{U}$. Hence

$$|\widetilde{U}| + \sum_{\widetilde{K}} \lfloor \tfrac{1}{2} |\widetilde{K}| \rfloor = |U| + \sum_{K} \lfloor \tfrac{1}{2} |K \cap T| \rfloor + |V \setminus T| \geq \mu + |V \setminus T|, \tag{73.3}$$

where K ranges over the components of $G - U$. Thus we have (73.2).

So $\widetilde{G}$ has a matching M of size $\mu + |V \setminus T|$. Let N be the matching $\{vv' \mid v \in V \setminus T\}$ in $\widetilde{G}$. As $|M| = \mu + |V \setminus T| = \mu + |N|$, the union $M \cup N$ has at least μ components with more edges in M than in N. Each such component is a path connecting two vertices in T. Then contracting the edges in N yields μ disjoint T-paths in G. ∎

We now derive Mader's theorem. Let $G = (V, E)$ be a graph and let $\mathcal{S}$ be a collection of disjoint subsets of V. A path in G is called an *$\mathcal{S}$-path* if it connects two different sets in $\mathcal{S}$ and has no internal vertex in any set in $\mathcal{S}$. Denote $T := \bigcup \mathcal{S}$.

Theorem 73.2 (Mader's disjoint $\mathcal{S}$-paths theorem)**.** *The maximum number of disjoint $\mathcal{S}$-paths is equal to the minimum value of*

$$|U_0| + \sum_{i=1}^{n} \lfloor \tfrac{1}{2} |B_i| \rfloor, \tag{73.4}$$

taken over all partitions $U_0, \ldots, U_n$ of V such that each $\mathcal{S}$-path intersects U_0 or traverses some edge spanned by some U_i. Here B_i denotes the set of vertices in U_i that belong to T or have a neighbour in $V \setminus (U_0 \cup U_i)$.

Proof. Let μ be the minimum value of (73.4). Trivially, the maximum number of disjoint $\mathcal{S}$-paths is at most μ, since any $\mathcal{S}$-path disjoint from U_0 and traversing an edge spanned by U_i, traverses at least two vertices in B_i.

Fixing V, choose a counterexample E, $\mathcal{S}$ minimizing

$$|E| - |\{\{x, y\} \mid x, y \in V, \exists X, Y \in \mathcal{S} : x \in X, y \in Y, X \neq Y\}|. \tag{73.5}$$

Then each $X \in \mathcal{S}$ is a stable set of G, since deleting any edge e spanned by X does not change the maximum and minimum value in Mader's theorem (as no $\mathcal{S}$-path traverses e and as deleting e does not change any set B_i), while it decreases (73.5).

If $|X| = 1$ for each $X \in \mathcal{S}$, the theorem reduces to Gallai's disjoint T-paths theorem (Theorem 73.1): we can take for U_0 any set U minimizing (73.1), and for $U_1, \ldots, U_n$ the components of $G - U$.

So $|X| \geq 2$ for some $X \in \mathcal{S}$. Choose $s \in X$. Define

$$\mathcal{S}' := (\mathcal{S} \setminus \{X\}) \cup \{X \setminus \{s\}, \{s\}\}. \tag{73.6}$$

Replacing $\mathcal{S}$ by $\mathcal{S}'$ decreases (73.5), but it does not decrease the minimum in Mader's theorem (as each $\mathcal{S}$-path is an $\mathcal{S}'$-path and as $\bigcup \mathcal{S}' = T$). Hence there exists a collection $\mathcal{P}$ of μ disjoint $\mathcal{S}'$-paths.

Necessarily, there is a path $P_0 \in \mathcal{P}$ connecting s with another vertex in X (otherwise $\mathcal{P}$ forms μ disjoint $\mathcal{S}$-paths). Then all other paths in $\mathcal{P}$ are $\mathcal{S}$-paths. Let u be an internal vertex of P_0 (u exists, since X is a stable set). Define

$$\mathcal{S}'' := (\mathcal{S} \setminus \{X\}) \cup \{X \cup \{u\}\}. \tag{73.7}$$

Replacing $\mathcal{S}$ by $\mathcal{S}''$ decreases (73.5), but it does not decrease the minimum in Mader's theorem (as each $\mathcal{S}$-path is an $\mathcal{S}''$-path and as $\bigcup \mathcal{S}'' \supseteq T$). So there exists a collection $\mathcal{Q}$ of μ disjoint $\mathcal{S}''$-paths. Choose $\mathcal{Q}$ such that $\mathcal{Q}$ uses a minimal number of edges not used by $\mathcal{P}$.

Necessarily, u is an end of some path $Q_0 \in \mathcal{Q}$ (otherwise $\mathcal{Q}$ forms μ disjoint $\mathcal{S}$-paths). Then all other paths in $\mathcal{Q}$ are $\mathcal{S}$-paths. As $|\mathcal{P}| = |\mathcal{Q}|$ and as u is not an end of any path in $\mathcal{P}$, there exists an end r of some path $P \in \mathcal{P}$ that is not an end of any path in $\mathcal{Q}$.

Then P intersects some path in $\mathcal{Q}$ (otherwise $(\mathcal{Q} \setminus \{Q_0\}) \cup \{P\}$ would form μ disjoint $\mathcal{S}$-paths). So when following P starting from r, there is a first vertex w that is on some path in $\mathcal{Q}$, say on $Q \in \mathcal{Q}$. Let Q be split at w into subpaths Q' and Q'' say (possibly of length 0). Let P' be the $r - w$ part of P.

If $EQ' \not\subseteq EP$ and $EQ'' \not\subseteq EP$, we may assume that r is not in the same class of $\mathcal{S}''$ as the end of Q' is. Then after replacing part Q'' of Q by P', Q remains an $\mathcal{S}''$-path disjoint from the other paths in $\mathcal{Q}$. This contradicts our minimality assumption on $\mathcal{Q}$.

So we can assume that $EQ' \subseteq EP$. If $P \neq P_0$, then after resetting Q to P, Q remains an $\mathcal{S}''$-path disjoint from the other paths in $\mathcal{Q}$. Again this contradicts our minimality assumption on $\mathcal{Q}$.

So $P = P_0$, and hence (since $EQ' \subseteq EP$) we have $Q = Q_0$. Then replacing part Q' of Q by P', we obtain μ disjoint $\mathcal{S}$-paths as required. ∎

(The case splitting finishing this proof is due to A. Frank (personal communication 2002).)

Theorem 73.2 is equivalent to the original form of Mader's theorem on internally vertex-disjoint T-paths (instead of fully disjoint $\mathcal{S}$-paths), which reads as follows.

For any graph G, let $B_G(U)$ denote the set of vertices in U having a neighbour that is not in U.

Corollary 73.2a (Mader's internally disjoint T-paths theorem). *Let $G = (V, E)$ be a graph and let T be a stable subset of V. Then the maximum number of internally vertex-disjoint T-paths is equal to the minimum value of*

$$(73.8) \qquad |U_0| + \sum_{i=1}^{n} \lfloor \tfrac{1}{2} |B_{G-U_0}(U_i)| \rfloor,$$

where $U_0, U_1, \ldots, U_n$ partition $V \setminus T$ such that each T-path intersects U_0 or traverses some edge spanned by some U_i.

Proof. Trivially, the maximum is not more than the minimum (since each T-path not intersecting U_0 traverses at least two vertices in some U_i, hence it traverses at least two vertices in U_i that have a neighbour out of $U_i \cup U_0$).

To see equality, we can assume that no two vertices in T have a common neighbour v. Otherwise we can apply induction by deleting v, which reduces both the maximum and the minimum by 1.

Now the present corollary follows from Theorem 73.2 applied to $G - T$ and the collection $\mathcal{S} := \{N(s) \mid s \in T\}$. ∎

Mader's internally disjoint T-paths theorem in turn implies the edge-disjoint version, proved by Mader [1978b]:

Corollary 73.2b (Mader's edge-disjoint T-paths theorem). *Let $G = (V, E)$ be a graph and let $T \subseteq V$. Then the maximum number of edge-disjoint T-paths is equal to the minimum value of*

$$(73.9) \qquad \tfrac{1}{2}\Big(\sum_{s \in T} d_E(X_s) - \kappa\Big),$$

where the X_s are disjoint sets with $s \in X_s$ (for $s \in T$), and where κ denotes the number of components K of the graph $G - \bigcup_{s \in T} X_s$ with $d_E(K)$ odd.

Proof. Let t be the maximum number of edge-disjoint T-paths. It is easy to see that t cannot exceed the minimum value of (73.9).

To see equality, first observe that, if G has an edge e such that by deleting e, the maximum drops by 1, we can apply induction on $|E|$, since the minimum drops by at most 1.

So we can assume that no such edge exists. We make an auxiliary graph $G' = (V', E')$ as follows. For each $u \in V \setminus T$, let W_u be a stable set of size $3t + 1$. For each edge $e \in E$, let v_e be a new vertex. Let v_e be adjacent to all vertices in W_u if $u \in e$, and to $s \in T$ if $s \in e$. This defines the graph G' (with vertex set $V' = T \cup \{v_e \mid e \in E\} \cup \bigcup_{u \in V \setminus T} W_u$).

Then t is equal to the maximum number of disjoint T-paths in G'. Hence, by Corollary 73.2a, there exist disjoint subsets $U_0, \ldots, U_n$ of $V' \setminus T$ such that

(73.10) each T-path in G' intersects U_0 or traverses an edge spanned by some U_i, and such that

$$(73.11) \qquad t \geq |U_0| + \sum_{i=1}^{n} \lfloor \tfrac{1}{2}|B_i| \rfloor,$$

where B_i is the set of vertices in U_i having a neighbour in $V' \setminus (U_0 \cup U_i)$.

By our assumption that the maximum does not drop by deleting any edge e, we know that U_0 contains no vertex v_e.

We may assume that $|B_i| \geq 2$ for each i, since if $|B_i| \leq 1$, we can delete U_i, as no T-path in G' avoiding U_0 traverses any edge spanned by U_i. This implies that $|B_i| \leq 3\lfloor \frac{1}{2}|B_i| \rfloor$, and hence

$$(73.12) \qquad |U_0| + \sum_{i=1}^{n} |B_i| \leq 3(|U_0| + \sum_{i=1}^{n} \lfloor \tfrac{1}{2}|B_i| \rfloor) < 3t + 1.$$

So for each $u \in V \setminus T$, there exists a $w_u \in W_u$ with $w_u \notin U_0 \cup B_1 \cup \cdots \cup B_n$. For $u \in T$, let $w_u := u$.

For each $i = 1, \ldots, n$, let $Y_i := \{u \in V \setminus T \mid w_u \in U_i\}$ and let E_i be the set of edges $e \in E$ with $v_e \in B_i$. Then

$$(73.13) \qquad \delta_E(Y_i) \subseteq E_i$$

for each $i = 1, \ldots, n$. To see this, let $e \in \delta_E(Y_i)$, with $e = uv$ and $u \in Y_i$ and $v \notin Y_i$. Then $u \in Y_i$ implies $w_u \in U_i$. Hence $w_u \in U_i \setminus B_i$, implying $v_e \in U_i$. As $v \notin Y_i$, we know $w_v \notin U_i$. Hence v_e has a neighbour out of $U_0 \cup U_i$, and so $v_e \in B_i$. Therefore, $e \in E_i$, proving (73.13).

Hence no edge of G connects two different Y_i and Y_j (since $E_i \cap E_j = \emptyset$). Suppose now that $G - Y_1 - \cdots - Y_n$ contains a T-path P. Route P as a T-path P' in G', by replacing each edge of P by v_e and any $u \in V \setminus T$ by w_u. Then P' is disjoint from U_0. So P' traverses an edge spanned by some U_i. Then P' traverses a vertex $w_u \in U_i$ for some $u \in V \setminus T$. Hence P traverses Y_i, a contradiction.

For $s \in T$, let X_s be the set of vertices of G reachable in $G - Y_1 - \cdots - Y_n$ from s. Then we have

$$(73.14) \qquad t \geq \sum_{i=1}^{n} \lfloor \tfrac{1}{2}|E_i| \rfloor \geq \tfrac{1}{2}\big(\sum_{s \in T} d_E(X_s) - \kappa\big),$$

where κ is the number of components K of $G - \bigcup_{s \in T} X_s$ with $d_E(K)$ odd. ∎

(This min-max formula was proved also in an unpublished manuscript of Lomonosov [1978b].)

73.1a. Disjoint T-paths with the matroid matching algorithm

As Lovász [1980a] showed, Mader's theorem can be derived from matroid matching theory, and also a polynomial-time algorithm to find a maximum packing of T-paths follows from it. We restrict ourselves to deriving polynomial-time solvability, and consider the equivalent problem of finding a maximum packing of $\mathcal{S}$-paths.

Let $G = (V, E)$ be a graph and let $S_1, \ldots, S_k$ be disjoint subsets of V. Let $\mathcal{S} := \{S_1, \ldots, S_k\}$ and $T := S_1 \cup \cdots \cup S_k$.

We can assume that each S_i is a stable set. Consider the linear space $(\mathbb{R}^2)^V$, considered as the set of functions $x : V \to \mathbb{R}^2$. For each edge $e = uw$ of G, let L_e be the linear subspace of $(\mathbb{R}^2)^V$ given by:

(73.15) $$L_e := \{x \in (\mathbb{R}^2)^V \mid x(v) = \mathbf{0} \text{ for each } v \in V \setminus \{u, w\}, x(u) + x(w) = \mathbf{0}\}.$$

So $\dim L_e = 2$.

Choose distinct 1-dimensional subspaces $l_1, \ldots, l_k$ of $\mathbb{R}^2$. For each $v \in V$, let $L_v := l_i$ if $v \in S_i$ for some i, and $L_v := \{\mathbf{0}\}$ otherwise. Define

(73.16) $$Q := \{x \in (\mathbb{R}^2)^V \mid \forall v \in V : x(v) \in L_v\}.$$

Let $\mathcal{E}$ be the collection of subspaces L_e/Q (for $e \in E$) of $(\mathbb{R}^2)^V/Q$. Then $\dim(L_e/Q) = 2$ for each edge e, since e connects no two vertices in the same S_i (so $L_e \cap Q = \{\mathbf{0}\}$).

For any $F \subseteq E$, let $\mathcal{L}_F$ denote the corresponding collection of lines in $\mathcal{E}$:

(73.17) $$\mathcal{L}_F := \{L_e/Q \mid e \in F\}.$$

We show that for each $F \subseteq E$:

(73.18) $\mathcal{L}_F$ is a matching if and only if F is a forest such that each component of (V, F) has at most two vertices in common with T, and at most one with each S_i.

Let $X := \sum(L_e \mid e \in F)$. Then one easily checks that X consists of all $x : V \to \mathbb{R}^2$ with $\sum_{v \in K} x(v) = \mathbf{0}$ for each component K of (V, F). So $\dim(X) = 2(|V| - \kappa)$, where κ is the number of components of (V, F). Also, $\dim(X \cap Q) = 0$ if and only if each component of (V, F) has at most two vertices in common with T, and at most one with each S_i. Now

(73.19) $$\dim(\mathcal{L}_F) = \dim(X/Q) = \dim(X) - \dim(X \cap Q) \leq \dim(X) \leq 2|F|.$$

Hence $\mathcal{L}_F$ is a matching if and only if $\dim(X) = 2|F|$ and $\dim(X \cap Q) = 0$. By the previous this gives (73.18).

(73.18) then implies the following relation to $\mathcal{S}$-paths:

(73.20) if G is connected, the maximum number of disjoint $\mathcal{S}$-paths is equal to $\nu(\mathcal{E}) - |V| + |T|$.

To see this, let t be the maximum number of disjoint $\mathcal{S}$-paths. Let Π form a packing of t $\mathcal{S}$-paths and let F' be the set of edges contained in these paths. Extend F' to a forest F such that each component of (V, F) contains either a unique path in Π or a unique vertex in T. Then F satisfies the condition given in (73.18), and $|F| = t + |V| - |T|$. So $\mathcal{L}_F$ forms a matching of size $t + |V| - |T|$, and hence $\nu(\mathcal{E}) \geq t + |V| - |T|$.

Conversely, let $\mathcal{F} \subseteq \mathcal{E}$ be a matching of size $\nu(\mathcal{E})$. Then $\mathcal{F} = \mathcal{L}_F$ for some forest $F \subseteq E$ satisfying the condition in (73.18). Let t be the number of components of (V, F) intersecting T twice. Then deleting t edges from F, we obtain a forest such that each component intersects T at most once. So $|F| - t \leq |V| - |T|$, and hence $t \geq \nu(\mathcal{E}) - |V| + |T|$. This shows (73.20).

Theorem 43.4 implies with (73.20) the polynomial-time solvability of finding a maximum packing of $\mathcal{S}$-paths:

(73.21) Given a graph $G = (V, E)$ and a collection $\mathcal{S}$ of disjoint subsets of V, a maximum number of disjoint $\mathcal{S}$-paths can be found in polynomial time.

73.1b. Polynomial-time findability of edge-disjoint T-paths

J.C.M. Keijsper, R.A. Pendavingh, and L. Stougie (personal communication 2000) showed that with the ellipsoid method one can derive from Mader's edge-disjoint T-paths theorem (Corollary 73.2b) that a maximum number of edge-disjoint T-paths can be found in polynomial time.

To see this, let $G = (V, E)$ be a graph and let $T \subseteq V$. Consider the polyhedron P in $\mathbb{R}^E$ consisting of all $x \in \mathbb{R}^E$ satisfying

(73.22)
$$\begin{array}{rlll} \text{(i)} & 0 \leq x_e \leq 1 & \text{for each } e \in E, \\ \text{(ii)} & x(\delta(U)) \leq |\delta(U)| - 1 & \text{for each } U \subseteq V \setminus T \text{ with } |\delta(U)| \text{ odd}, \\ \text{(iii)} & x(\delta(s)) \leq x(\delta(X)) & \text{for each } s \in T \text{ and } X \subseteq V \\ & & \text{with } X \cap T = \{s\}. \end{array}$$

These conditions can be tested in polynomial time: (i) is easy (one by one). To test (ii), let G' be the graph obtained from G by contracting T to one vertex. Moreover, define $T' := \{v \in VG' \mid \deg_{G'}(v) \text{ odd}\}$. Define a capacity function c by $c_e := 1 - x_e$ for $e \in E$. Then (ii) is valid if and only if the minimum capacity of a T'-cut in G' is at least 1. This can be tested in polynomial time (Corollary 29.6a). Finally, testing (iii) amounts to finding a cut separating s and $T \setminus \{s\}$ of minimum capacity, taking x as capacity function.

So by the ellipsoid method, we can optimize any linear function over P in polynomial time. Now the maximum value λ of

(73.23)
$$\tfrac{1}{2} \sum_{s \in T} x(\delta(s))$$

over $x \in P$ is equal to the maximum number μ of edge-disjoint T-paths in G.

The inequality $\lambda \geq \mu$ follows from the fact that the incidence vectors of μ edge-disjoint T-paths sum up to a vector x satisfying (73.22) and having (73.23) equal to μ.

To see equality, by Corollary 73.2b there exist disjoint sets X_s ($s \in T$) such that $s \in X_s$ and such that

(73.24)
$$\mu = \tfrac{1}{2}\big(\sum_{s \in T} d_E(X_s) - \kappa\big),$$

where κ denotes the number of components K of the graph $G' := G - \bigcup_{s \in T} X_s$ with $d(K)$ odd. This implies a dual solution of the linear program defining λ, of value at most μ. Indeed, let x attain the maximum value of (73.23) over P. Let $W := VG'$, let $\mathcal{K}$ be the collection of components of G', and let F be the set of edges connecting different sets X_s. Then

(73.25)
$$\begin{aligned} 2\lambda &= \sum_{s \in T} x(\delta(s)) \leq \sum_{s \in T} x(\delta(X_s)) = 2x(F) + x(\delta(W)) \\ &= 2x(F) + \sum_{K \in \mathcal{K}} x(\delta(K)) \leq 2|F| + \sum_{K \in \mathcal{K}} x(\delta(K)) \\ &\leq 2|F| + \sum_{K \in \mathcal{K}} 2\lfloor \tfrac{1}{2} d_E(K) \rfloor = \sum_{s \in T} d_E(X_s) - \kappa = 2\mu. \end{aligned}$$

Concluding, we have $\lambda = \mu$.

This implies that μ can be determined in polynomial time. The paths can be found explicitly by iteratively deleting edges if it does not reduce μ. Similarly, we can replace pairs of adjacent edges uv, vw by one edge uw, if it does not reduce μ. We end up with a graph with μ edges spanned by T. Working our way back, we find the required paths in the original graph.

This approach can be extended to obtain a strongly polynomial-time algorithm for the capacitated case, where each edge e has an integer capacity $c(e)$ and we want to find a maximum number of T-paths such that each edge e is contained in at most $c(e)$ of them.

73.1c. A feasibility characterization for integer K_3-flows

Seymour [1980b] showed that Corollary 73.2b also implies the following feasibility characterization for integer K_3-flows (we follow the formulation and proof given by Frank [1990e]). The cut condition is applied to $R = \{s_1s_2, s_1s_3, s_2s_3\}$ with demand $d(s_is_j) = d_{i,j}$, and capacity $\mathbf{1}$:

Corollary 73.2c. *Let $G = (V, E)$ be a graph, let $s_1, s_2, s_3 \in V$, and let $d_{1,2}, d_{1,3}, d_{2,3} \in \mathbb{Z}_+$. Then there exists a collection of edge-disjoint paths such that $d_{i,j}$ of them connect s_i and s_j ($1 \leq i < j \leq 3$), if and only if the cut condition holds and*

(73.26) $$s(U_1) + s(U_2) + s(U_3) \geq \kappa$$

for each choice of disjoint sets U_1, U_2, U_3 with $s_i \in U_i$ ($i = 1, 2, 3$). Here $s(X) := |\delta_E(X)| - d(\delta_R(X))$ and κ is number of components K of $G - U_1 - U_2 - U_3$ with $|\delta_E(K)|$ odd.

Proof. Necessity is easy: we have

(73.27) $$d(\delta_R(U_1))+d(\delta_R(U_2))+d(\delta_R(U_3)) \leq |\delta_E(U_1)|+|\delta_E(U_2)|+|\delta_E(U_3)|-\kappa,$$

since from any component K of $G - U_1 - U_2 - U_3$ with $|\delta_E(K)|$ odd, we cannot use all edges of $\delta_E(K)$.

Next we show sufficiency. We can assume that G is connected. For $i = 1, 2, 3$, extend G by a new vertex r_i and $k_i := \deg_R(s_i)$ parallel edges connecting r_i and s_i. Let $G' = (V', E')$ be the extended graph, and let $T := \{r_1, r_2, r_3\}$. It suffices to show that G' has $d_{1,2} + d_{1,3} + d_{2,3} = \frac{1}{2}(k_1 + k_2 + k_3)$ edge-disjoint T-paths (since then $\frac{1}{2}(k_1 + k_2 - k_3) = d_{1,2}$ of them connect r_1 and r_2; similarly for $d_{1,3}$ and $d_{2,3}$). For this we can invoke Corollary 73.2b. Hence suppose to the contrary that there exist three disjoint subsets X_1, X_2, X_3 of V' with $r_i \in X_i$ ($i = 1, 2, 3$) such that

(73.28) $$\sum_{i=1}^{3} |\delta_{E'}(X_i)| - \kappa < k_1 + k_2 + k_3,$$

where κ denotes the number of components K of the graph $G' - X_1 - X_2 - X_3$ with $d_{E'}(K)$ odd.

We can assume that each X_i induces a connected subgraph of G'. For suppose that L is a component of $G'[X_1]$ not containing r_1. Let $X_1' := X_1 \setminus L$, and let κ' be the number of components K of $G' - X_1' - X_2 - X_3$ with $|\delta_{E'}(K)|$ odd. Then $\kappa' \geq \kappa - |\delta_{E'}(L)|$, and hence

(73.29) $$|\delta_{E'}(X_1')| = |\delta_{E'}(X_1)| - |\delta_{E'}(L)| \leq |\delta_{E'}(X_1)| - \kappa + \kappa'.$$

So replacing X_1 by X'_1 preserves (73.28).

If $s_i \in X_i$ for $i = 1, 2, 3$, then $U_i := X_i \setminus \{r_i\}$ for $i = 1, 2, 3$ would violate (73.26). So we can assume that $s_3 \notin X_3$, and so $X_3 = \{r_3\}$.

Then we can assume that $G - X_1 - X_2 - X_3$ has only one component. Otherwise it has a component L not containing s_3, and so L is not connected to X_3. We can assume that $|E'[L, X_1]| \geq |E'[L, X_2]|$. Let $X'_1 := X_1 \cup L$ and let κ' be the number of components K of $G' - X'_1 - X_2 - X_3$ with $|\delta_{E'}(K)|$ odd. Then $|\delta_{E'}(X'_1)| \leq |\delta_{E'}(X_1)| - \kappa + \kappa'$, and so replacing X_1 by X'_1 preserves (73.28).

So we may assume $\kappa \leq 1$, and hence, as by parity the left-hand side in (73.28) is even, we obtain the contradiction

(73.30) $$k_1 + k_2 + k_3 \geq \sum_{i=1}^{3} |\delta_{E'}(X_i)| - \kappa + 2 > \sum_{i=1}^{3} |\delta_{E'}(X_i)| \geq k_1 + k_2 + k_3,$$

where the last inequality follows from the cut condition. ∎

A polynomial-time algorithm to find a circuit traversing three prescribed vertices in an undirected graph, was given by LaPaugh and Rivest [1978,1980].

73.2. Fractional packing of T-paths

If all vertices not in T have even degree, Mader's edge-disjoint T-paths theorem (Corollary 73.2b) reduces to the following result of Cherkasskiĭ [1977b] and Lovász [1976b] (thus answering a question of Kupershtokh [1971]):

Corollary 73.2d. *Let $G = (V, E)$ be a graph and let $T \subseteq V$, with $\deg_G(v)$ even for each $v \in V \setminus T$. Then the maximum number of edge-disjoint T-paths in G is equal to*

(73.31) $$\tfrac{1}{2} \sum_{s \in T} \gamma_G(s).$$

Here $\gamma_G(s)$ denotes the minimum size of a cut in G separating s and $T \setminus \{s\}$.

Proof. Directly from Corollary 73.2b, since $\kappa = 0$. ∎

This corollary has the following consequence on multiflows, also due to Cherkasskiĭ [1977b] (the fractional version was stated, with incorrect proof, by Kupershtokh [1971]):

Corollary 73.2e. *Let $G = (V, E)$ be a graph, let $T \subseteq V$, and let $c : E \to \mathbb{R}_+$ be a capacity function. Then the maximum total value of a multiflow for the nets $\{st \mid s, t \in T, s \neq t\}$ is equal to*

(73.32) $$\tfrac{1}{2} \sum_{s \in T} \gamma_c(s),$$

where $\gamma_c(s)$ denotes the minimum capacity of a cut separating s and $T \setminus \{s\}$. If all capacities are integer there is a half-integer maximum-value multiflow. If moreover $c(\delta(v))$ is even for each $v \in V \setminus T$, there is an integer maximum-value multiflow.

Proof. By continuity and compactness, we can assume that c is integer and that $c(\delta(v))$ is even for each $v \in V \setminus T$.

Replacing each edge e by $c(e)$ parallel edges we obtain a graph to which we can apply Corollary 73.2d. The paths obtained in the new graph give an integer multiflow as required in the original graph. ∎

Notes. Karzanov [1979a] gave an $O(\mathrm{MF}(n,m) \cdot \log |T|)$ algorithm to find a half-integer maximum-value multiflow for integer c. ($\mathrm{MF}(n,m)$ is the time needed to find a maximum flow in a digraph with n vertices and m arcs.) Ibaraki, Karzanov, and Nagamochi [1998] extended this algorithm to obtain an integer solution if $c(\delta_E(v))$ is even for each $v \in V \setminus T$. They also gave an extension to directed graphs.

Lovász [1976b] mentioned the following consequence of Corollary 73.2b:

(73.33) Let $G = (V, E)$ be a graph and let $c : E \to \mathbb{Z}_+$ be a capacity function with $c(\delta(v))$ even for each $v \in V$. Then for each $u \in V$, the maximum number of circuits in G that traverse u, such that no edge e is in more than $c(e)$ of these circuits, is equal to half of the minimum capacity of a family of edges meeting each circuit through u at least twice.

To prove this, let $s_1, \ldots, s_d$ be the neighbours of u. Replace u by d new vertices $u_1, \ldots, u_d$, and for each $i = 1, \ldots, d$, add $c(us_i)$ parallel edges connecting u_i and s_i. Moreover, replace each edge e of G not containing u by $c(e)$ parallel edges. Then the assertion follows from Corollary 73.2b applied to the new graph and to $T := \{u_1, \ldots, u_d\}$.

73.2a. Direct proof of Corollary 73.2d

Let G, T form a counterexample with $|V| + |E|$ as small as possible. Let μ be equal to (73.31). Then:

(73.34) for any $s \in T$ and any minimum-size cut $\delta(U)$ separating s and $T \setminus \{s\}$, with $U \cap T = \{s\}$, one has $U = \{s\}$.

To see this, suppose $U \neq \{s\}$. Contract U to one vertex, s' say, obtaining graph G'. Let $T' := (T \setminus \{s\}) \cup \{s'\}$. By the minimality of G, G' contains μ' edge-disjoint T'-paths, where μ' equals (73.31) for G', T'. Each edge in $\delta(U)$ belongs to one of these T'-paths (as in G' it is a minimum-size cut separating s' and $T' \setminus \{s'\}$). Let G'' be the graph obtained from G by contracting $V \setminus U$ to one new vertex, u say. By the minimality of $\delta(U)$, G'' contains $d_E(U)$ edge-disjoint $s - u$ paths (by Menger's theorem). By concatenation, we find μ' edge-disjoint T-paths in G. As $\mu' \geq \mu$, this contradicts the fact that G is a counterexample. This proves (73.34).

As G, T form a counterexample, there is at least one vertex $v \in V \setminus T$ with at least two different neighbours. Let uv and vw be two of the edges incident with v, with $u \neq w$. Replacing these two edges by one new edge uw, we obtain a graph G'''. As G is a counterexample, G''' has no μ edge-disjoint T-paths. As G''' is smaller than G, it is no counterexample, and so there is an $s \in T$ with $\gamma_{G'''}(s) < \gamma_G(s)$. Hence there is a $U \subseteq V$ with $U \cap T = \{s\}$ and $d_{G'''}(U) < \gamma_G(s)$. Then, by parity, $d_{G'''}(U) \leq \gamma_G(s) - 2$, and hence $d_G(U) \leq \gamma_G(s)$. So by (73.34), $U = \{s\}$. Hence $d_G(U) = d_{G'''}(U) < \gamma_G(s)$, a contradiction.

By similar methods one may prove an analogous result for *directed graphs*, due to M.V. Lomonosov (cf. Karzanov [1979b]) and Frank [1989]: Given a digraph $D = (V, A)$ and $T \subseteq V$, call a directed path P an *T-path* if its end vertices are distinct and belong to T, and no internal vertex of P belongs to T. Then, if D is Eulerian, the maximum number of edge-disjoint T-paths in G is equal to the minimum value of

(73.35) $$\sum_{s\in T} d_A^{\text{out}}(X_s),$$

taken over disjoint sets $X_s \subseteq V$ with $s \in X_s$ for $s \in T$.

73.3. Further results and notes

73.3a. Further notes on Mader's theorem

In general it is not true that given any subset T of the vertex set of a graph, the maximum number M of edge-disjoint T-paths is equal to the minimum size m of an edge set intersecting each T-path: the complete bipartite graph $K_{t,n}$, with t odd and T the colour class with t vertices, has $M = \frac{1}{2}n(t-1)$ and $m = n(t-1)$. Mader's edge-disjoint T-paths theorem (Corollary 73.2b) implies the conjecture of Gallai [1961] (cf. Lovász [1976b]) that $M \geq \frac{1}{2}m$ for any graph. (Lovász [1976b] showed that $M \geq \frac{1}{4}m$, and P.D. Seymour (personal communication 1977) that $M \geq \frac{1}{3}m$.)

For Eulerian graphs, Corollary 73.2d implies the sharper inequality

(73.36) $$M \geq \frac{t}{2(t-1)}m,$$

where $t := |T|$. Indeed, for each $s \in T$, let E_s be a minimum-size $s - T \setminus s$ cut. Let E_t have the largest size among them. Then $\bigcup_{s\neq t} E_s$ intersects each T-path. Hence

(73.37) $$m \leq |\bigcup_{s\neq t} E_s| \leq \sum_{s\neq t} |E_s| \leq (1 - \frac{1}{t})\sum_{s\in T} |E_s| = \frac{t-1}{t}2M.$$

This proves Gallai's conjecture that $M \geq \frac{1}{2}m$ for Eulerian graphs.

The graph which arises from the complete bipartite graph $K_{t,n}$ by replacing each edge by two parallel edges, with T the colour class with t elements, has $M = tn$ and $m = 2(t-1)n$. So inequality (73.36) is sharp for Eulerian graphs.

Gallai [1961] derived, from matching theory, the following on edge-disjoint paths with both ends in T (not necessarily distinct). Let $G = (V, E)$ be a graph and $T \subseteq V$. Call a path a *weak T-path* if it has length at least 1, and connects two (not necessarily distinct) vertices in T, while no internal vertex belongs to T. For any $U \subseteq V$, let $\mathcal{K}_U$ denote the set of components of $G - U$. Then the maximum number of edge-disjoint weak T-paths is equal to the minimum value of

(73.38) $$|E[U]| + \sum_{K\in\mathcal{K}_U} \lfloor\frac{d_E(K)}{2}\rfloor,$$

over U with $T \subseteq U \subseteq V$. The maximum number of internally vertex-disjoint weak T-paths is equal to the minimum value of

$$(73.39) \qquad |E[U]| + |W \setminus U| + \sum_{K \in \mathcal{K}_W} \lfloor \frac{d_E(K)}{2} \rfloor,$$

over U, W satisfying $T \subseteq U \subseteq W \subseteq V$.

A min-max relation and a polynomial-time algorithm for the minimum cost of a maximum collection of edge-disjoint T-paths were given by Karzanov [1993,1997]. A corresponding polyhedron was described by Burlet and Karzanov [1998].

Nash-Williams [1961a] gave necessary and sufficient conditions for a graph $G = (V, E)$ and a function $g : V \to \mathbb{Z}_+$ such that the edges of G can be partitioned into (nonclosed) paths such that $g(v)$ of these paths end at v, for each $v \in V$.

More on Mader's theorem can be found in Mader [1989], and on Gallai's theorem in Mader [1980].

73.3b. A generalization of fractionally packing T-paths

The following theorem was announced by Karzanov and Lomonosov [1978] and proved by Karzanov [1985d,1987d] and Lomonosov [1985] (the latter paper does not consider the parity case). Taking H to be a complete graph we obtain Corollary 73.2d.

Theorem 73.3. *Let $G = (V, E)$ and $H = (T, R)$ be graphs, where H is the complement of the line graph of some triangle-free graph H_0. Let $c : E \to \mathbb{Z}_+$ be a capacity function. Then there exists a quarter-integer maximum-value multiflow. If H_0 is bipartite, there exists a half-integer maximum-value multiflow. If $c(\delta(v))$ is even for each $v \in V \setminus T$, there exists a half-integer maximum-value multiflow. If $c(\delta(v))$ is even for each $v \in V$ and H_0 is bipartite, there exists an integer maximum-value multiflow.*

(For the special case where H is the union of two complete bipartite graphs H' and H'' such that $VH' \subseteq VH''$ or such that $H' = K_2$, Cherkasskiĭ [1976] showed that the maximum multiflow is attained by a half-integer multiflow (for integer capacities).)

Related is the following characterization of the maximum value of a multiflow, announced by Karzanov and Lomonosov [1978], and proved by Karzanov [1979b, 1985d,1987d] and Lomonosov [1985]:

Theorem 73.4. *Let $G = (V, E)$ and $H = (T, R)$ be graphs, where H is the complement of the line graph of some triangle-free graph. Let $c : E \to \mathbb{R}_+$ be a capacity function. Let $\mathcal{U}$ denote the collection of subsets U of V such that $U \cap T$ is a stable set of H. Then the maximum total value of a multiflow subject to c is equal to the minimum value of*

$$(73.40) \qquad \sum_U \lambda_U c(\delta_G(U))$$

taken over $\lambda : \mathcal{U} \to \mathbb{R}_+$ satisfying

$$(73.41) \qquad \sum_U \lambda_U \chi^{\delta_R(U)} \geq \mathbf{1}_R.$$

It implies that if H is the complement of the line graph of some triangle-free graph, then in Theorem 70.2 one can restrict the length functions l to nonnegative combinations of cut functions. Karzanov and Pevzner [1979] showed that if H is not the line graph of a triangle-free graph, then Theorem 73.4 does not hold for some G, c.

Karzanov [1987b,1989] proved that for any graph $H = (T, R)$:

(73.42) if there exists an integer $k \geq 1$ such that for any graph $G = (V, E)$ with $T \subseteq V$ and any $c : E \to \mathbb{Z}_+$, there is a $\frac{1}{k}$-integer maximum-value multiflow, then any three pairwise intersecting inclusionwise maximal stable sets A, B, C of H satisfy $A \cap B = A \cap C = B \cap C$.

Karzanov [1991] conjectured that the reverse implication holds and that $k = 4$ will do. (Karzanov [1987a] announced a proof of this, but the proof failed.) The techniques of Karzanov [1987d] yield a strongly polynomial-time algorithm for the problems in Theorems 73.3 and 73.4.

73.3c. Lockable collections

Let T be a set and let $H = (T, R)$ be the complete graph on T. A collection $\mathcal{A}$ of subsets of T is called *lockable* if for each (supply) graph $G = (V, E)$ with $V \supseteq T$ and for each capacity function $c : E \to \mathbb{R}_+$, there is a multiflow for demand graph H such that

(73.43) for each $U \in \mathcal{A}$, the sum of the flow values of those nets split by U is equal to the minimum of $c(\delta_E(X))$ taken over $X \subseteq V$ satisfying $X \cap T = U$.

(Here U *splits* a pair of vertices if precisely one of them is in U.)

The following characterization of lockable collections was proved jointly by Karzanov [1979b,1984] and Lomonosov [1985] (announced in Lomonosov [1979b]). Recall that two subsets X, Y of T are called *crossing* if each of $X \cap Y$, $X \setminus Y$, $Y \setminus X$, and $T \setminus (X \cup Y)$ is nonempty. (The 1979 references did not consider the Euler condition.) A short proof was given by Frank, Karzanov, and Sebő [1992, 1997].

(73.44) A collection $\mathcal{A}$ is lockable if and only if $\mathcal{A}$ contains no three pairwise crossing sets. If $\mathcal{A}$ is lockable and c is integer, there is a half-integer multiflow satisfying (73.43). If moreover $c(\delta(v))$ is even for each $v \in V \setminus T$, there is an integer multiflow satisfying (73.43).

We show that this generalizes two results proved earlier. First we show that Corollary 73.2d can be derived. Let $G = (V, E)$ be a graph and let $T \subseteq V$ be such that each vertex $v \in V \setminus T$ has even degree. Let $\mathcal{A} := \{\{v\} \mid v \in T\}$. Then $\mathcal{A}$ contains no three pairwise crossing sets, and hence (73.44) applies. Let $c := \mathbf{1}$. By (73.44), there exists a collection $\mathcal{P}$ of edge-disjoint T-paths such that for each $v \in T$, there are $\gamma_G(v)$ paths in $\mathcal{P}$ with end vertex v. So $|\mathcal{P}| = \frac{1}{2} \sum_{v \in T} \gamma_G(v)$, and we have Corollary 73.2d.

Second we derive Theorem 72.2 for $H = C_5$. Let $G = (V, E)$ be a graph and let $H = (T, R)$ be the graph C_5, with $T \subseteq V$. Let $c : E \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$ be a capacity and demand function satisfying the Euler and cut conditions. We show that there is a feasible integer multiflow. To this end we can assume that

(73.45) $\quad c(\delta_E(v)) = d(\delta_R(v))$ for each $v \in T$.

If this is not the case, add an edge $e = v'v$, where v' is a new vertex, define $c(e) := d(\delta_R(v))$, and replace v by v' in H. This does not violate the Euler and cut conditions.

Define

(73.46) $\quad \mathcal{A} := \{\{v\} \mid v \in T\} \cup \{\{u,v\} \mid u,v \in T, u \neq v, uv \notin R\}$.

Then no three sets in $\mathcal{A}$ are pairwise crossing, and so (73.44) applies; that is, there is an integer multiflow $(x_r \mid r \in R')$ such that (73.43) holds, where

(73.47) $\quad R' := \{st \in T \mid s,t \in T, s \neq t\}$.

. (So x_r is an $s-t$ flow in G for $r = st \in R'$.) We show that the value of x_r is equal to d_r for each $r \in R$, and is equal to 0 for each $r \in R' \setminus R$, as required.

Let b_r be the value of x_r, for $r \in R'$. By (73.43) and the cut condition,

(73.48) $\quad b(\delta_{R'}(U)) \geq d(\delta_R(U))$ for each $U \in \mathcal{A}$,

since there exists an $X \subseteq V$ with $X \cap T = U$ and

(73.49) $\quad b(\delta_{R'}(U)) = c(\delta_E(X)) \geq d(\delta_R(X)) = d(\delta_R(U))$.

Moreover, equality holds if $|U| = 1$, since for $v \in T$ we have $b(\delta_{R'}(v)) \leq c(\delta_E(v)) = d(\delta_R(v))$, by (73.45). Now add up all inequalities (73.48) for those $U \in \mathcal{A}$ with $|U| = 1$. Similarly, add up all inequalities (73.48) for those $U \in \mathcal{A}$ with $|U| = 2$. Both sums have the same terms at the right-hand sides of the inequality sign. But the first sum has more terms at the left-hand side than the second sum has. As the first one has equality, the second one also has equality, and the terms are equal. That is, equality holds in (73.48) for each $U \in \mathcal{A}$. This implies that $b_r = d_r$ for each $r \in R$ and $b_r = 0$ for each $r \in R' \setminus R$, as (73.48) yields a nonsingular system of equations.

This shows Theorem 72.2 for the case $H = C_5$. Lomonosov [1985] argued how also the case $H = K_4$ can be derived from (73.44).

Pevzner [1987] studied the maximum size of a collection of sets no three of which are pairwise crossing. For a short proof, see Fleiner [2001b]. More on lockable collections and related structures can be found in Ibaraki, Karzanov, and Nagamochi [1998], Ilani, Korach, and Lomonosov [2000], and Ilani and Lomonosov [2000].

73.3d. Mader matroids

The exchange phenomenon for $\mathcal{S}$-paths used in the proof of Mader's disjoint $\mathcal{S}$-paths theorem (Theorem 73.2) gives rise to a matroid as follows.

Let $G = (V, E)$ be an undirected graph and let $\mathcal{S} = \{S_1, \ldots, S_k\}$ be a collection of disjoint subsets of V. Define $T := S_1 \cup \cdots \cup S_k$. Let $\mathcal{I}$ be the collection of all subsets I of T with the property that there exists a collection $\mathcal{P}$ of disjoint $\mathcal{S}$-paths with $I \subseteq \text{ends}(\mathcal{P})$. Here ends$(\mathcal{P})$ denotes the set of ends of the paths in $\mathcal{P}$.

Theorem 73.5. *$M = (T, \mathcal{I})$ is a matroid.*

Proof. $\mathcal{I}$ trivially is nonempty and closed under taking subsets. To see that it gives a matroid, we apply Theorem 39.1. For any collection $\mathcal{R}$ of paths, let $E\mathcal{R}$ denote the set of edges traversed by the paths in $\mathcal{R}$. Choose $I, J \in \mathcal{I}$ with $|I \setminus J| = 1$ and $|J \setminus I| = 2$. We show that $I + j \in \mathcal{I}$ for some $j \in J \setminus I$. The proof of this is by induction on $|E\mathcal{Q} \setminus E\mathcal{P}|$, where $\mathcal{P}$ and $\mathcal{Q}$ are collections of disjoint $\mathcal{S}$-paths with $I \subseteq \text{ends}(\mathcal{P})$ and $J \subseteq \text{ends}(\mathcal{Q})$.

Let $I \setminus J = \{r\}$. Let r be an end of path $P \in \mathcal{P}$, and let r belong to S_i say. If P is disjoint from all paths in $\mathcal{Q}$, then $J + r \subseteq \text{ends}(\mathcal{Q} \cup \{P\})$, and hence $I + j \in \mathcal{I}$ for each $j \in J \setminus I$.

If P intersects some path in $\mathcal{Q}$, follow path P starting at r, until we meet, at vertex v say, a path in $\mathcal{Q}$, Q say. Let Q have ends s and t. Let Q^s and Q^t be the $s - v$ and $t - v$ part of Q. By symmetry, we may assume that

(73.50) $\qquad EQ^s \not\subseteq EP$ and $t \notin S_i$.

Indeed, if $EQ^s \not\subseteq EP$ and $EQ^t \not\subseteq EP$, then by symmetry we can assume $t \notin S_i$ (as $s \notin S_i$ or $t \notin S_i$). If $EQ^s \subseteq EP$ or $EQ^t \subseteq EP$, then by symmetry we can assume $EQ^t \subseteq EP$, hence $EQ^s \not\subseteq EP$ (as $Q \neq P$) and $t \notin S_i$ (as t is the other end of P and as $r \in S_i$). So we may assume (73.50).

Let Q' be the path obtained by concatenating Q^t and the $v - r$ part of P. Then Q' is an $\mathcal{S}$-path disjoint from all paths in $\mathcal{Q} \setminus \{Q\}$. Define $\mathcal{Q}' := (\mathcal{Q} \setminus \{Q\}) \cup \{Q'\}$ and $J' := J - s + r$. So $J' \subseteq \text{ends}(\mathcal{Q}')$. Hence $J' \in \mathcal{I}$.

If $s \notin I$, we are done, since then there is a $j \in J \setminus I$ with $I + j \subseteq J - s + r$. If $s \in I$, then $J' \setminus I = J \setminus I$, and we can apply the induction hypothesis, since

(73.51) $\qquad |E\mathcal{Q}' \setminus E\mathcal{P}| < |E\mathcal{Q} \setminus E\mathcal{P}|$.

Hence, by induction, there is a $j \in J \setminus I$ with $I + j \in \mathcal{I}$ as required. ∎

We call a matroid $M = (T, \mathcal{I})$ obtained in this way a *Mader matroid*. If $k = 2$, we call the Mader matroid also a *Menger matroid*. The *matching matroids* (cf. Section 39.4a) are the special case of Mader matroids where $\mathcal{S} = \{\{v\} \mid v \in V\}$.

The question is how Mader matroids relate to known classes of matroids. The class of gammoids seems close to Mader matroids. Hence the question:

(73.52) $\qquad$ Is each Mader matroid a gammoid?

What can be proved is that each *Menger* matroid is a gammoid. More precisely:

Theorem 73.6. *A matroid is a gammoid if and only if it is a contraction of a Menger matroid.*

Proof. To see necessity, each gammoid is the contraction of a transversal matroid (Corollary 39.5a). Hence it suffices to show that each transversal matroid $M = (T, \mathcal{I})$ is a contraction of a Menger matroid. We can assume that the transversal matroid is obtained from a bipartite graph G with colour classes S and T, such that the independent sets of M are the subsets of T covered by some matching in G, and such that G has a matching of size $|S|$. Let M' be the Menger matroid on $S \cup T$ obtained from G by taking $\mathcal{S} := \{S, T\}$. Then contracting S in M' gives M. So M is the contraction of a Menger matroid.

To prove sufficiency, it suffices to show that each Menger matroid is a gammoid (as the class of gammoids is closed under contractions). Let $G = (V, E)$ be an undirected graph and let S_1 and S_2 be disjoint subsets of V. Define $\mathcal{S} := \{S_1, S_2\}$. Let M be the Menger matroid obtained this way. So a subset B of $S_1 \cup S_2$ is a base of M if and only if there exists a maximum-size collection of disjoint $\mathcal{S}$-paths in G such that B is the set of ends of these paths. We can assume that neither S_1 nor S_2 spans an edge of G (as it is not in any $\mathcal{S}$-path).

Let $D = (V, A)$ be the directed graph obtained from G by orienting each edge incident with S_1 away from S_1 and by orienting each edge incident with S_2 towards S_2, and by replacing each remaining edge e by two oppositely oriented arcs connecting the ends of e. So a subset B of $S_1 \cup S_2$ is a base of M if and only if there exists a maximum-size collection of disjoint directed paths in D from S_1 to S_2, such that B is the set of ends of these paths.

Derive an undirected graph $\widetilde{G}$ from D as follows. Replace each vertex $v \notin S_1 \cup S_2$ by two vertices, v' and v''. For $v \in S_1$ define $v' := v$, and for $v \in S_2$ define $v'' := v$. Replace each arc (u, v) of D by an edge $u'v''$ of $\widetilde{G}$. Moreover, for each $v \in V \setminus (S_1 \cup S_2)$, make an edge $v'v''$ of $\widetilde{G}$. This makes the undirected graph $\widetilde{G}$. Then for any subset I of $S_1 \cup S_2$ one has, by a well-known argument (cf. Theorem 39.5):

(73.53) D contains disjoint directed paths from S_1 to S_2, such that I is the collection of the ends of these paths $\iff$ $\widetilde{G}$ contains a matching N which covers all vertices except those in $(S_1 \cup S_2) \setminus I$.

So a subset B of $S_1 \cup S_2$ is a base of M if and only if $\widetilde{G}$ has a maximum-size matching N which covers all vertices except those in $(S_1 \cup S_2) \setminus B$. So M is the matroid obtained from the matching matroid of $\widetilde{G}$ by contracting all vertices in $V \setminus (S_1 \cup S_2)$. As each matching matroid is a transversal matroid (cf. Section 39.4a), this proves that each Menger matroid is the contraction of a transversal matroid, and hence is a gammoid (Corollary 39.5a). ∎

By the results in Section 39.4a, the class of gammoids is also equal to the class of contractions of matching matroids. So contractions of Menger matroids and those of matching matroids (two special cases of Mader matroids) coincide.

A question related to (73.52) is:

(73.54) Is each Mader matroid linear?

As gammoids are representable over all large enough fields, a positive answer to question (73.52) implies a positive answer to question (73.54). The constructions given in Section 73.1a suggest a positive answer to (73.54).

73.3e. Minimum-cost maximum-value multiflows

Karzanov [1979d] showed that if H is a complete graph and all capacities are integer, there exists a half-integer minimum-cost maximum-value multiflow (and he gave a pseudo-polynomial-time algorithm to find it). This can be directly extended to the case where H is a complete multipartite graph.

A short proof, together with a strongly polynomial-time algorithm, was given by Karzanov [1994a], where also the existence of a half-integer optimum dual solution was shown. Other algorithms (based on scaling) were given by Goldberg and Karzanov [1997].

On the other hand, Karzanov [1987b] showed that if $H = (T, R)$ is not a complete multipartite graph (that is, H contains two intersecting inclusionwise maximal stable sets), then there is no fixed integer k such that for each graph $G = (V, E)$ with $V \supseteq T$ and each integer capacity function and each cost function, there is a $\frac{1}{k}$-integer minimum-cost maximum-value multiflow.

73.3f. Further notes

Lomonosov [1985] (announced in Lomonosov [1979a]) gave a min-max formula for the maximum total value of a multiflow if H is the union of two (not necessarily disjoint) cliques.

Karzanov and Manoussakis [1996] showed: Let $G = (V, E)$ and $H = (T, R)$ be graphs, with $T \subseteq V$, where $H = K_{2,r}$, and where $\deg_G(v)$ is even for each $v \in V \setminus T$. For any T-path P, let $\alpha(P)$ denote the distance in H between the ends of P. Then the maximum value of

(73.55) $$\sum_{P \in \mathcal{P}} \alpha(P),$$

where $\mathcal{P}$ is a collection of edge-disjoint T-paths, is equal to the minimum value of

(73.56) $$\sum_{u,v \in T} |E[X_u, X_v]| \cdot \mathrm{dist}_H(u, v),$$

where $(X_u \mid u \in T)$ is a partition of V with $u \in X_u$ for $u \in T$. (As usual, $E[X, Y]$ is the set of edges connecting X and Y.) Extensions and related results are given by Karzanov [1998a,1998b,1998c].

Rothfarb and Frisch [1969] showed that the maximum total value of a 3-commodity flow equals the minimum capacity of a set of edges disconnecting all nets, if $|V| = 3$.

Dahlhaus, Johnson, Papadimitriou, Seymour, and Yannakakis [1992,1994] showed that it is NP-complete to find a minimal number of edges disconnecting any two vertices among three given vertices in an undirected graph. Chopra and Rao [1991] studied the corresponding polyhedron.

Chapter 74

Planar graphs

Finding disjoint paths in *planar* graphs is of interest not only for planar communication or transportation networks, but especially also for the design of VLSI-circuits. The routing of the wires should follow certain channels on layers of the chip. On each layer, these channels form a planar graph.

Even for planar graphs, disjoint paths problems are in general hard. However, for some special cases, polynomial-time algorithms and good characterizations have been found. In this chapter we discuss some of these cases.

Except if stated otherwise, throughout this chapter $G = (V, E)$ and $H = (T, R)$ denote the supply and demand graph, in the sense of Chapter 70. The pairs in R are called the *nets*. If $s_1, t_1, \ldots, s_k, t_k$ are given, then $R := \{s_1t_1, \ldots, s_kt_k\}$. If demands $d_1, \ldots, d_k$ are given, then $d(s_it_i) := d_i$. We denote $G + H = (V, E \cup R)$, where the disjoint union of E and R is taken, respecting multiplicities.

Recall that the *Euler condition* states that $G + H$ is Eulerian.

74.1. All nets spanned by one face: the Okamura-Seymour theorem

The complexity of the edge-disjoint paths problem for planar graphs with all nets on the outer boundary, is open. However, Okamura and Seymour [1981] showed that if the Euler condition holds, the edge-disjoint paths problem is polynomial-time solvable, and the cut condition is sufficient for solvability. We follow their method of proof.

Theorem 74.1 (Okamura-Seymour theorem)**.** *Let $G = (V, E)$ be a planar graph and let $H = (T, R)$ be a graph where T is the set of vertices of G incident with the unbounded face of G. Let the Euler condition hold. Then the edge-disjoint paths problem has a solution if and only if the cut condition holds.*

Proof. Necessity of the cut condition being trivial, we show sufficiency. The cut condition implies that $|R| \leq |E|$ (assuming that each $r \in R$ consists of two distinct vertices), since

$$2|R| = \sum_{v\in V} \deg_R(v) \le \sum_{v\in V} \deg_E(v) = 2|E|. \tag{74.1}$$

So we can consider a counterexample with $2|E| - |R|$ minimal. Then

(74.2) G is 2-connected.

Indeed, if G is disconnected, we can deal with the components separately. Suppose next that G is connected and has a cut vertex v. We may assume that for no $r = st \in R$, the vertices s and t belong to different components of $G - v$, since otherwise we can replace r by sv and vt, without violating the Euler or cut condition. For any component K of $G - v$ consider the graph induced by $K \cup \{v\}$. Again, the Euler and cut conditions hold (with respect to those nets contained in $K \cup \{v\}$). So by the minimality of $2|E| - |R|$, we know that paths as required exist in $K \cup \{v\}$. As this is the case for each component of $G - v$, we have paths as required in G. This proves (74.2).

Let C be the circuit formed by the outer boundary of G. If some $r \in R$ has the same ends as some edge e of G, we can delete e from G and r from R, and obtain a smaller counterexample. So no such r exists.

Call a subset X of V *tight* if $d_E(X) = d_R(X)$. Then

(74.3) there exists a tight subset X of V such that $\delta_E(X)$ intersects EC in precisely two edges.

Indeed, if there is no tight set X with $\emptyset \ne X \ne V$, we can choose an edge $e \in EC$, and replace E and R by $E \setminus \{e\}$ and $R \cup \{e\}$. This does not violate the cut condition, and hence would give a smaller counterexample.

So there exists a tight proper nonempty subset X of V. Choose X with $|\delta_E(X)|$ minimal. Then $G[X]$ and $G - X$ are connected. For suppose that (say) $G[X]$ is not connected. Let K be a component of $G[X]$. Then

$$\begin{aligned} |\delta_E(K)| + |\delta_E(X \setminus K)| &\ge |\delta_R(K)| + |\delta_R(X \setminus K)| \ge |\delta_R(X)| \\ &= |\delta_E(X)| = |\delta_E(K)| + |\delta_E(X \setminus K)|. \end{aligned} \tag{74.4}$$

So K is tight, while $|\delta_E(K)| < |\delta_E(X)|$, contradicting the minimality assumption. Hence $G[X]$ and $G - X$ are connected, implying (74.3).

Choose a set X as in (74.3) with $|X|$ minimal. Let e be one of the two edges in EC that belong to $\delta_E(X)$. Say $e = uw$ with $u \notin X$ and $w \in X$.

Since $d_R(X) = d_E(X) \ge 2$, we know $\delta_R(X) \ne \emptyset$. For each $r \in \delta_R(X)$, let s_r be the vertex in $r \cap X$, and t_r the vertex in $r \setminus X$. Choose $r \in \delta_R(X)$ such that t_r is as close as possible to u in the graph $C - X$.

Since s_r and t_r are nonadjacent, we know that $\{s_r, t_r\} \ne \{u, w\}$. So we can choose $v \in \{u, w\} \setminus \{s_r, t_r\}$. Let $R' := (R \setminus \{r\}) \cup \{s_r v, v t_r\}$. Trivially the Euler condition is maintained. We show that also the cut condition is maintained, yielding a contradiction as $2|E| - |R'| < 2|E| - |R|$ and as a solution for R' yields a solution for R.

To see that the cut condition is maintained, suppose to the contrary that there is a $Y \subseteq V$ satisfying

(74.5) $\qquad d_E(Y) < d_{R'}(Y).$

By Theorem 70.4, we can take Y such that $G[Y]$ and $G - Y$ are connected. So $\delta_E(Y)$ has two edges on C. By symmetry we can assume that $t_r \notin Y$. By the Euler condition, (74.5) implies $d_E(Y) \leq d_{R'}(Y) - 2$. So

(74.6) $\qquad d_{R'}(Y) \geq d_E(Y) + 2 \geq d_R(Y) + 2 \geq d_{R'}(Y).$

Hence we have equality throughout. So $\delta_{R'}(Y)$ contains both $s_r v$ and vt_r, that is, $s_r, t_r \notin Y$ and $v \in Y$. Moreover, $d_E(Y) = d_R(Y)$.

By the choice of r, there is no pair r' in R connecting $X \setminus Y$ and $Y \setminus X$ (since then $t_{r'} \in Y \setminus X$, and hence $t_{r'}$ is closer than t_r to u in $C - X$). So (using Theorem 3.1)

(74.7) $\qquad d_R(X \cap Y) + d_R(X \cup Y) = d_R(X) + d_R(Y).$

Moreover,

(74.8) $\qquad d_E(X \cap Y) + d_E(X \cup Y) \leq d_E(X) + d_E(Y).$

As the cut condition holds for $X \cap Y$ and $X \cup Y$, we have equality in (74.8), and therefore $X \cap Y$ is tight. Since $s_r \in X \setminus Y$, we know $|X \cap Y| < |X|$. So by the minimality of X we have $X \cap Y = \emptyset$. So $w \notin Y$, hence $u = v \in Y$. Then edge $e = uw$ connects $X \setminus Y$ and $Y \setminus X$, contradicting equality in (74.8). ∎

For multiflows, the Okamura-Seymour theorem implies the following result of H. Okamura (cf. note on p. 80 of Okamura and Seymour [1981]):

Corollary 74.1a. *Let $G = (V, E)$ be a planar graph, let R be a set of pairs of vertices on the outer boundary of G, and let $c : E \to \mathbb{R}_+$ and $d : R \to \mathbb{R}_+$. Then there exists a feasible multiflow if and only if the cut condition holds. If moreover c and d are integer, there is a half-integer multiflow.*

Proof. By compactness, continuity, and scaling, we can assume that c and d are integer. Replacing any edge e by $2c(e)$ parallel copies, and any pair $r \in R$ by $2d(r)$ parallel nets, we can apply the Okamura-Seymour theorem. The paths in the new graph give the multiflow in the original graph as required. ∎

Notes. The proof of Theorem 74.1 yields a polynomial-time algorithm for finding the edge-disjoint paths, since we can determine a minimum-size cut containing e' and e'', for any pair of edges e', e'' on the outer boundary of G (by finding a shortest path in the dual graph). Frank [1985] outlined that it in fact leads to an $O(n^3 \log n)$-time algorithm. (As P.D. Seymour observed, also the splitting-off technique used by Lins [1981] to prove Corollary 74.1b below yields a polynomial-time algorithm to find paths as required.)

Here $k := |R|$, t is the number of vertices that belong to at least one pair in R, and $\log^* n$ is the minimum l such that $\log^{(l)} n \leq 1$, where $\log^{(l)} n$ is obtained from n by taking l times the logarithm.

For sketches of the linear-time method of Wagner and Weihe [1993,1995], see Wagner [1993] or Ripphausen-Lipa, Wagner, and Weihe [1995].

Research problem. Is the undirected edge-disjoint paths problem polynomial-time solvable for planar graphs with all nets on the outer boundary? Is it NP-complete?

74.1b. Graphs on the projective plane

The Okamura-Seymour theorem is equivalent to a theorem of Lins [1981] on Eulerian graphs embedded in the projective plane. A closed curve in the projective plane is called *orientation-reversing* if after one turn the meaning of 'left' and 'right' is flipped. If a graph is embedded in a space S, we identify G with its image in S.

Corollary 74.1b (Lins' theorem)**.** *Let $G = (V, E)$ be an Eulerian graph embedded in the projective plane P^2. Then the maximum number of edge-disjoint orientation-*

reversing circuits in G is equal to the minimum number of intersections with G of any orientation-reversing closed curve in $P^2 \setminus V$.

Proof. Since any two orientation-reversing closed curve in the projective plane intersect, the maximum does not exceed the minimum. To see equality, let D be an orientation-reversing closed curve in $P^2 \setminus V$ having a minimum number, k say, of intersections with G. Necessarily, any intersection of D with G is a crossing of D and an edge of G. Let R be the set of edges of G intersected by D and let $G' := (V, E \setminus R)$. Then G' is a planar graph, embedded in the open sphere obtained from P^2 by deleting D. Each pair in R connects two vertices on the outer boundary of G'. It suffices to show that G' contains edge-disjoint paths P_r for $r \in R$, where P_r connects the vertices in r. Then the $P_r \cup \{r\}$ for $r \in R$ form a set of k edge-disjoint orientation-reversing circuits in G as required.

To show that the paths P_r exist, we can apply the Okamura-Seymour theorem. To this end, we must test the cut condition for G', R. Note that the pairs in R can be ordered as $r_1, \ldots, r_k$ such that when following the boundary of $P^2 \setminus D$, in one round we first meet $r_1, \ldots, r_k$ consecutively, and next we meet again $r_1, \ldots, r_k$ consecutively.

Let $X \subseteq V$, with $G'[X]$ and $G' - X$ connected, and with $d_R(X) > 0$. Then $\delta_{E \setminus R}(X)$ contains exactly two edges on the outer boundary of G'. Hence we can find an orientation-reversing closed curve in P^2 intersecting the edges of G' in $\delta_{E \setminus R}(X)$ and those in $R \setminus \delta_R(X)$. Hence

$$(74.9) \qquad d_{E \setminus R}(X) + |R| - d_R(X) \geq k = |R|,$$

that is, $d_{E \setminus R}(X) \geq d_R(X)$. So the cut condition holds for G' and R. ∎

In turn, the Okamura-Seymour theorem can be derived from Lins' theorem. To this end, we first show that in the Okamura-Seymour theorem one can make a number of assumptions that do not restrict the generality. Let $G = (V, E)$ be a planar graph, and let R be a set of pairs of vertices on the outer boundary of G, such that the Euler condition and the cut condition hold.

First one can assume that the pairs in R are disjoint: if $r = st$ and $r' = st'$ are two pairs in R, we can add a new vertex s' in the outer face, and a new edge $s's$, and reset $r' := s't'$. Second one may assume that any two pairs $r = st$, $r' = s't'$ in R are 'crossing' around the outer boundary of G; that is, s, s', t, t' occur in this order cyclically around the outer boundary. If this is not the case, there exist two pairs $r = st$ and $r' = s't'$ such that s, s', t', t occur in this order cyclically around the outer boundary and such that no vertex between s and s' (along the outer boundary) belongs to any pair in R. Now we can add three new vertices, q, q' and p, and edges qp, $q'p$, ps, ps', and reset $r := qt$ and $r' := q't'$ (Figure 74.1).

Let $G' = (V', E')$ be the new graph, and let R' be the new set of pairs. This construction maintains the cut condition. To see this, let $X \subseteq V \cup \{q, q', p\}$. Without loss of generality, $p \in X$. Suppose $d_{E'}(X) < d_{R'}(X)$. Then (using parity)

$$(74.10) \qquad d_{R'}(X) - 2 \geq d_{E'}(X) \geq d_E(X \cap V) \geq d_R(X \cap V) \geq d_{R'}(X) - 2,$$

and hence we have equality throughout. In particular, none of the new edges belong to $\delta_{E'}(X)$, and so $s, s', q, q' \in X$. But then $d_R(X \cap V) = d_{R'}(X)$, a contradiction.

So the cut condition is maintained. Also, any edge-disjoint pair of a $q - t$ path P and a $q' - t'$ path P' in G' contains an edge-disjoint pair of an $s - t$ path Q and

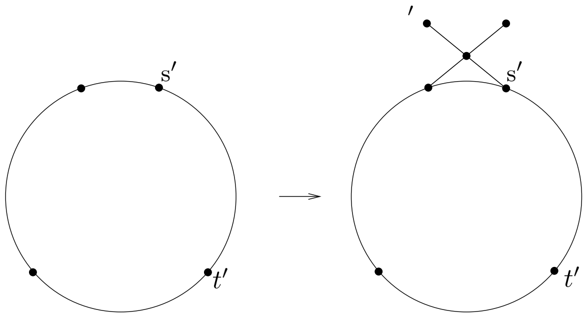

Figure 74.1

an $s' - t'$ path Q': if P traverses s and P' traverses s', this is trivial; if P traverses s' and P' traverses s, then P and P' intersect necessarily in V (as the pairs $s't$ and st' cross), and hence we can exchange P and P' at this intersection to obtain Q and Q' as required.

As we can embed G' such that q, q', t, t' occur in this order cyclically around the outer boundary of G', we have decreased the number of noncrossing pairs in R. Repeating this we can assume that all pairs in R are crossing.

Now, assuming that G is embedded in $\mathbb{R}^2$, we can embed $\mathbb{R}^2$ in the projective plane P^2. Then $P^2 \backslash \mathbb{R}^2$ is a 'cross-cap' (Möbius strip). We can extend the embedding of G to an embedding of the Eulerian graph $G + H = (V, E \cup R)$, by embedding any $r \in R$ as an edge over the cross-cap. (Since any two nets cross in $\mathbb{R}^2$, they can be drawn disjoint in $P^2 \setminus \mathbb{R}^2$.)

We derive from Lins' theorem that $G + H$ has $|R|$ edge-disjoint orientation-reversing circuits: this gives paths as required for the Okamura-Seymour theorem, as each of the circuits must contain at least one edge traversing the cross-cap, and hence at least one edge in R. As there are $|R|$ circuits, each contains exactly one edge in R, and so deleting the edges in R we obtain paths as required in the Okamura-Seymour theorem.

In order to apply Lins' theorem, we must show that each orientation-reversing closed curve D in $P^2 \setminus V$ has at least $|R|$ intersections with $G + H$. To show this, we can assume that D traverses any face of $G + H$ at most once (otherwise we can shortcut D). As D is orientation-reversing, it traverses the cross-cap an odd number of times. Between any two traversals of D over the cross-cap, we can reroute D (in $\mathbb{R}^2$) such that instead of intersecting edges of G, it intersects edges in R, in such a way that the number of new intersections with R is not more than the number of deleted intersections with E (this follows from the cut condition in the Okamura-Seymour theorem). Doing this between any two traversals of the cross-cap, we obtain an orientation-reversing closed curve only intersecting edges in R. As each of the edges in R must be intersected (since D is orientation-reversing), we see that D has at least $|R|$ intersections with $G + H$. This shows that we can apply Lins' theorem.

74.1c. If only inner vertices satisfy the Euler condition

Frank [1985] showed an interesting extension of the Okamura-Seymour theorem, to the case where the parity condition is only required for the vertices not on the outer boundary. The proof amounts to appropriately pairing those vertices v on the outer boundary for which $\deg_E(v) + \deg_R(v)$ is odd. To this end, Frank first showed the following 'pairing lemma'. We say that a pair u, v of vertices of a circuit C *crosses* a pair e, f of edges of C, if u and v are in different components of the graph $C - e - f$.

For any set X let $\binom{X}{2}$ denote the collection of unordered pairs from X. A *pairing* of a set is a partition into pairs.

Lemma 74.2α (pairing lemma)**.** *Let $C = (V, E)$ be a circuit with $|V|$ even, and let $s : \binom{E}{2} \to \mathbb{Z}$ be such that, for each $x \in \binom{E}{2}$, $s(x)$ has the same parity as the size of any of the two components of $C - x$. Then V has a pairing M such that each $x \in \binom{E}{2}$ is crossed by at most $s(x)$ pairs in M if and only if*

(74.11) $$\sum_{x \in \mathcal{B}} s(x) \geq \tfrac{1}{2} q$$

for each collection $\mathcal{B}$ consisting of disjoint pairs in $\binom{E}{2}$. Here q denotes the number of odd components of the graph G obtained from the complete graph on V by deleting all edges crossing at least one pair in $\mathcal{B}$.

Proof. For any $x \in \binom{E}{2}$ and any $R \subseteq \binom{V}{2}$, let $\mathrm{cr}_R(x)$ denote the number of pairs in R crossing x.

Necessity of the condition is easy: if M as required exists, let $N \subseteq M$ be the set of those pairs in M leaving at least one odd component of G. Since each odd component of G is left by at least one pair in N, we have $|N| \geq \frac{1}{2}q$. On the other hand, each pair in N crosses at least one pair in $\mathcal{B}$, and so

(74.12) $$\tfrac{1}{2} q \leq |N| \leq \sum_{x \in \mathcal{B}} \mathrm{cr}_N(x) \leq \sum_{x \in \mathcal{B}} s(x),$$

proving (74.11).

To see sufficiency, first assume that $s(x) > 0$ for each $x \in \binom{E}{2}$. Let M be any of the two perfect matchings in C. Then for any $x \in \binom{E}{2}$, $\mathrm{cr}_M(x)$ is at most 2 and has the same parity as $s(x)$; therefore $\mathrm{cr}_M(x) \leq s(x)$.

Hence we can assume that there is a $y \in \binom{E}{2}$ with $s(y) = 0$. Let K be a component of $C - y$. Among all such y, K, choose y, K such that K is smallest. Let $V' := V \setminus K$, let u and w be the end vertices of the path $C - K$, and let $C' = (V', E')$ be the circuit obtained from $C - K$ by adding the new edge $f = uw$. As $s(y)$ is even, both K and V' have even size. Let N be the unique perfect matching in the path $C[K]$.

For each $x \in \binom{E'}{2}$, define $s'(x)$ by: $s'(x) := s(x)$ if $f \notin x$, and

(74.13) $$s'(x) := \min\{\min\{s(\{e, g\}) \mid g \in E \setminus E', g \notin N\}, \min\{s(\{e, g\}) - 1 \mid g \in N\}\}$$

if $x = \{e, f\}$. Trivially, $s'(x)$ has the same parity as any component of $C' - x$ for each $x \in \binom{E'}{2}$.

We show that condition (74.11) holds for the smaller structure. That is, for any collection $\mathcal{B}'$ of disjoint pairs in $\binom{E'}{2}$ one has

$$(74.14) \qquad \sum_{x \in \mathcal{B}'} s'(x) \geq \tfrac{1}{2} q',$$

where q' is the number of odd components of the graph G' obtained from the complete graph on V' by deleting all edges crossing at least one pair in $\mathcal{B}'$.

If $f \notin x$ for each $x \in \mathcal{B}'$, let $\mathcal{B} := \mathcal{B}'$. Then (74.14) follows from (74.11), as $s'(x) = s(x)$ for each $x \in \mathcal{B}$ and as $q' = q$.

If $f \in x$ for some $x \in \mathcal{B}'$, this x is unique. Let $z = \{e, g\} \in \binom{E}{2}$ attain the minimum in (74.13). If $g \notin N$, let $\mathcal{B} := (\mathcal{B}' \setminus \{x\}) \cup \{z\}$. Again (74.14) follows from (74.11), as $q' = q$.

If $g \in N$, let $\mathcal{B} := (\mathcal{B}' \setminus \{x\}) \cup \{y, z\}$. Then $q = q' + 2$ (as each component of G is a component of G' or is one of the odd components of $C[K] - g$). Also $s'(a) = s(a)$ for each $a \in \mathcal{B}' \setminus \{x\}$, while $s(z) = s'(x) - 1$ and $s(y) = 0$. Hence by (74.11) we have (74.14).

Hence, by (74.14), there exists a pairing M' of V' such that for each $x \in \binom{E'}{2}$, $\text{cr}_{M'}(x) \leq s'(x)$. Then $M := N \cup M'$ is a pairing of V. We show that $\text{cr}_M(z) \leq s(z)$ for each $z \in \binom{E}{2}$. If $z \in \binom{E'}{2}$, then $\text{cr}_M(z) = \text{cr}_{M'}(z) \leq s'(z) = s(z)$. If $z \notin \binom{E'}{2}$, let $z = \{e, g\}$ with $g \in E \setminus E'$. If $e \in E'$, let $x := \{e, f\}$. If $g \notin N$, then $\text{cr}_M(z) = \text{cr}_{M'}(x) \leq s'(x) \leq s(z)$. If $g \in N$, then $\text{cr}_M(z) = \text{cr}_{M'}(x) + 1 \leq s'(x) + 1 \leq s(z)$. Finally, if $e \in E \setminus E'$, then $\text{cr}_M(z) = \text{cr}_N(z) \leq s(z)$, since, by the choice of y, $s(z)$ is positive and has the same parity as $\text{cr}_N(z)$, while $\text{cr}_N(z) \leq 2$. ∎

The proof gives a polynomial-time algorithm to find the pairing: iteratively one finds a pair x with $s(x) = 0$ and applies the reduction described in the proof; if no pair x with $s(x) = 0$ exists, one takes any perfect matching in C.

The pairing lemma implies (Frank [1985]):

Theorem 74.2. *Let $G = (V, E)$ be a planar graph such that each vertex not on the outer boundary has even degree. Let R be a set of pairs of vertices on the outer boundary of G. Then there exist edge-disjoint paths P_r for $r \in R$, where P_r connects the vertices in r, if and only if*

$$(74.15) \qquad \sum_{j=1}^{l} (d_E(X_j) - d_R(X_j)) \geq \tfrac{1}{2} q$$

for each collection of subsets $X_1, \ldots, X_l$. Here q denotes the number of components K of $G' := G - \delta_E(X_1) - \cdots - \delta_E(X_l)$ with $d_E(K) + d_R(K)$ odd.

Proof. Call a vertex v or a subset X of V *odd* if $\deg_E(v) - \deg_R(v)$ or $d_E(X) - d_R(X)$ is odd.

Necessity of (74.15) is easy: let E' be the set of edges not used by the P_r. Then for any set X, $d_{E'}(X) \leq d_E(X) - d_R(X)$, while on the other hand $d_{E'}(X) \geq 1$ if X is odd. Thus at least $\frac{1}{2}q$ edges from $\bigcup_j \delta_E(X_j)$ belong to E'. So

$$(74.16) \qquad \tfrac{1}{2} q \leq \Big|\bigcup_j \delta_{E'}(X_j)\Big| \leq \sum_j d_{E'}(X_j) \leq \sum_j (d_E(X_j) - d_R(X_j));$$

that is, we have (74.15).

Sufficiency follows from the pairing lemma (Lemma 74.2α) and the Okamura-Seymour theorem. Indeed, let $v_1, \ldots, v_{2n}$ be the odd vertices, in cyclic order along the outer boundary. Let C be the circuit with vertices $v_1, \ldots, v_{2n}$ and edges $v_{i-1}v_i$ for $i = 1, \ldots, 2n$, setting $v_0 := v_{2n}$. For each pair x of edges e, e' of C, define

(74.17) $$s(x) := \min\{d_E(U) - d_R(U) \mid U \subseteq V, \delta_F(U) = \{e, e'\}\}.$$

Then s satisfies the conditions described in the pairing lemma. Indeed, the parity condition is easily checked. To see (74.11), let $\mathcal{B}$ be a collection of disjoint pairs from EC. For each $x \in \mathcal{B}$, let U_x attain the minimum (74.17). Let $G' := G - \bigcup_{x\in\mathcal{B}} \delta_E(U_x)$. Let H be the graph obtained from the complete graph on VC by deleting all edges crossed by at least one pair in $\mathcal{B}$. Then for each component K of G' one has: the odd vertices in K are contained in some component of H (since $K \cap VC \subseteq U_x$ or $K \cap VC \subseteq V \setminus U_x$ for each $x \in \mathcal{B}$; so no two vertices in $K \cap VC$ cross any x in $\mathcal{B}$). Hence the number of odd components of G' is at least the number of odd components of H. So the condition in the pairing lemma follows from condition (74.15).

Applying the pairing lemma, we obtain a matching M of the odd vertices with $d_M(U) \leq d_E(U) - d_R(U)$ for each $U \subseteq V$. Also we have that $\deg_E(v) + \deg_R(v) + \deg_M(v)$ is even for each $v \in V$. So for $R' := R \cup M$, we can apply the Okamura-Seymour theorem, to obtain in G for each $r = st \in R'$ an $s-t$ path P_r, such that the P_r are edge-disjoint. Restriction to R gives paths as required. ∎

In the theorem one can assume that $l \leq |E|$, since for each edge e of G we need at most one X_i splitting e. So the theorem is a good characterization.

As the pairing lemma is polynomial-time constructive, one can find edge-disjoint paths as required if the condition is met — similarly for the capacitated case. Frank [1985] showed that under the conditions of Theorem 74.2, the edge-disjoint paths problem, and its capacitated version, can be solved in $O(n^3 \log n)$ time. Also Becker and Mehlhorn [1986] showed that this problem is polynomial-time solvable, and they gave a time bound of $O(tn + T(n))$, where $T(n)$ is the time needed to solve a problem where the Euler condition holds, and where t is the number of vertices on the outer boundary. Weihe [1999] finally gave a linear-time algorithm.

The special case where G is a rectangular grid was solved by Frank [1982c], showing that condition (74.15) can be simplified in this case.

74.1d. Distances and cut packing

With planar duality one may derive another, dual result of the Okamura-Seymour theorem, that relates distances to packings of cuts in planar graphs (Hurkens, Schrijver, and Tardos [1988]):

Corollary 74.2a. *Any planar bipartite graph G contains disjoint cuts such that any two vertices s, t on the outer boundary of G are separated by $\mathrm{dist}_G(s,t)$ of these cuts.*

Proof. Let $\mathcal{X}$ be the set of pairs e, e' of edges along the outer boundary of G such that if $e = st$ and $e' = s't'$ where s, t, s', t' occur in this order cyclically around the outer boundary, then

(74.18) $$\mathrm{dist}_G(s,s') + \mathrm{dist}_G(t,t') - \mathrm{dist}_G(s,t') - \mathrm{dist}_G(s',t) = 2.$$

(Note that for any e, e', the left-hand side equals 0 or 2, by the triangle inequality, and by the fact that each $s-s'$ path intersect each $t-t'$ path.)

We say that a pair e, e' of edges along the outer boundary *crosses* a pair u, v of vertices along the outer boundary if any $u - v$ path along the outer boundary traverses exactly one of e and e'. We show that for any two vertices u, v on the outer boundary of G:

(74.19) $\quad \text{dist}_G(u, v) = \text{number of pairs in } \mathcal{X} \text{ that cross } u, v.$

To see this, assume that $v_1, \ldots, v_n$ are the vertices of G cyclically along the outer boundary, and let $u = v_n$ and $v = v_k$. Then (setting $v_0 := v_n$):

(74.20)
$$\begin{aligned}&\text{number of pairs in } \mathcal{X} \text{ that cross } u, v\\ &= \tfrac{1}{2}\sum_{i=1}^{k}\sum_{j=k+1}^{n}(\text{dist}_G(v_{i-1}, v_{j-1}) + \text{dist}_G(v_i, v_j) - \text{dist}_G(v_{i-1}, v_j)\\ &-\text{dist}_G(v_i, v_{j-1})) =\\ &\tfrac{1}{2}\sum_{i=1}^{k}\big(\text{dist}_G(v_{i-1}, v_k) - \text{dist}_G(v_{i-1}, v_n) + \text{dist}_G(v_i, v_n) - \text{dist}_G(v_i, v_k)\big)\\ &= \tfrac{1}{2}\text{dist}_G(v_0, v_k) + \tfrac{1}{2}\text{dist}_G(v_k, v_n) = \text{dist}_G(u, v)\end{aligned}$$

(by cancellation).

This shows (74.19), which implies that it suffices to show that we can find disjoint cuts C_π for $\pi \in \mathcal{X}$, such that C_π intersects the outer boundary of G in the two edges in π. To show that these cuts exist, we can apply the Okamura-Seymour theorem to a modification of the planar dual graph G^* of G. Indeed, we must show that there exist edge-disjoint circuits D_π in G^*, for $\pi \in \mathcal{X}$, such that D_π traverses the two edges of G^* dual to the edges of G in π. The existence of these circuits follows from the Okamura-Seymour theorem applied to the graph G' obtained from G^* by deleting the vertex of G^* dual to the unbounded face of G, and all edges incident with it. Let R be the set of pairs of vertices of G' that are ends of pairs of edges dual to $\pi \in \mathcal{X}$. Then (74.19) implies that the cut condition holds, and that paths in G', and hence circuits in G^*, as required exist. ∎

This corollary is related to the Okamura-Seymour theorem by two different forms of duality: by planar duality and by polarity. As for planar duality, this is shown in the proof of this corollary. For polarity, this can be seen with Theorem 70.5, which gives that there exist $\lambda_U \in \mathbb{R}_+$ for $U \subseteq V$ such that

(74.21)
$$\begin{aligned}&\sum_U \lambda_U \chi^{\delta_R(U)}(r) \geq \text{dist}_G(s, t) \text{ for each } r = st \in R \text{ and}\\ &\sum_U \lambda_U \chi^{\delta_E(U)}(e) \leq 1 \text{ for each } e \in E.\end{aligned}$$

Now Corollary 74.2a asserts that the λ_U can be taken integer if G is bipartite.

74.1e. Linear algebra and distance realizability

As for the results on distances and cut packings discussed in Section 74.1d, the following further observations were made by Hurkens, Schrijver, and Tardos [1988]. Let $C = (V, E)$ be a circuit with n vertices and n edges, say:

(74.22) $\quad V = \{v_1, \ldots, v_n\},\ E = \{e_1 = v_0v_1, \ldots, e_n = v_{n-1}v_n\},$

where $v_0 := v_n$. Again, let $\binom{V}{2}$ and $\binom{E}{2}$ denote the sets of unordered pairs of distinct elements from V and E, respectively. Let M be the $\binom{V}{2} \times \binom{E}{2}$ matrix given by:

(74.23) $$M_{\{v_i,v_j\},\{e_g,e_h\}} := \begin{cases} 1 & \text{if } \{v_i, v_j\} \text{ and } \{e_g, e_h\} \text{ cross,} \\ 0 & \text{otherwise,} \end{cases}$$

where $\{v_i, v_j\}$ and $\{e_g, e_h\}$ are said to *cross* if v_i and v_j belong to different components of the graph $C - e_g - e_h$. Then the matrix M is nonsingular, with $\binom{E}{2} \times \binom{V}{2}$ inverse N given by:

(74.24) $$N_{\{e_g,e_h\},\{v_i,v_j\}} := \begin{cases} +\frac{1}{2} & \text{if } \{i,j\} = \{g,h\} \text{ or } \{i,j\} = \{g-1,h-1\}, \\ -\frac{1}{2} & \text{if } \{i,j\} = \{g,h-1\} \text{ or } \{i,j\} = \{g-1,h\}, \\ 0 & \text{otherwise.} \end{cases}$$

To see

(74.25) $$N = M^{-1},$$

choose $\{e_g, e_h\}, \{e_a, e_b\} \in \binom{E}{2}$. Then

(74.26) $$(NM)_{\{e_g,e_h\},\{e_a,e_b\}} = \tfrac{1}{2}M_{\{v_g,v_h\},\{e_a,e_b\}} + \tfrac{1}{2}M_{\{v_{g-1},v_{h-1}\},\{e_a,e_b\}} - \tfrac{1}{2}M_{\{v_g,v_{h-1}\},\{e_a,e_b\}} - \tfrac{1}{2}M_{\{v_{g-1},v_h\},\{e_a,e_b\}}.$$

If $\{g, h\} = \{a, b\}$, then it is easy to see that this last expression is equal to 1. If $\{g, h\} \neq \{a, b\}$, then without loss of generality $g \notin \{a, b\}$. Then

(74.27) $$M_{\{v_g,v_h\},\{e_a,e_b\}} = M_{\{v_{g-1},v_h\},\{e_a,e_b\}} \text{ and } M_{\{v_g,v_{h-1}\},\{e_a,e_b\}} = M_{\{v_{g-1},v_{h-1}\},\{e_a,e_b\}},$$

which implies that (74.26) equals 0. This proves (74.25). (It can be shown that $|\det M| = 2^{\binom{n-1}{2}}$.)

(74.25) implies that for any function $d : \binom{V}{2} \to \mathbb{R}$ there is a unique $b : \binom{E}{2} \to \mathbb{R}$ such that

(74.28) $$d(\{v_i, v_j\}) = \sum(b(\{e_g, e_h\}) \mid \{e_g, e_h\} \in \tbinom{E}{2} \text{ where } \{e_g, e_h\} \text{ crosses } \{v_i, v_j\}).$$

Indeed, (74.28) is equivalent to: $d = Mb$. Hence $b := Nd$ is the unique b satisfying (74.28).

This can be applied to $d = \text{dist}_G$ for some bipartite planar graph $G = (V', E')$ with $C = (V, E)$ being the outer boundary of G. Consider the collection $\mathcal{X}$ of pairs of edges on the outer boundary of G defined in the proof of Corollary 74.2a. ($\mathcal{X}$ is a partition of E into pairs.) Then the uniqueness of b in (74.28) yields that $\mathcal{X}$ is the unique collection of pairs of edges on the boundary of G with the property that for any two vertices s, t on the outer boundary of G, the distance $\text{dist}_G(s, t)$ is equal to the number of pairs in $\mathcal{X}$ crossing $\{s, t\}$.

Another consequence of (74.25) is as follows. Consider again the circuit $C = (V, E)$ given by (74.22). Call a function $m : \binom{V}{2} \to \mathbb{R}_+$ *realizable as the distance function of a planar graph with boundary* C, or briefly *realizable*, if there exists a planar graph $G = (V', E')$, with $V' \supseteq V$, $E' \supseteq E$ such that $v_1, \ldots, v_n$ occur in this order cyclically around the outer boundary, and a length function $l : E' \to \mathbb{R}_+$ such that for all $s, t \in V$, $m(\{s, t\}) = \text{dist}_G(s, t)$. Then

(74.29) a function $m : \binom{V}{2} \to \mathbb{R}_+$ is realizable if and only if for all $i, j = 1, \ldots, n$ we have

$$m(\{v_i, v_j\}) + m(\{v_{i-1}, v_{j-1}\}) \geq m(\{v_i, v_{j-1}\}) + m(\{v_{i-1}, v_j\}),$$

setting $m(\{v_i, v_i\}) := 0$ for all i.

Necessity of the condition is trivial, since any $v_i - v_j$ path in G crosses any $v_{i-1} - v_{j-1}$ path in G. To see sufficiency, we construct a graph G as follows. Let $w_1, \ldots, w_n$ be points on the unit circle, in this cyclic order. Set $w_0 := w_n$. Add all line-segments $\overline{w_g w_h}$ $(g, h = 1, \ldots, n;\ g \neq h)$. The figure now forms a planar graph H, with vertices the points that are on two or more of these line segments. Let H^* be the dual graph. Put a new point v_i on the edge of H^* dual to the edge $w_i w_{i+1}$ of H $(i = 0, \ldots, n-1)$. Next delete the vertex of H^* dual to the outer face of H and delete all edges incident with it. This makes the graph $G = (V', E')$.

Let $d := Nm$. By the condition given in (74.29), $d \geq \mathbf{0}$. For each edge e of G, define $l(e) := d(\{e_g, e_h\})$ if e is dual to an edge of H which is on the line segment $\overline{w_g w_h}$. Using the fact that $Md = m$ it is easy to see that this gives a realization as required.

Also the 'pairing lemma' (Lemma 74.2α) can be interpreted in terms of the matrix M: it characterizes when there exists an $x : \binom{V}{2} \to \mathbb{Z}_+$ with $x(\delta(v))$ odd for each $v \in V$ and with $x^{\mathsf{T}} M \leq s$ for some given $s : \binom{E}{2} \to \mathbb{Z}_+$.

74.1f. Directed planar graphs with all terminals on the outer boundary

It was observed by Diaz and de Ghellinck [1972] that if the supply graph is directed and planar, and all terminals are on the outer boundary in the order $s_1, \ldots, s_k, t_k, \ldots, t_1$, then the integer multicommodity flow problem is solvable in polynomial time, and the cut condition suffices. This follows by a reduction to a minimum-cost circulation problem: add arcs from t_i to s_i for $i = 1, \ldots, k$.

Related, and more difficult, is the following result of Nagamochi and Ibaraki [1990]. Let the supply digraph $D = (V, A)$ be planar and acyclic, and let the demand digraph $H = (T, R)$ have all terminals on the outer boundary of D. Then for each $c : A \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$ satisfying the directed analogue of the Euler condition (that is, $(V, A \cup R^{-1})$ is Eulerian), if there is a fractional multiflow, there is an integer multiflow.

Nagamochi and Ibaraki also gave a polynomial-time algorithm to find the integer multiflow. Moreover, they extended the results to the case where the set of vertices that violate the Euler condition, all lie on the outer boundary of D, in such a way that the vertices v with $c(\delta_A^{\text{out}}(v)) - d(\delta_R^{\text{in}}(v)) > c(\delta_A^{\text{in}}(v)) - d(\delta_R^{\text{out}}(v))$ can be separated (on the outer boundary of D) by two vertices from those vertices v where the opposite strict inequality holds.

74.2. $G + H$ planar

Seymour [1981d] gave another tractable case of the planar edge-disjoint paths problem if the Euler condition holds: the case where the graph together with all its nets (taken as edges) is a planar graph; that is, if $G = (V, E)$ and $H = (V, R)$ are graphs with

(74.30) $\qquad G + H := (V, E \cup R)$

planar (where $E \cup R$ is the disjoint union, respecting multiplicities in E and R). This case can be handled with the help of matching theory (more specifically, minimum-size T-joins and disjoint T-cuts).

Theorem 74.3. *Let $G = (V, E)$ and $H = (V, R)$ be supply and demand graphs with $G+H$ planar and Eulerian. Then the edge-disjoint paths problem has a solution if and only if the cut condition holds.*

Proof. Necessity being trivial, we show sufficiency. Let the cut condition be satisfied. Consider the dual graph $(G+H)^*$ of $G+H$. Let R^* be the family of edges of $(G+H)^*$ dual to those in R. Let T be the set of vertices of $(G+H)^*$ which are incident with an odd number of edges in R^*. So R^* is a T-join in $(G+H)^*$.

In fact, R^* is a minimum-size T-join in $(G+H)^*$. For suppose not. Then there exist $E_0 \subseteq E$ and $R_0 \subseteq R$ such that $E_0^* \cup R_0^*$ is a T-join and $|E_0|+|R_0| < |R|$. As $E_0^* \cup R_0^*$ is a T-join, each vertex of $(G+H)^*$ is incident with an even number of edges in

(74.31) $$(E_0^* \cup R_0^*) \triangle R^* = E_0^* \cup (R \setminus R_0)^*.$$

Hence $E_0 \cup (R \setminus R_0)$ forms a cut in $G+H$. Since $|E_0| < |R \setminus R_0|$, this contradicts the cut condition.

So R^* is a minimum-size T-join in $(G+H)^*$. As $(G+H)^*$ is bipartite, by Theorem 29.2, there exist disjoint cuts $D_1, \ldots, D_t$ in $(G+H)^*$ such that (i) each cut D_j intersects R^* in exactly one element and (ii) each edge of R^* is in exactly one of the D_j. Condition (i) implies that the dual C_j of each D_j is a circuit in $G+H$ containing exactly one edge in R. Hence the C_j give edge-disjoint paths in G as required. ∎

Notes. The reduction to matching theory given in this proof implies that feasibility can be tested, and edge-disjoint paths can be found, in strongly polynomial time (also for the capacitated case). Matsumoto, Nishizeki, and Saito [1986] showed that feasibility can be tested in $O(n^{3/2} \log n)$ time, and edge-disjoint paths can be found in $O(n^{5/2} \log n)$ time (also for the capacitated case). The latter bound was improved by Barahona [1990] to $O(n^{3/2} \log n)$.

With the help of Wagner's theorem (Theorem 3.3), Theorem 74.3 can be extended to the case where $G+H$ has no K_5 minor. We derive this result from Guenin's theorem in Section 75.6.

The fractional version of Theorem 74.3 was published in Seymour [1979b].

74.2a. Distances and cut packing

By Theorem 70.5, Theorem 74.3 implies that if $G = (V, E)$ and $H = (V, R)$ are graphs with $G+H$ planar, then there is a fractional packing of cuts in G such that for any $r = st \in R$, s and t are separated by $\mathrm{dist}_G(s, t)$ of these cuts. A.V. Karzanov (personal communication 1986) observed that in fact from a theorem of Seymour [1979b] the existence of a half-integer packing can be derived. More generally:

(74.32) Let $G = (V, E)$ and $H = (V, R)$ be graphs with G bipartite and $G+H$ planar. Then there exist disjoint cuts in G such that for each $r = st \in R$, s and t are separated by $\text{dist}_G(s,t)$ of these cuts.

This can be derived from Theorem 29.3 above (of Seymour [1979b]), saying:

(74.33) Let $G = (V, E)$ be a planar graph and let $p : E \to \mathbb{Z}_+$. Then p is a nonnegative integer sum of incidence vectors of circuits of G if and only if $p(\delta(v))$ is even for each $v \in V$ and $p(e) \leq p(D \setminus \{e\})$ for each cut D of G and each $e \in D$.

Applying planar duality, (74.33) becomes:

(74.34) Let $G = (V, E)$ be a planar graph and let $p : E \to \mathbb{Z}_+$. Then p is a nonnegative integer sum of incidence vectors of cuts of G if and only if $p(C)$ is even for each circuit C of G and $p(e) \leq p(C \setminus \{e\})$ for each circuit C of G and each $e \in C$.

(Here we consider circuits as edge sets.) We apply this to the graph $G+H$, where G is bipartite and $G + H$ is planar. Define $p(e) := 1$ for $e \in E$ and $p(r) := \text{dist}_G(s,t)$ for $r = st \in R$. Then $p(C)$ is even for each circuit C of $G+H$ and $p(e) \leq p(C \setminus \{e\})$ for each circuit of $G + H$ and each $e \in E$. (The latter property is trivial if $e \in E$. If $e = st \in R$, we can replace any occurrence of an r in $C \setminus \{e\}$ with $r = uv \in R$, by a shortest $u - v$ path in G. This does not increase $p(C \setminus \{e\})$. Repeating this, we can assume that $C \cap R = \{e\}$, and so $C \setminus \{e\}$ is an $s - t$ path in G, implying $p(e) = \text{dist}_G(s,t) \leq |C \setminus \{e\}| = p(C \setminus \{e\})$.)

Therefore, by (74.34), p is a nonnegative integer sum of incidence vectors of cuts of $G + H$. By definition of p, this gives edge-disjoint cuts in G as required in (74.32).

74.2b. Deleting the Euler condition if $G + H$ is planar

Middendorf and Pfeiffer [1993] showed that if $G + H$ is planar (but not necessarily Eulerian), then the edge-disjoint paths problem is NP-complete. (With construction (70.9), it implies the same result for the directed case.) In fact they showed that if $G + H$ is planar and cubic, then the edge-disjoint paths problem is NP-complete. Hence, also the vertex-disjoint paths problem is NP-complete if $G+H$ is planar and cubic. (Assuming P≠NP, this disproves a conjecture of Schrijver [1990b].) Middendorf and Pfeiffer [1990b,1993] showed that, on the other hand, if $G + H$ is planar and the edges of H belong to a bounded number of faces of G, then the edge-disjoint paths problem is polynomial-time solvable.

Middendorf and Pfeiffer [1990b,1993] also presented a counterexample to a conjecture of A. Frank (cf. Sebő [1988a]) that if $G+H$ is planar, then the edge-disjoint paths problem has a solution if and only if G contains a fractional packing of paths as required and of a T'-join, where T' is the set of vertices having odd degree in $G + H$.

Korach and Penn [1992] showed that if $G + H$ is planar and the cut condition holds, then there is an 'almost complete' packing of paths as required: there is at most one edge in R on each bounded face of G such that leaving out these edges from R, the problem has a solution. A generalization of this was given by Frank and Szigeti [1995]. (Related work can be found in Granot and Penn [1992,1993,1996].)

Seymour [1981d] also showed the following:

(74.35) Let $G = (V, E)$ and $H = (V, R)$ be supply and demand graphs such that $G + H$ is planar and such that R consists of two classes of parallel edges. Then there exist edge-disjoint paths if and only if the cut condition holds and we cannot contract edges of G to obtain a graph G' with at most four vertices in which the corresponding edge-disjoint paths do not exist.

Frank [1990d] observed that the latter condition can be formulated as:

(74.36) $d_{E\cup R}(X \cap Y)$ is even for any two tight sets $X, Y \subseteq V$,

which Frank called the *intersection criterion.* (A subset X of Y is called *tight* if $d_E(X) = d_R(X)$.)

The intersection criterion is a necessary condition for the existence of edge-disjoint paths: if paths as required exists, then for each tight X all edges in $\delta_E(X)$ are used by these paths; hence if X and Y are tight, all edges in $\delta_E(X \cap Y)$ are used; hence $d_E(X \cap Y) \equiv d_R(X \cap Y) \pmod 2$, that is, $d_{E\cup R}(X \cap Y)$ is even.

In other words, Frank observed that (74.35) is equivalent to:

(74.37) Let $G = (V, E)$ and $H = (V, R)$ be graphs such that $G+H$ is planar and such that R consists of two classes of parallel edges. Then there exist edge-disjoint paths if and only if the cut condition and the intersection criterion hold.

This was extended by Frank [1990d] to:

(74.38) Let $G = (V, E)$ and $H = (V, R)$ be graphs such that $G + H$ is planar and such that the edges of H are on at most two of the faces of G. Then there exist edge-disjoint paths if and only if the cut condition and the intersection criterion hold.

Lomonosov [1983] proved a maximization version of (74.35), which Frank [1990e] showed to follow from (74.35). Korach and Penn [1993] gave an $O(n\sqrt{\log n})$-time algorithm for the edge-disjoint paths problem if $G + H$ is planar and H consists of two parallel classes of nets.

Sebő [1993c] showed that for each fixed k, if $G + H$ is planar and $|VH| \leq k$, then the integer multiflow problem is polynomial-time solvable. (The demands can be arbitrarily large, so there is no reduction to the edge-disjoint paths problem for a fixed number of paths. It was shown for $k = 3$ by Korach [1982].) Sebő showed this by proving a more general result on the complexity of packing T-cuts for fixed $|T|$.

It is an open question if one may relax this condition to H being spanned by a fixed number of faces of G. (For demand $d = \mathbf{1}$ this was shown by Middendorf and Pfeiffer, as mentioned above.)

Pfeiffer [1990] raised the question if the edge-disjoint paths problem has a half-integer solution if $G + H$ is embeddable in the torus and there is a quarter-integer solution. He gave the example of Figure 70.5 with 8 vertices to show that this generally does not hold if $G + H$ is embeddable in the double torus.

Pfeiffer [1994] showed that the half-integer multiflow problem is NP-complete if $G + H$ is apex. (An *apex graph* is a graph having a vertex whose deletion makes the graph planar.) Pfeiffer also showed that the half-integer multiflow problem is NP-complete if the supply and demand digraphs form a directed planar graph.

74.3. Okamura's theorem

Okamura [1983] gave the following extension of the Okamura-Seymour theorem. We follow the proof found in 1984 by G. Tardos (cf. Frank [1990e]). The first half of the proof below is similar to the proof of the Okamura-Seymour theorem (Theorem 74.1).

Theorem 74.4 (Okamura's theorem)**.** *Let $G = (V, E)$ be a planar graph and let F_1 and F_2 be two of its faces. Let R be a set of pairs of vertices of G such that each $r = st \in R$ satisfies $s, t \in \mathrm{bd}(F_1)$ or $s, t \in \mathrm{bd}(F_2)$. Let the Euler condition hold. Then the edge-disjoint paths problem has a solution if and only if the cut condition holds.*

Proof. Necessity of the cut condition being trivial, we show sufficiency. The cut condition implies that $|R| \leq |E|$ (assuming that each $r \in R$ consists of two distinct vertices), since

(74.39) $$2|R| = \sum_{v \in V} \deg_R(v) \leq \sum_{v \in V} \deg_E(v) = 2|E|.$$

So we can consider a counterexample with $2|E| - |R|$ minimal. Then

(74.40) G is 2-connected.

Indeed, if G is disconnected, we can deal with the components separately. Suppose next that G is connected and has a cut vertex v. We may assume that for no $r = st \in R$, the vertices s and t belong to different components of $G - v$, since otherwise we can replace r by sv and vt, without violating the Euler or cut condition. For any component K of $G - v$ consider the graph induced by $K \cup \{v\}$. Again, the Euler and cut conditions hold (with respect to those nets contained in $K \cup \{v\}$). So by the minimality of $2|E| - |R|$ we know that paths as required exist in $K \cup \{v\}$. As this is the case for each component of $G - v$, we have paths as required in G. This proves (74.40).

If some $r \in R$ is parallel to an edge of G we can delete this edge from G, and r from R, to obtain a smaller counterexample. Hence such r, e do not exist.

Call a subset X of V *tight* if $d_E(X) = d_R(X)$. Let C_1 and C_2 be the circuits forming the boundaries of F_1 and F_2 respectively. Then

(74.41) Each tight set X with $|\delta_E(X) \cap EC_1| = 2$ intersects VC_2.

For suppose that $X \cap VC_2 = \emptyset$. Choose such a set X with $|X|$ minimal. Let e be one of the two edges in $\delta_E(X) \cap EC_1$. Say $e = uw$ with $u \notin X$ and $w \in X$.

Since $d_R(X) = d_E(X) \geq 2$, we know $\delta_R(X) \neq \emptyset$. For each $r \in \delta_R(X)$, let s_r be the vertex in $r \cap X$, and t_r the vertex in $r \setminus X$. Choose $r \in \delta_R(X)$ such that t_r is as close as possible to u in the graph $C_1 - X$.

Since $\{u, w\} \neq \{s_r, t_r\}$, we can choose $v \in \{u, w\}$ with $v \notin \{s_r, t_r\}$. Let $R' := (R \setminus \{r\}) \cup \{s_r v, v t_r\}$. Trivially the Euler condition is maintained. We prove that also the cut condition is maintained, which is a contradiction as $2|E| - |R'| < 2|E| - |R|$ and as a solution for R' yields a solution for R.

To see that the cut condition is maintained, suppose to the contrary that there is a $Y \subseteq V$ satisfying

$$(74.42) \qquad d_E(Y) < d_{R'}(Y).$$

By Theorem 70.4, we can take Y such that $G[Y]$ and $G - Y$ are connected. By symmetry we can assume that $t_r \notin Y$. By the Euler condition, (74.42) implies $d_E(Y) \leq d_{R'}(Y) - 2$. So

$$(74.43) \qquad d_{R'}(Y) \geq d_E(Y) + 2 \geq d_R(Y) + 2 \geq d_{R'}(Y).$$

Hence we have equality throughout. So $\delta_{R'}(Y)$ contains both $s_r v$ and vt_r, that is, $s_r, t_r \notin Y$ and $v \in Y$. Moreover, $d_E(Y) = d_R(Y)$.

As Y and $V \setminus Y$ intersect VC_1 and as $G[Y]$ and $G - Y$ are connected, we know $|\delta_E(Y) \cap EC_1| = 2$. By the choice of r, there is no pair r' in R connecting $X \setminus Y$ and $Y \setminus X$ (otherwise, $t_{r'} \in Y \setminus X$ and hence $t_{r'}$ would be closer than t_r to u in $C_1 - X$). So (using Theorem 3.1)

$$(74.44) \qquad d_R(X \cap Y) + d_R(X \cup Y) = d_R(X) + d_R(Y).$$

Moreover,

$$(74.45) \qquad d_E(X \cap Y) + d_E(X \cup Y) \leq d_E(X) + d_E(Y).$$

As the cut condition holds for $X \cap Y$ and $X \cup Y$, we have equality in (74.45), and therefore $X \cap Y$ is tight. Since $s_r \in X \setminus Y$, we know $|X \cap Y| < |X|$. So by the minimality of X we have $X \cap Y = \emptyset$. So $w \notin Y$, hence $u = v \in Y$. Then edge $e = uw$ connects $X \setminus Y$ and $Y \setminus X$, contradicting equality in (74.45). This proves (74.41).

Now choose $r = st \in R$. By symmetry of F_1 and F_2, we may assume that $s, t \in VC_1$. Let P and Q be the two $s - t$ paths along C_1. Deleting the edges of P from G and r from R, must violate the cut condition (as the Euler condition is maintained, and as for the new data there is no solution, since with P it gives a solution for the original data). So $|\delta_{E \setminus EP}(K)| < |\delta_{R \setminus \{r\}}(K)|$ for some $K \subseteq V$, with $G[K]$ and $G - K$ connected (by Theorem 70.4 taking $c := \chi^{E \setminus EP}$ and $d := \chi^{R \setminus \{r\}}$). Since $G[K]$ and $G - K$ are connected, and using (74.41), $|\delta_E(K) \cap EC_i| = 2$ for $i = 1, 2$. Moreover, K is tight, $\delta_E(K)$ contains two edges of P, and K does not split r. So we may assume that $s, t \notin K$. Similarly, there is a tight subset L of V such that $|\delta_E(L) \cap EC_i| = 2$ for $i = 1, 2$, such that $\delta_E(L)$ contains two edges of Q, and such that $s, t \notin L$.

As each of K, $V \setminus K$, L, and $V \setminus L$ intersects VC_2, each $s - t$ path in G intersects $K \cup L$ (since K contains a path from VP to VC_2 and L contains a path from VQ to VC_2). Hence we can partition $V \setminus (K \cup L)$ into sets M and N, with $s \in M$, $t \in N$, and $E[M, N] = \emptyset$. (Here and below, $E[X, Y]$ and $R[X, Y]$ denote the set of pairs xy in E and R respectively with $x \in X$ and $y \in Y$.)

We can assume by symmetry that $R[M, K \cap L] = \emptyset$. For suppose that $R[M, K \cap L] \neq \emptyset$ and $R[N, K \cap L] \neq \emptyset$. Since $K \cap L$ does not intersect VC_1, it would follow that both M and N intersect VC_2. However, this implies $K \cap L = \emptyset$, and hence $R[M, K \cap L] = \emptyset$.

Then we have the contradiction

$$
\begin{aligned}
(74.46)\qquad & d_R(K) + d_R(L) = d_E(K) + d_E(L) \\
& = (d_E(K \cup M) + |E[M, K]| - |E[M, L \setminus K]| - |E[M, N]|) \\
& +(d_E(L \cup M) + |E[M, L]| - |E[M, K \setminus L]| - |E[M, N]|) \\
& \geq d_E(K \cup M) + d_E(L \cup M) \geq d_R(K \cup M) + d_R(L \cup M) \\
& = (d_R(K) - |R[M, K]| + |R[M, L \setminus K]| + |R[M, N]|) \\
& + (d_R(L) - |R[M, L]| + |R[M, K \setminus L]| + |R[M, N]|) \\
& > d_R(K) + d_R(L).
\end{aligned}
$$

This follows from a straightforward count of edges, and from the facts that $E[M, L \setminus K] \subseteq E[M, L]$, $E[M, K \setminus L] \subseteq E[M, K]$, $E[M, N] = \emptyset$, $R[M, K] = R[M, K \setminus L]$ (as $R[M, K \cap L] = \emptyset$), $R[M, L] = R[M, L \setminus K]$ (similarly), and $R[M, N] \neq \emptyset$ (as $st \in R[M, N]$). ∎

Notes. Suzuki, Nishizeki, and Saito [1985b,1989] gave an $O(kn + nt_1 \cdot \mathrm{SP}_+(n))$-time algorithm for finding the edge-disjoint paths in this case (similarly for the capacitated case), where $k := |R|$, t_1 is the number of vertices on the boundary of F_1, and $\mathrm{SP}_+(n)$ is any upper bound on the time needed to find a shortest path in a planar n-vertex graph with nonnegative edge lengths.

The example of Figure 70.2 shows that Okamura's theorem cannot be extended to more than two selected faces, and also is not maintained if we allow 'mixed pairs'; that is, nets that connect the two selected faces. Under certain conditions one can allow such pairs — see (74.55) and (76.50) below.

74.3a. Distances and cut packing

By Theorem 70.5, Okamura's theorem implies that for any planar graph $G = (V, E)$ and any choice of two faces F_1 and F_2, there is a fractional packing of cuts such that any two vertices s, t that are either both incident with F_1 or both incident with F_2, are separated by $\mathrm{dist}_G(s, t)$ of these cuts. In fact, there is a half-integer packing, as follows from the following result of Schrijver [1989a], generalizing Corollary 74.2a:

(74.47) Let $G = (V, E)$ be a bipartite planar graph and let F_1 and F_2 be two of its faces. Then there exist edge-disjoint cuts such that any two vertices s, t with $s, t \in \mathrm{bd}(F_1)$ or $s, t \in \mathrm{bd}(F_2)$ are separated by $\mathrm{dist}_G(s, t)$ of these cuts.

Karzanov [1990a] gave an alternative proof of this, yielding a strongly polynomial-time algorithm for finding the cuts, also for the weighted case (that is, for length function $l : E \to \mathbb{Z}_+$ with $l(C)$ even for each circuit C of G, finding an integer packing of cuts).

74.3b. The Klein bottle

In Schrijver [1989b] the following relation between Okamura's theorem and graphs embedded in the Klein bottle is given. It generalizes the relation between the Okamura-Seymour theorem and graphs embedded in the projective plane, as described in Section 74.1b.

We can represent the Klein bottle as obtained from the 2-sphere by adding two cross-caps. A closed curve C on the Klein bottle is called *orientation preserving* if after one turn of C the meaning of 'left' and 'right' is unchanged. Otherwise, it is called *orientation-reversing.*

Thus a closed curve is orientation-preserving if and only if it traverses the cross-caps an even number of times. It is orientation-reversing if and only if it traverses the cross-caps an odd number of times. So, if $G = (V, E)$ is a graph embedded in the Klein bottle, there is a subset R of E such that a circuit in G is orientation-reversing if and only if it traverses the edges in R an odd number of times.

Let $G = (V, E)$ be a graph embedded in the Klein bottle. Define

(74.48) $\mathcal{C}$:= collection of orientation-reversing circuits in G;
$\mathcal{D}$:= collection of edge sets intersecting each orientation-reversing circuit of G.

(Here we take circuits as edge sets.)

In Schrijver [1989b], the following is derived from (74.47):

(74.49) Let $G = (V, E)$ be a bipartite graph embedded in the Klein bottle. Then the minimum length of an orientation-reversing circuit in G is equal to the maximum number of disjoint sets in $\mathcal{D}$.

(In fact it suffices to require, instead of bipartiteness, that each face of G is surrounded by an even number of edges.)

(74.49) implies that the up hull of the incidence vectors of sets in $\mathcal{C}$ is determined by:

(74.50)
$$\begin{aligned} x_e &\geq 0 && \text{for } e \in E, \\ x(D) &\geq 1 && \text{for } D \in \mathcal{D}. \end{aligned}$$

This follows from the fact that for any $l : E \to \mathbb{Z}_+ \setminus \{0\}$, the minimum value of

(74.51)
$$\sum_{e \in E} l(e)x_e$$

over (74.50) is achieved by an integer vector x. To see this, we may assume that $l(e)$ is even for each $e \in E$. Now replace each edge e of G by a path of length $l(e)$. We obtain a bipartite graph G'. Let C' be a minimum-length orientation-reversing circuit in G'. By (74.49), there exist disjoint edge sets $D'_1, \ldots, D'_t$ in G' each intersecting all orientation-reversing circuits in G', such that t is equal to the number of edges in C'. Let $C, D_1, \ldots, D_t$ be the edge sets in G corresponding to $C', D'_1, \ldots, D'_t$. So $D_1, \ldots, D_t \in \mathcal{D}$. Then

(74.52)
$$\sum_{e \in E} l(e)\chi^C(e) = t = \sum_{i=1}^{t} 1 \text{ and } \sum_{i=1}^{t} \chi^{D_i} \leq l.$$

So $D_1, \ldots, D_t$ give a dual solution to minimizing (74.51) over (74.50) of value t, and hence $x := \chi^C$ is an optimum solution.

So the vertices of the polyhedron determined by (74.50) are incidence vectors of orientation-reversing circuits. By the theory of blocking polyhedra, this implies that the up hull of the incidence vectors of the sets in $\mathcal{D}$ is determined by:

(74.53) $x_e \geq 0$ for $e \in E$,
$x(C) \geq 1$ for $C \in \mathcal{C}$.

From this the following stronger property has been derived in Schrijver [1989b], generalizing Lins' theorem (Corollary 74.1b):

(74.54) Let $G = (V, E)$ be an Eulerian graph embedded in the Klein bottle. Then the maximum number of edge-disjoint orientation-reversing circuits is equal to the minimum number of edges intersecting all orientation-reversing circuits.

This result cannot be extended to compact surfaces with more than two cross-caps, as we can embed K_5 in such a surface in such a way that the orientation-reversing circuits are exactly the odd-size circuits of K_5. Then the maximum number of edge-disjoint orientation-reversing circuits is equal to 2, while at least 4 edges are needed to intersect all orientation-reversing circuits.

From (74.54) one can derive Okamura's theorem (Theorem 74.4) and also another disjoint paths theorem for planar graphs (Schrijver [1989b]):

(74.55) Let $G = (V, E)$ be a planar graph, and let $H = (V, R)$ be a graph, with $R = \{s_1t_1, \ldots, s_kt_k\}$, such that G has two bounded faces F_1 and F_2 with the property that $s_1, \ldots, s_k$ occur in clockwise order along $\mathrm{bd}(F_1)$ and $t_1, \ldots, t_k$ occur in clockwise order along $\mathrm{bd}(F_2)$. Let $G+H$ be Eulerian. Then there exist edge-disjoint paths P_r, where P_r is an r-path for $r \in R$, if and only if the cut condition holds.

(Here $G+H$ is the graph $(V, E \cup R)$, taking multiplicities of edges into account. An *r-path* is a path connecting the vertices in r.) To see this, we can extend the plane to a Klein bottle, by adding a cylinder between the boundaries of F_1 and F_2. (That is, we first make the plane to a sphere, next take out the interiors of the faces F_1 and F_2, and then add the cylinder, in such a way that we obtain a nonorientable surface.) By the condition on the orders of the s_i and t_i along the boundaries of F_1 and F_2, we can extend the embedding of G to an embedding of $G + H$ in the Klein bottle, by embedding the edges s_it_i over the cylinder. Then a circuit in $G + H$ is orientation-reversing if and only if it contains an odd number of edges in R. So it suffices to show that $G + H$ contains k orientation-reversing circuits.

By (74.54) one must show that each set D of edges of $G + H$ intersecting all orientation-reversing circuits has size at least k. We may assume that D is a minimal set of edges in $G+H$ intersecting all orientation-reversing circuits in $G+H$. This implies that for each circuit C of $G + H$, $|D \cap C|$ is odd if and only if C is orientation-reversing. (Indeed, for each $e \in D \cap C$ there is an orientation-reversing circuit C_e disjoint from $D \setminus \{e\}$ (by the minimality of D). As C_e intersects D we know $e \in C_e$. Hence the symmetric difference X of C and the C_e for $e \in D \cap C$ is disjoint from D. So X contains no orientation-reversing circuit. Therefore, X is the symmetric difference of an even number of orientation-reversing circuits. So C is orientation-reversing if and only if $|D \cap C|$ is odd.)

In particular, $|D \cap C|$ is even for each circuit C in G. So $D \cap E$ is a cut $\delta_E(X)$ in G. Then for each $i = 1, \ldots, k$:

(74.56) if X does not separate s_i and t_i, then $s_i t_i \in D$.

Indeed, if X does not separate s_i and t_i, then there is an $s_i - t_i$ path P in G containing an even number of edges in D. As $P \cup \{s_i t_i\}$ is an orientation-reversing circuit, it intersects D an odd number of times, and hence $s_i t_i \in D$.

(74.56) implies $|D \cap R| \geq |R \setminus \delta_R(X)|$. Hence

(74.57) $$|D| = |D \cap E| + |D \cap R| \geq |\delta_E(X)| + |R \setminus \delta_R(X)| \geq |R| = k,$$

since $|\delta_E(X)| \geq |\delta_R(X)|$ by the cut condition. So $|D| \geq k$ as required.

One can similarly derive Okamura's theorem. First one may assume, without loss of generality, that $R = \{s_1 t_1, \ldots, s_k t_k\}$ such that $s_1, \ldots, s_l, t_1, \ldots, t_l$ occur cyclically around $\mathrm{bd}(F_1)$ and $s_{l+1}, \ldots, s_k, t_{l+1}, \ldots, t_k$ occur cyclically around $\mathrm{bd}(F_2)$. This can be achieved with the construction described in Section 74.1b (cf. Figure 74.1).

Now we can obtain a Klein bottle by adding a cross-cap in the interior of F_1 and a cross-cap in the interior of F_2 (assuming that G is embedded in the 2-sphere). We can extend the embedding of G to an embedding of $G + H$, by adding edges $s_i t_i$ for $i = 1, \ldots, l$ over the first cross-cap, and adding edges $s_i t_i$ for $i = l+1, \ldots, k$ over the second cross-cap. Applying (74.54), we obtain Okamura's theorem.

74.3c. Commodities spanned by three or more faces

Karzanov [1994c,1994b] showed that Okamura's theorem and the dual cut packing result (74.47) can be extended in a certain way to planar graphs where the nets are on three or more faces. These results can be compared to those in Section 72.2a.

We repeat the definition of Γ-metric. Let Γ be a graph, and let V be a finite set. A metric μ on V is called a *Γ-metric* if there is a function $\phi : V \to V\Gamma$ with

(74.58) $$\mu(u, v) = \mathrm{dist}_\Gamma(\phi(u), \phi(v))$$

for all $u, v \in V$. (Here $\mathrm{dist}_\Gamma(x, y)$ denotes the distance of x and y in Γ.)

The *Γ-metric condition*, a necessary condition for the existence of a feasible multiflow in a supply graph $G = (V, E)$ with demand graph $H = (V, R)$, capacities $c : E \to \mathbb{R}_+$ and demands $d : R \to \mathbb{R}_+$, reads:

(74.59) $$\sum_{r=st \in R} d(r)\mu(s,t) \leq \sum_{e=uv \in E} c(e)\mu(u,v) \text{ for each } \Gamma\text{-metric } \mu \text{ on } V.$$

The $K_{2,3}$-metric condition generalizes the cut condition.

For the edge-disjoint paths problem, Karzanov [1994b] showed that for extending Okamura's theorem to three faces, adding the $K_{2,3}$-metric condition suffices:

(74.60) Let $G = (V, E)$ be a planar graph, let F_1, F_2, and F_3 be three of its faces, and let $H = (V, R)$ be a graph such that for each $r = st \in R$ there is an $i = 1, 2, 3$ with s and t on the boundary of F_i. Let $G + H$ be Eulerian. Then there exist edge-disjoint paths P_r for $r \in R$, where P_r connects the vertices in r, if and only if the $K_{2,3}$-metric condition holds.

In particular, if a fractional solution exists, then an integer solution exists.

Karzanov [1994b] derived (74.60) from a dual result on packing cuts and $K_{2,3}$-metrics, proved in Karzanov [1994c]:

(74.61) Let $G = (V, E)$ be a bipartite planar graph and let $\mathcal{F}$ be a set of three of its faces. Then there exist $K_{2,3}$-metrics $\mu_1, \ldots, \mu_k$ such that $\text{dist}_G(u, v) \geq \mu_1(u, v) + \cdots + \mu_k(u, v)$ for all $u, v \in V$, with equality if there is an $F \in \mathcal{F}$ with both u and v incident with F.

Sebő [1993a] showed that a related result on surfaces with three cross-caps also holds (in the same way as the results on the Klein bottle above relate to Okamura's theorem (Theorem 74.4)). Let S be the compact surface with three cross-caps. Let $G = (V, E)$ be a graph embedded in S, and consider the system:

(74.62)
$$\begin{array}{ll} x_e \geq 0 & \text{for each } e \in E, \\ x(C) \geq 1 & \text{for each orientation-reversing circuit } C. \end{array}$$

Sebő showed that the polyhedron determined by (74.62) has half-integer vertices only. Moreover, if Z denotes the set of minimal $\{0, \frac{1}{2}, 1\}$ solutions of (74.62), then the system

(74.63)
$$\begin{array}{ll} x_e \geq 0 & \text{for each } e \in E, \\ z^{\mathsf{T}} x \geq 1 & \text{for each 0,1 vector } z \in Z, \\ 2z^{\mathsf{T}} x \geq 2 & \text{for each } z \in Z \end{array}$$

(which determines the blocking polyhedron of (74.62)) is totally dual half-integral. More strongly, for each $c : E \to \mathbb{Z}_+$ with $c(C)$ even for each circuit C of G, the dual of minimizing $c^{\mathsf{T}} x$ over (74.63) has an integer optimum solution.

From this, Sebő derived a result related to (74.61), in the same was as (74.54) is related to Okamura's theorem (Theorem 74.4):

(74.64) Let $G = (V, E)$ be a bipartite planar graph and let F_1, F_2, F_3 be three of its faces, with F_1 and F_2 bounded. Let $s_1, \ldots, s_k$ occur clockwise along $\text{bd}(F_1)$ and let $t_1, \ldots, t_k$ occur clockwise along $\text{bd}(F_2)$. Then there exist $K_{2,3}$-metrics $\mu_1, \ldots, \mu_k$ such that $\text{dist}_G(u, v) \geq \mu_1(u, v) + \cdots + \mu_k(u, v)$ for all $u, v \in V$, with equality if there is an i with $u = s_i$, $v = t_i$, or if both u and v are incident with F_3.

For the extension of (74.61) to four or more faces, there is not a finite collection $\mathcal{G}$ of graphs such that in (74.60) and (74.61) one can consider Γ-metrics for Γ in $\mathcal{G}$. However, for four faces, Karzanov [1994c] proved:

(74.65) Let $G = (V, E)$ be a bipartite planar graph and let $\mathcal{F}$ be a set of four of its faces. Then there exists a collection of metrics $\mu_1, \ldots, \mu_k$ such that each μ_i is a Γ-metric for some bipartite planar graph Γ with four faces, and such that $\text{dist}_G(u, v) \geq \mu_1(u, v) + \cdots + \mu_k(u, v)$ for all $u, v \in V$, with equality if there is an $F \in \mathcal{F}$ with both u and v incident with F.

This implies, with the usual polarity argument, that if $G = (V, E)$ is a planar graph, $\mathcal{F}$ a set of four of its faces, $H = (V, R)$ a graph such that for each $r = st \in F$ there is an $F \in \mathcal{F}$ with s and t incident with F, $c : E \to \mathbb{R}_+$, and $d : R \to \mathbb{R}_+$, then there is a feasible multiflow if and only if the Γ-metric condition (74.59) holds for each planar bipartite graph Γ with four faces.

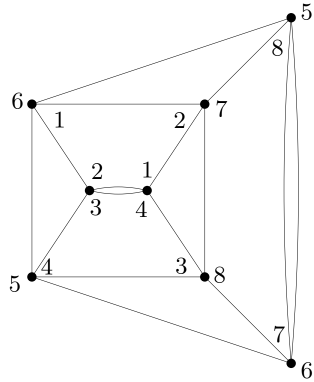

Figure 74.2
An example of a planar graph where each commodity is spanned by one of the four 4-sided faces and where there exists a half-integer, but no integer multiflow, while the Euler condition holds. The nets are indicated by pairs of indices at the vertices. All capacities and demands are 1. The half-integer multiflow is obtained by putting, for each index i, a flow of value $\frac{1}{2}$ along each of the two paths along the boundary of the (unique) face incident with both vertices i.

However, if $G + H$ is Eulerian, an integer solution (for $c = \mathbf{1}$, $d = \mathbf{1}$) need not exist, as is shown in Karzanov [1994b]. In fact, Karzanov gave an example where $G + H$ is Eulerian and where a half-integer solution exists, but no integer solution (Figure 74.2). Karzanov [1995] however showed that if c and d are integer and satisfy the Euler condition, then the existence of a fractional multiflow implies the existence of a half-integer multiflow. Hence, if c and d are integer (but not necessarily satisfy the Euler condition), then the existence of a fractional multiflow implies the existence of a quarter-integer multiflow.

Karzanov [1994c] showed that (74.65) cannot be extended to a set $\mathcal{F}$ of five faces by adding Γ-metrics for planar bipartite graphs Γ with five faces.

74.4. Further results and notes

74.4a. Another theorem of Okamura

Next to Theorem 74.4 ('Okamura's theorem'), Okamura [1983] gave another generalization of the Okamura-Seymour theorem:

Theorem 74.5. *Let $G = (V, E)$ be a planar graph. Let R be a set of nets such that there is a vertex q on the outer boundary of G with the property that each net is spanned by the outer boundary of G or it contains q. Let the Euler condition hold. Then the edge-disjoint paths problem has a solution if and only if the cut condition holds.*

Proof. Necessity being trivial, we show sufficiency. As in the proof of Theorem 74.4 we consider a counterexample with $2|E| - |R|$ minimal. It again implies that G is 2-connected, and that no $r \in R$ is parallel to an edge of G. Moreover, R contains at least one pair r with $q \notin r$, as otherwise the theorem follows easily from Menger's theorem.

Let C be the circuit formed by the outer boundary of G. Consider any pair $g = xy$ in R with $q \notin g$ (so $x, y \in VC$), such that the $x - y$ path P along C not containing q, is as short as possible. Deleting the edges in P from G, and net g from R, the cut condition is not maintained (as otherwise we have a smaller counterexample). As in the proof of Theorem 74.4 it implies that there exists a tight X with $x, y \notin X$ and such that X intersects C in a subpath of P. Choose X with $|X|$ minimal. Note that by the choice of g, X spans no pair in R.

If $\delta_R(X)$ contains no pair $r = st$ with both ends on C, it contains only pairs qv with $v \in X$. Hence we can contract X to one vertex and obtain a smaller counterexample (note that $|X| \geq 2$, since any net in $\delta_R(X)$ is equal to $qv \in R$ for some $v \in X$ with $v \notin VC$).

So we can assume that $\delta_R(X)$ contains a pair with both ends on C. Let e be one of the (two) edges in EC that belong to $\delta_E(X)$. We choose e such that there is a pair $r = st$ in $\delta_R(X)$ such that $s, t \in VC$ and such that the $s - t$ path along C containing e does not traverse q except possibly at its ends. Let $e = uw$ with $u \notin X$ and $w \in X$. For each $r \in \delta_R(X)$, let s_r be the vertex in $r \cap X$, and t_r the vertex in $r \setminus X$. Since $q \notin X$, we know that each such t_r is on C. Choose $r \in \delta_R(X)$ such that s_r belongs to VC, such that the $s_r - t_r$ path along C containing e does not traverse q except possibly at its ends, and such that t_r is as close as possible to u when following $C - X$. By the choice of e, such an r exists.

Since s_r and t_r are nonadjacent, we know that $\{s_r, t_r\} \neq \{u, w\}$. So we can choose $v \in \{u, w\}$ with $v \notin \{s_r, t_r\}$. Let $R' := (R \setminus \{r\}) \cup \{s_r v, v t_r\}$. Trivially the Euler condition is maintained. We show that also the cut condition is maintained, contradicting the minimality of the counterexample.

To see that the cut condition is maintained, suppose to the contrary that there is a $Y \subseteq V$ satisfying

(74.66) $$d_E(Y) < d_{R'}(Y).$$

By Theorem 70.4, we can assume that $G[Y]$ and $G - Y$ are connected. By symmetry we can assume that $t_r \notin Y$. By the Euler condition, (74.66) implies $d_E(Y) \leq d_{R'}(Y) - 2$. So

(74.67) $$d_{R'}(Y) \geq d_E(Y) + 2 \geq d_R(Y) + 2 \geq d_{R'}(Y).$$

Hence we have equality throughout. So $\delta_{R'}(Y)$ contains both $s_r v$ and $v t_r$, that is, $s_r, t_r \notin Y$ and $v \in Y$. Moreover, $d_E(Y) = d_R(Y)$.

By the choice of r, there is no pair in R connecting $X \setminus Y$ and $Y \setminus X$. So (using Theorem 3.1)

(74.68) $$d_R(X \cap Y) + d_R(X \cup Y) = d_R(X) + d_R(Y).$$

Moreover,

(74.69) $$d_E(X \cap Y) + d_E(X \cup Y) \leq d_E(X) + d_E(Y).$$

As the cut condition holds for $X \cap Y$ and $X \cup Y$, we have equality in (74.69), and therefore $d_E(X \cap Y) = d_R(X \cap Y)$. Since $s_r \in X \setminus Y$, we know $|X \cap Y| < |X|$. So by the minimality of X we have $X \cap Y = \emptyset$. So $w \notin Y$, hence $u = v \in Y$. Then edge $e = uw$ connects $X \setminus Y$ and $Y \setminus X$, contradicting equality in (74.69). ∎

Suzuki, Nishizeki, and Saito [1985a,1985b] gave an $O(t^2 n + n \cdot \mathrm{SP}_+(n))$-time algorithm for finding the edge-disjoint paths in this case (similarly for the capacitated case), where t is the number of vertices on the outer boundary, and where $\mathrm{SP}_+(n)$ is any upper bound on the time needed to find a shortest path in a planar n-vertex graph with nonnegative edge lengths.

With Theorem 70.5, Theorem 74.5 implies that for any planar graph $G = (V, E)$ and any vertex q on the outer boundary, there is a fractional cut packing such that any pair s, t of vertices, with s, t both on the outer boundary or $s = q$, is separated by $\mathrm{dist}_G(s, t)$ of these cuts. It seems to be open if the corresponding integer packing theorem for bipartite planar graphs holds.

74.4b. Some other planar cases where the cut condition is sufficient

It was announced by Gerards [1993] that if $G = (V, E)$ is a bipartite planar graph and $s, t \in V$, then there exist disjoint cuts such that for each $u, v \in V$ with u, v both on the outer boundary, or with $u = s$, $v = t$, the distance of u and v is equal to the number of cuts separating u and v. By Theorem 70.5, this implies that the cut condition implies the existence of a fractional multiflow, if each net is spanned by the outer boundary or is equal to some fixed pair $\{s, t\}$ of vertices.

Gerards [1993] also announced that if G is a graph embedded in the Möbius strip, and if $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$ are nets such that the terminals are either in the order $s_1, \ldots, s_k, t_1, \ldots, t_k$ along the boundary, or in the order or $s_1, \ldots, s_k, t_k, \ldots, t_1$, then the cut condition and the Euler condition imply the existence of an integer multiflow.

74.4c. Vertex-disjoint paths in planar graphs

Let $G = (V, E)$ be a planar graph, embedded in the plane $\mathbb{R}^2$ and let $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$ be disjoint pairs of vertices (the 'nets'). Robertson and Seymour [1986] observed that there is an easy greedy-type algorithm for the vertex-disjoint paths problem if all vertices $s_1, t_1, \ldots, s_k, t_k$ belong to the outer boundary of G. That is, there exists a polynomial-time algorithm for the following problem:

(74.70) given: a planar graph $G = (V, E)$ and disjoint pairs $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$ of vertices on the outer boundary of G,
find: vertex-disjoint paths $P_1, \ldots, P_k$ in G, where P_i connects s_i and t_i $(i = 1, \ldots, k)$.

We describe the simple intuitive idea of the method. (Pinter [1983] attributed this idea to C.P. Hsu (1982), and applied it to the vertex-disjoint paths problem in rectangular grids.)

We say that two disjoint pairs $\{s, t\}$ and $\{s', t'\}$ cross (around G) if there exist no disjoint curves in the unbounded face, connecting s and t, and connecting s' and t'. The following *noncrossing condition* is a necessary condition for (74.70) to have a solution:

(74.71) No two distinct nets $\{s_i, t_i\}, \{s_j, t_j\}$ cross.

The noncrossing condition implies that there exists an i such that at least one of the two $s_i - t_i$ paths along $\text{bd}(F)$ contains no s_j or t_j for $j \neq i$: just choose i such that the shortest $s_i - t_i$ path along the outer boundary is shortest among all $i = 1, \ldots, k$.

Without loss of generality, $i = k$. Let Q be a shortest $s_k - t_k$ path along the outer boundary. Let $G' := G - VQ$. Next solve the vertex-disjoint paths problem for input G', $\{s_1, t_1\}, \ldots, \{s_{k-1}, t_{k-1}\}$. If this gives a solution $P_1, \ldots, P_{k-1}$, then $P_1, \ldots, P_{k-1}, Q$ forms a solution to the original problem (trivially).

If the reduced problem turns out to have no solution, then the original problem also has no solution. This follows from the fact that if $P_1, \ldots, P_{k-1}, P_k$ would be a solution to the original problem, we may assume without loss of generality that $P_k = Q$, since we can 'push' P_k 'against' the outer boundary. Hence $P_1, \ldots, P_{k-1}$ would form a solution to the reduced problem. This intuitive idea is the basis of a polynomial-time algorithm for problem (74.70):

Theorem 74.6. *The vertex-disjoint paths problem is polynomial-time solvable for planar graphs with all terminals on the outer boundary.*

Proof. See above. ∎

Linear-time implementations were given by Suzuki, Akama, and Nishizeki [1988c,1990] and Liao and Sarrafzadeh [1991].

The method implies moreover a characterization by means of a cut condition for the existence of a solution to (74.70). A *simple closed curve* C in $\mathbb{R}^2$ is by definition a one-to-one continuous function from the unit circle to $\mathbb{R}^2$. We will identify the function C with its image.

We say that C *separates* the pair $\{s, t\}$ if each curve connecting s and t intersects C. (In particular, if s or t is on C.) Now the following *cut condition* clearly is necessary for the existence of a solution to the vertex-disjoint paths problem in planar graphs:

(74.72) each simple closed curve in $\mathbb{R}^2$ intersects G at least as often as it separates pairs $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$.

Robertson and Seymour [1986] showed with the method above:

Theorem 74.7. *Let $G = (V, E)$ be a planar graph embedded in $\mathbb{R}^2$ and let $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$ be pairs of vertices on the outer boundary of G. Then there exist vertex-disjoint paths $P_1, \ldots, P_k$ where P_i connects s_i and t_i ($i = 1, \ldots, k$) if and only if the noncrossing condition* (74.71) *and the cut condition* (74.72) *hold.*

Proof. Necessity of the conditions is trivial. We show sufficiency by induction on k, the case $k = 0$ being trivial. Let $k \geq 1$ and let (74.71) and (74.72) be satisfied. Suppose that paths $P_1, \ldots, P_k$ as required do not exist. Trivially, $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$ are disjoint (otherwise there would exist a simple closed curve C with $|C \cap G| = 1$ and intersecting two nets, thus violating the cut condition).

We may assume that G is connected, as we can decompose G into its components. (If some s_i and t_i would belong to different components, there trivially exists a closed curve C violating the cut condition.) We can also assume that there is no cut vertex v such that $G-v$ has a component K containing no terminal (otherwise we could delete K from G without violating the cut condition).

Now there exists an i and a simple $s_i - t_i$ path P_i such that P_i follows the outer boundary and traverses no other terminals than s_i and t_i. We can assume that $i = k$. Let $G' := G - VP_k$.

Then G' contains no vertex-disjoint $s_i - t_i$ paths ($i = 1, \ldots, k-1$), since otherwise G contains vertex-disjoint $s_i - t_i$ paths ($i = 1, \ldots, k$). Hence, by the induction hypothesis, there exists a simple closed curve C with $|C \cap G'|$ smaller than the number of pairs $\{s_1, t_1\}, \ldots, \{s_{k-1}, t_{k-1}\}$ separated by C.

We can assume that C traverses the unbounded face of G' exactly once and that it intersects G only in vertices of G. We choose C such that it has a minimum number of intersections with P_k. Then C intersects P_k at most once. If C does not intersect P_k, then $|C \cap G| = |C \cap G'|$, and C violates the cut condition also for G. If C intersects P_k, then $|C \cap G| = |C \cap G'| + 1$ and C separates s_k and t_k, and so again C violates the cut condition for G. ∎

It is easy to extend the algorithm and Theorem 74.7 to the directed case, and also to the following *vertex-disjoint trees problem*:

(74.73) given: a planar graph $G = (V, E)$ and sets $S_1, \ldots, S_k$ of vertices on the outer boundary of G,
find: vertex-disjoint subtrees $T_1, \ldots, T_k$ of G such that T_i covers S_i ($i = 1, \ldots, k$).

More generally, with similar techniques, Ding, Schrijver, and Seymour [1992] generalized Theorem 74.7 (and the polynomial-time algorithm) as follows.

Theorem 74.8. *Let $D = (V, A)$ be a directed planar graph, let B be a family of ordered pairs of vertices on the outer boundary of D (with $s \neq t$ if $(s, t) \in B$), for each $b \in B$ let $A_b \subseteq A$, and let H be a set of unordered pairs from B. Then there exist paths P_b for $b \in B$ such that:*

(74.74) (i) *for $b = (s, t) \in B$, P_b is a directed $s - t$ path in (V, A_b),*
(ii) *P_b and P_c are vertex-disjoint for each $\{b, c\} \in H$,*

if and only if the following two conditions hold: the 'noncrossing condition':

(74.75) *if $\{(r, s), (t, u)\} \in H$, then (r, s) and (t, u) are disjoint and do not cross,*

and the 'cut condition':

(74.76) *for each curve C starting and ending in the unbounded face and not intersecting any s, t with $(s, t) \in B$ and for each choice of $b_1, \ldots, b_n \in B$ satisfying:*
- *$\{b_j, b_{j+1}\} \in H$ for $j = 1, \ldots, n-1$,*
- *$f, x_1, \ldots, x_n, l, y_n, \ldots, y_1$ are all distinct and occur in this order clockwise around the outer boundary, where x_j and y_j are such that $b_j = (x_j, y_j)$ or $b_j = (y_j, x_j)$, and where f and l denote the first and last point of intersection of C with D,*

there exist distinct points $p_1, \ldots, p_n$ traversed by C in this order such that for each $j = 1, \ldots, n$:

- *p_i is on the image of D in $\mathbb{R}^2$, if $b_j = (x_j, y_j)$, then some arc in A_{b_j} is entering C at p_j from the left and some arc in A_{b_j} is leaving C at p_j from the right,*
- *if $b_j = (y_j, x_j)$, then some arc in A_{b_j} is entering C at p_j from the right and some arc in A_{b_j} is leaving C at p_j from the left.*

(The points p_i can be vertices of D or be on arcs of D.)

Theorem 74.8 implies an even more general characterization and algorithm for disjoint rooted subarborescences. Let $D = (V, A)$ be a planar digraph, let B be a collection of ordered pairs (r, S) where r is a vertex on the outer boundary of D, and S is a set of vertices on the outer boundary of D with $r \notin S$. For each $b \in B$, let $A_b \subseteq A$, and let H be a set of unordered pairs from B. Then Theorem 74.8 implies necessary and sufficient conditions for the existence of rooted subarborescences T_b in D (for $b \in B$), with the property that

(74.77) (i) for $b = (r, S) \in B$, T_b is rooted at r, covers S, and is contained in A_b,
(ii) T_b and T_c are vertex-disjoint for each $\{b, c\} \in H$.

The reduction to Theorem 74.8 is by replacing each pair (r, S) in B by the pairs (r, s) for $s \in S$, and reset H to all pairs $\{(r, s), (r', s')\}$ coming from pairs $\{(r, S), (r', S')\}$ in the original H.

Notes. Suzuki, Akama, and Nishizeki [1988c,1990] and Liao and Sarrafzadeh [1991] gave linear-time algorithms for problem (74.73). For a description, see also Wagner [1993].

Theorem 74.6 implies that the vertex-disjoint paths problem is polynomial-time solvable for outerplanar graphs. This was generalized to series-parallel graphs by Korach and Tal [1993].

Takahashi, Suzuki, and Nishizeki [1992] gave an $O(n \log n)$-time algorithm to find pairwise noncrossing paths of minimum total length, connecting prescribed terminals in a planar graph with all terminals on two specified face boundaries.

74.4d. Grid graphs

Grid graphs form a class of planar graphs that are of special interest for disjoint paths problem, as they arise in the design of VLSI-circuits, in particular in routing the wires on the layers of a chip.

Any finite subgraph of the 2-dimensional rectangular grid is called a *grid graph*. So its vertex set is a finite subset of $\mathbb{Z}^2$, and any two adjacent vertices have Euclidean distance 1. (It is not required conversely that any two vertices at Euclidean distance 1 are adjacent; so the subgraph need not be an *induced* subgraph.)

Kramer and van Leeuwen [1984] showed that both the vertex-disjoint and the edge-disjoint paths problems are NP-complete even when restricted to grid graphs. Pinter [1983] showed that the vertex-disjoint paths problem remains NP-complete for grid graphs in which all faces are bounded by a rectangle (including a square).

A *rectangular grid* is a grid graph whose outer boundary is a rectangle and whose bounded faces all are unit squares. The *channel routing problem* is the vertex-disjoint paths problem in a rectangular grid, where all nets connect a vertex on the upper horizontal border with one on the lower horizontal border. A criterion for the feasibility of the channel routing problem was given by Dolev, Karplus, Siegel, Strong, and Ullman [1981], while Rivest, Baratz, and Miller [1981] gave a heuristic algorithm approximating the minimal height of the rectangle, given the positions of the terminals (cf. Preparata and Lipski [1984] and Mehlhorn, Preparata, and Sarrafzadeh [1986]). A linear-time algorithm for channel-routing, allowing also multiterminal nets, was given by Greenberg and Maley [1992].

The feasibility criterion was extended by Pinter [1983] to *switchboxes*, which are rectangular grids in which the terminals can be anywhere along the outer boundary. For the vertex-disjoint paths problem in switchboxes, Pinter showed Theorem 74.7 and described the corresponding greedy-type algorithm. He attributes the idea to C.P. Hsu (1982).

Algorithms for the *edge*-disjoint paths problem in a switchbox were given by Frank [1982c] ($O(n \log n)$) and Mehlhorn and Preparata [1986] ($O(u \log u)$, where u is the circumference of the rectangle — note that this is sufficient to specify the graph). Frank also showed that solvability only depends on horizontal and vertical cuts.

A *generalized switchbox* is a grid graph with all bounded faces being unit squares. Nishizeki, Saito, and Suzuki [1985] gave an $O(n^2)$-time algorithm for routing in generalized switchboxes for which any two vertices on the outer boundary are connected by a path with at most one bend; all terminals are on the outer boundary. They also showed that in this case one may restrict the cuts to those that are either horizontal or vertical, if the global Euler condition holds. (A correction and generalization was given by Lai and Sprague [1987].)

Kaufmann and Mehlhorn [1986] described an $O(n \log^2 n + q^2)$-time algorithm for the edge-disjoint paths problem in a generalized switchbox, with all terminals on the outer boundary. Here q denotes the number of vertices v with $\deg_G(v)+\deg_H(v)$ odd. So if the Euler condition holds, the time bound is $O(n \log^2 n)$.

Kaufmann and Mehlhorn [1986] also showed that in a generalized switchbox satisfying the Euler condition and such that no vertex is end point of more than two curves, the cut condition holds whenever it holds for all 1-bend cuts. (A cut is called a 1-*bend cut* if it is the set of edges crossed by the union of some horizontal and some vertical halfline with one common end vertex.)

Kaufmann and Klär [1993] gave an $O(u \log^2 u)$-time algorithm for generalized switchboxes, whose outer boundary is simple and has no 'rectilinearly visible corners'. (Two corners p and q of the outer boundary are called *rectilinearly visible* if the (unique) rectangle of which p and q are opposite vertices, has a nonempty interior and intersects the outer boundary only in p and q.)

Wagner and Weihe [1993,1995] showed that for such problems, if $G + H$ is Eulerian, then there is even a linear-time algorithm, even for general planar graphs. (This improves earlier results of Becker and Mehlhorn [1986] and Kaufmann [1990].)

If G is a rectangle with one rectangular hole, and all nets join two vertices either on the outer rectangle or on the inner rectangle, and if the Euler condition holds, Suzuki, Ishiguro, and Nishizeki [1990] gave a linear-time algorithm. Related results are given in Frank, Nishizeki, Saito, Suzuki, and Tardos [1992].

Takahashi, Suzuki, and Nishizeki [1993] gave a polynomial-time algorithm for the minimum-length 'noncrossing' paths problem in certain grid graphs.

The problem of finding edge-disjoint trees connecting specified sets of vertices on the outer boundary of a rectangle is NP-complete (Sarrafzadeh [1987b]). More on channel routing can be found in Preparata and Sarrafzadeh [1985], Sarrafzadeh and Preparata [1985], Mehlhorn, Preparata, and Sarrafzadeh [1986], Sarrafzadeh [1987a], Formann, Wagner, and Wagner [1991,1993], Greenberg and Shih [1995, 1996], and Chan and Chin [1997,2000]. Surveys on disjoint paths problems in grid graphs are given by Kaufmann and Mehlhorn [1990] and in the book by Lengauer [1990].

74.4e. Further notes

The Lucchesi-Younger theorem (Theorem 55.2) implies the following. Let $D = (V, A)$ and $H = (V, R)$ be digraphs with D acyclic and $(V, A \cup R)$ planar. Then D has arc-disjoint paths P_r for $r \in R$, where P_r runs from s to t if $r = (s, t)$, if and only if for each $B \subseteq A$:

(74.78) $|B| \geq$ number of $r = (s, t) \in R$ such that B intersects each $s-t$ path in D.

Trivially, this condition is necessary. The derivation of sufficiency from the Lucchesi-Younger theorem is as follows. Consider the planar digraph $Q = (V, A \cup R^{-1})$. We need to show that if (74.78) holds for each $B \subseteq A$, then Q contains $|R|$ arc-disjoint directed circuits. Equivalently, the planar dual Q^* contains $|R|$ disjoint directed cuts. Applying the Lucchesi-Younger theorem to Q^* yields for Q that we should show that (74.78) implies that each set C of arcs of Q intersecting each directed circuit of Q has size at least $|R|$. Set $B := C \cap A$ and $R' := C^{-1} \cap R$. Then for each $r = (s, t) \in R \setminus R'$, each $s-t$ path in D intersects B. So by (74.78), $|B| \geq |R \setminus R'|$, and hence $|C| = |B| + |R'| \geq |R|$.

Similarly the polynomial-time solvability of the corresponding arc-disjoint paths problem follows (using Theorem 55.7).

Korte, Prömel, and Steger [1990] showed that the edge-disjoint trees problem is NP-complete, even if we ask for two disjoint trees in a planar graph, where the trees should cover two prescribed sets of vertices.

Surveys on linear-time methods for disjoint paths problems in planar graphs were given by Wagner [1993] and Ripphausen-Lipa, Wagner, and Weihe [1995]. For extensions to nets spanned by a fixed number of faces, see Section 76.7a.

Chapter 75

Cuts, odd circuits, and multiflows

Minimum-size cuts in a graph are well under control from an algorithmic point of view, as we saw in Parts I and V. Finding a *maximum*-size cut is however an NP-complete problem.
The complement of a maximum-size cut is a minimum-size odd circuit cover — a set of edges intersecting all odd circuits. By duality, this relates to maximum collections of edge-disjoint odd circuits. This in turn relates to multiflows.
Weakly bipartite graphs are those graphs where the polyhedral approach works. It makes that the maximum cut problem is polynomial-time solvable for these graphs.
Key result in this chapter is a theorem of Guenin characterizing weakly bipartite graphs, and its extension by Geelen and Guenin to evenly bipartite graphs. These results turn out to unify several multiflow and odd circuit packing theorems.

75.1. Weakly and strongly bipartite graphs

Let $G = (V, E)$ be an undirected graph. Call a subset B of E *bipartite* if (V, B) is bipartite; equivalently, if B does not contain the edge set of any odd circuit; equivalently, if B is contained in some cut C. So finding a maximum-size bipartite set of edges is equivalent to finding a maximum-size cut, and hence it is NP-complete (cf. Section 75.1a).

The *bipartite subgraph polytope* $P_{\text{bipartite subgraph}}(G)$ of G is the convex hull of the incidence vectors (in $\mathbb{R}^E$) of bipartite subsets B of E:

(75.1) $$P_{\text{bipartite subgraph}}(G) := \text{conv.hull}\{\chi^B \mid B \subseteq E \text{ bipartite}\}.$$

Any vector x in the bipartite subgraph polytope satisfies

(75.2) $$\begin{array}{lll} \text{(i)} & 0 \leq x_e \leq 1 & \text{for each } e \in E, \\ \text{(ii)} & x(C) \leq |C| - 1 & \text{for each odd circuit } C. \end{array}$$

In general, these constraints are not enough to determine the bipartite subgraph polytope: for the complete graph K_5, the vector x with $x_e = \frac{2}{3}$ for each edge e satisfies (75.2), but does not belong to the bipartite subgraph polytope (since the largest bipartite subgraph has 6 edges, while $10 \cdot \frac{2}{3} > 6$).

Following Grötschel and Pulleyblank [1981], a graph G is called *weakly bipartite* if its bipartite subgraph polytope is determined by (75.2). An equivalent characterization is in terms of odd circuit covers. An *odd circuit cover* in an undirected graph $G = (V, E)$ is a set of edges intersecting all odd circuits. The *odd circuit cover polytope* is the convex hull of the incidence vectors of odd circuit covers. It is contained in the polytope determined by

(75.3) $\quad 0 \leq x_e \leq 1 \quad$ for each $e \in E$,
$\quad\quad x(C) \geq 1 \quad$ for each odd circuit C.

Then a graph is weakly bipartite if and only the odd circuit polytope is determined by (75.3). This follows directly from the facts that a set of edges is an odd circuit cover if and only if its complement is bipartite, and that x satisfies (75.2) if and only if $\mathbf{1} - x$ satisfies (75.3).

The relevance of weakly bipartite graphs comes from the fact that a maximum-capacity cut in these graphs can be found in strongly polynomial time, with the ellipsoid method, since the separation problem over the polytopes (75.2) is polynomial-time solvable (cf. Section 5.11). Indeed, checking (75.2) is equivalent to checking (75.3). One can check the constraints in (75.3)(i) one by one, and so one may assume that $\mathbf{0} \leq x \leq \mathbf{1}$. Next, considering x as length function, one checks if there is an odd circuit of length < 1 (like in Theorem 68.1). If so, we find a violated constraint. If not, x satisfies (75.3).

Weakly bipartite graphs were characterized by Guenin [1998a,2001a], proving a conjecture of Seymour [1981a]. This characterization also holds for the more general structure of *signed graphs*, for which it is easier to prove as it allows a finer contraction operation — see Sections 75.2 and 75.5. For just undirected graphs the characterization can be formulated as follows.

Call a graph H an *odd minor* of a graph G if H arises from G by deleting edges and vertices and by contracting all edges in a cut. The class of weakly bipartite graphs is closed under taking odd minors. To see this, it is easily seen that this class is closed under deleting edges and vertices. To see that it is closed under contracting a cut, let $G = (V, E)$ be a weakly bipartite graph, let $U \subseteq V$ and $G' = G/\delta(U)$, and take $x \in \mathbb{R}^{E'}$, where $E' = E \setminus \delta(U)$ is the edge set of G'. Let x satisfy (75.3) with respect to G'. Define $x_e := 0$ for each $e \in \delta(U)$. Then the extended x satisfies (75.3) with respect to G. So the extended x belongs to the odd circuit cover polytope of G, implying that the original x belongs to the odd circuit cover polytope of G'.

Now Guenin's characterization reads for undirected graphs:

(75.4) $\quad$ an undirected graph G is weakly bipartite $\iff$ K_5 is not an odd minor of G.

Related is a characterization of those graphs for which (75.2) is totally dual integral. These graphs are called *strongly bipartite*[22]. A general hypergraph theorem of Seymour [1977b] implies a characterization of strongly bipartite graphs. They are precisely the graphs containing no odd K_4-subdivision — equivalently, the graphs not having K_4 as odd minor. Again, this is easier to handle in the context of signed graphs — see Section 75.4.

75.1a. NP-completeness of maximum cut

In this section we show (Karp [1972b]):

Theorem 75.1. *Finding the maximum size of a cut in an undirected graph is* NP-*complete.*

Proof. We reduce the problem of finding the minimum size of a vertex cover in a graph $G = (V, E)$ to the maximum-size cut problem. This is sufficient, since the first problem is NP-complete by Corollary 64.1a.

We can assume that G has no isolated vertices, since they will not occur in any minimum-size vertex cover. Extend G by a new vertex u and, for each $v \in V$, by $\deg_G(v) - 1$ parallel edges connecting v and u. Let G' be the extended graph. Then

(75.5) the minimum size of a vertex cover in G is equal to $2|E|$ minus the maximum size of a cut in G'.

To see this, we have for any $U \subseteq V$:

$$(75.6)\qquad \begin{aligned} |\delta_{G'}(U)| &= |\delta_G(U)| + \sum_{v \in U} (\deg_G(v) - 1) \\ &= 2|\{e \in E \mid e \text{ intersects } U\}| - |U|. \end{aligned}$$

Hence, if U is a minimum-size vertex cover of G, then $|\delta_{G'}(U)| = 2|E| - |U|$, proving $\geq$ in (75.5).

To see the reverse inequality, choose a subset U of V that determines a maximum-size cut $\delta_{G'}(U)$ in G'. Then U is a vertex cover of G. Otherwise, $V \setminus U$ spans an edge e of G. Then extending U by one of the ends of e increases (75.6), a contradiction. So U is a vertex cover and $|U| = 2|E| - |\delta_{G'}(U)|$, proving $\leq$ in (75.5). ∎

75.1b. Planar graphs

Although we do not use these results in later sections, we first show that planar graphs are weakly bipartite, as it gives an interesting relation with T-joins (Barahona [1980]):

Theorem 75.2. *A planar graph is weakly bipartite.*

Proof. Consider the dual graph $G^* = (V^*, E^*)$. An odd circuit in G corresponds to an odd-size cut in G^*, that is, to a T-cut, where T is the set of vertices of G^* of

[22] A strongly bipartite graph need not be bipartite, as is shown by K_3.

odd degree. For G it means that an odd circuit cover in G corresponds to a set of edges of G^* containing a T-join. By Corollary 29.2b, the convex hull of these edge sets in G^* is determined by

$$(75.7)\qquad \begin{array}{ll} 0 \leq x(e^*) \leq 1 & \text{for } e^* \in E^*, \\ x(C) \geq 1 & \text{for each } T\text{-cut } C \text{ in } G^*. \end{array}$$

Hence the odd circuit cover polytope of G is determined by (75.3). ∎

With the help of the decomposition theorem of Wagner [1937a] (Theorem 3.3), this result can be extended to graphs without K_5 minor (Fonlupt, Mahjoub, and Uhry [1992]). We will however derive this from Guenin's more general characterization of weakly bipartite graphs.

75.2. Signed graphs

Guenin's characterization of weakly bipartite graph is valid, and easier to prove, in the more general context of signed graphs. In this section we collect some general terminology and facts on signed graphs.

A *signed graph* is a triple $G = (V, E, \Sigma)$, where (V, E) is an undirected graph and $\Sigma \subseteq E$. The graph (V, E) is called the *underlying graph* and Σ is called a *signing*.

Call a set of edges, or a path, or a circuit *odd* (*even*, respectively) if it contains an odd (even, respectively) number of edges in Σ. An *odd circuit cover* is a set of edges intersecting all odd circuits.

It is easy to show that, for any undirected graph (V, E),

(75.8) Two signings Σ and Σ' give the same collection of odd circuits $\iff$ $\Sigma \triangle \Sigma'$ is a cut of (V, E).

If $\Sigma \triangle \Sigma'$ is a cut, we call the two signed graphs, or the two signings, *equivalent*. The following is an important observation: for any signed graph $G = (V, E, \Sigma)$,

(75.9) the collection of inclusionwise minimal odd circuit covers of G is equal to the collection of inclusionwise minimal signings equivalent to Σ.

Indeed, any signing Σ' equivalent to Σ intersects each odd circuit in an odd number of edges, and hence is an odd circuit cover. Conversely, any inclusionwise minimal odd circuit cover B intersects each odd circuit C in an odd number of edges: by the minimality of B, for each $e \in B \cap C$ there exists an odd circuit C_e disjoint from $B \setminus \{e\}$. If $|B \cap C|$ is even, the symmetric difference of C and the C_e gives an odd cycle disjoint from B, a contradiction.

(75.9) has several consequences. The inclusionwise minimal sets among $\Sigma \triangle \delta(U)$ (for $U \subseteq V$) are precisely the inclusionwise minimal odd circuit covers. For any two inclusionwise minimal odd circuit covers B_1, B_2 there exists a subset U of V with

(75.10) $B_1 \triangle B_2 = \delta(U)$

(since $B_1 = \Sigma \triangle \delta(U_1)$ and $B_2 = \Sigma \triangle \delta(U_2)$ for some $U_1, U_2 \subseteq V$, hence $B_1 \triangle B_2 = \delta(U_1) \triangle \delta(U_2) = \delta(U_1 \triangle U_2)$).

(75.9) also implies that for each inclusionwise minimal odd circuit cover B of G, the set $B \triangle \Sigma$ is a cut. (We recall that, by definition, the empty set is also a cut.)

We can define the concepts of deletion, contraction, subgraph, and minor in a signed graph $G = (V, E, \Sigma)$. *Deleting* an edge e means replacing G by $G - e := (V, E \setminus \{e\}, \Sigma \setminus \{e\})$. Similarly, *deleting* a vertex v means deleting v in V and deleting in E and Σ all edges incident with v.

Contracting a (nonloop) edge e means: if $e \notin \Sigma$, replacing G by $G/e := (\widetilde{V}, \widetilde{E}, \Sigma)$, where $(\widetilde{V}, \widetilde{E})$ is obtained from (V, E) by contracting e; if $e \in \Sigma$, choose $v \in e$, replace Σ by $\Sigma \triangle \delta(v)$, and apply the previous operation. So the operation of contraction is not uniquely defined, but the outcome is unique up to equivalence of signings. This is sufficient for our purposes.

A *subgraph* of a signed graph is obtained by a series of deletions of vertices and edges. A *minor* is obtained by a series of deletions of vertices and edges and contractions of edges, and by replacing the signing by an equivalent signing.

For any complete graph K_n, let *odd-K_n* be the signed graph

(75.11) $\text{odd-}K_n := (VK_n, EK_n, EK_n).$

A signed graph (V, E, Σ) is called an *odd K_4-subdivision* if (V, E) is a subdivision of K_4 such that each triangle has become an odd circuit (with respect to Σ). It is not difficult to show that:

(75.12) a signed graph contains an odd K_4-subdivision if and only if it has odd-K_4 as minor.

75.3. Weakly, evenly, and strongly bipartite signed graphs

In an obvious way, the notions of weakly and strongly bipartite graphs can be lifted to signed graphs. A signed graph $G = (V, E, \Sigma)$ is *weakly bipartite* if each vertex of the polyhedron (in $\mathbb{R}^E$) determined by:

(75.13)
$$\begin{array}{lll} \text{(i)} & 0 \leq x_e \leq 1 & \text{for each edge } e, \\ \text{(ii)} & x(C) \geq 1 & \text{for each odd circuit } C, \end{array}$$

is integer, that is, the incidence vector of an odd circuit cover.

System (75.13) gives rise to two stronger properties. First, a signed graph is called *strongly bipartite* if (75.13) is totally dual integral. Equivalently, for each function $w : E \to \mathbb{Z}_+$ the minimum of $w^\mathsf{T} x$ over (75.13) has integer primal and dual optimum solutions. Or: for each weight function $w : E \to \mathbb{Z}_+$, the minimum weight of an odd circuit cover is equal to the maximum size of a family of odd circuits such that each edge e is in at most $w(e)$ of them.

We also define an intermediate property (only seemingly intermediate, since it will turn out to be equivalent to weakly bipartite). A signed graph $G = (V, E, \Sigma)$ is called *evenly bipartite* if for each $w : E \to \mathbb{Z}_+$ with $w(\delta(v))$ even for each $v \in V$, the minimum of $w^\mathsf{T}x$ over (75.13) is attained by integer primal and dual optimum solutions. Equivalently, for each weight function $w : E \to \mathbb{Z}_+$ with $w(\delta(v))$ even for all $v \in V$, the minimum weight of an odd circuit cover is equal to the maximum size of a family of odd circuits such that each edge e is in at most $w(e)$ of them.

There are the following direct implications:

(75.14) strongly bipartite $\Longrightarrow$ evenly bipartite $\Longrightarrow$ weakly bipartite.

It is easy to check that the classes of weakly, evenly, and strongly bipartite signed graphs are closed under taking minors. So each class can be characterized by forbidden minors.

Now a theorem of Seymour [1977b] implies that a signed graph G is strongly bipartite if and only if it has no odd-K_4 minor (Corollary 75.3a below). Guenin [1998a,2001a] showed that G is weakly bipartite if and only if it has no odd-K_5 minor. This was sharpened by Geelen and Guenin [2001], who proved that G is evenly bipartite if and only if G has no odd-K_5 minor (Corollary 75.4a below). So weakly and evenly bipartite are equivalent.

75.4. Characterizing strongly bipartite signed graphs

A general hypergraph theorem of Seymour [1977b] (Theorem 80.1) implies a characterization of strongly bipartite signed graphs. This will be derived from the following equivalent result, which we prove with a method of Geelen and Guenin [2001]:

Theorem 75.3. *In a signed graph G without odd-K_4 minor, the maximum number of edge-disjoint odd circuits is equal to the minimum size of an odd circuit cover.*

Proof. For any signed graph $G = (V, E, \Sigma)$, let $\pi(G)$ denote the minimum size of an odd circuit cover and let $\mu(G)$ denote the maximum number of edge-disjoint odd circuits. We must show $\mu(G) = \pi(G)$ for any signed graph G without odd-K_4 minor.

Suppose that this is not true. Choose a counterexample $G = (V, E, \Sigma)$, with $\pi(G)$ minimum, $|V|$ minimum, and $|E|$ maximum, in this order of priority. Such a graph exists, since if there are more than $\pi(G)$ parallel edges connecting two vertices, we can contract them to obtain a counterexample with $|V|$ smaller.

Define $\pi := \pi(G)$. Fix an edge $e = xy$ not contained in every minimum-size odd circuit cover. By adding a parallel edge connecting x and y, we do not change $\pi(G)$ or $|V|$, but we increase $|E|$. Hence in the extended graph there exist π edge-disjoint odd circuits. This means that in the original graph G there exist odd circuits $C_1, \ldots, C_\pi$ with $e \in C_1 \cap C_2$ and with $C_1 \setminus \{e\}$, $C_2 \ldots, C_\pi$ disjoint. (Here we take circuits as edge sets.) We choose the C_i with $|C_1 \cup C_2|$ minimal.

For $i = 1, 2$, let P_i be the $x - y$ path $C_i \setminus \{e\}$, for $i = 1, 2$. (Also the paths are taken as edge sets.) Then

(75.15) $\quad P_1 \cup P_2$ contains no odd circuit C.

Otherwise, replacing C_1 and C_2 by C and $C_1 \triangle C_2 \triangle C$ gives π edge-disjoint odd circuits, a contradiction.

Moreover, let $x = v_0, v_1, \ldots, v_k = y$ be the common vertices of P_1 and P_2, in the order on which they occur along P_1. Then

(75.16) $\quad v_0, v_1, \ldots, v_k$ occur in this order also along P_2.

Indeed, orient P_1 and P_2 from x to y. Then we create no directed circuit, since otherwise there exist circuits $C_1', C_2' \subseteq C_1 \cup C_2$ with $C_1' \cap C_2' = \{e\}$ and $|C_1' \cup C_2'| < |C_1 \cup C_2|$. Then C_1' and C_2' are odd (since otherwise $C_1 \triangle C_1'$ is odd, and hence contains an odd circuit, contradicting (75.15)). This contradicts the minimality of $|C_1 \cup C_2|$.

Now choose j with $0 \leq j \leq k$ such that

(75.17) $\quad \pi(G - (P \cup \{e\})) \leq \pi - 2$

for each $v_j - y$ path P in $P_1 \cup P_2$ and such that j is as large as possible. Such a j exists, as (75.17) holds for each $x - y$ path P in $P_1 \cup P_2$ (otherwise, $G - (P \cup \{e\})$ contains $\pi - 1$ disjoint odd circuits; hence, with $P \cup \{e\}$ it gives π disjoint odd circuits in G as required).

Since $\pi(G) = \pi$ we know $\pi(G - \{e\}) \geq \pi - 1$, and hence $j < k$. By the maximality of j, there is a $v_{j+1} - y$ path R in $P_1 \cup P_2$ such that

(75.18) $\quad \pi(G - (R \cup \{e\})) \geq \pi - 1.$

Let Q_1 and Q_2 be the two $v_j - v_{j+1}$ paths in $P_1 \cup P_2$. By (75.17) we know

(75.19) $\quad \pi(G - (Q_i \cup R \cup \{e\})) \leq \pi - 2$

for $i = 1, 2$. Hence for each $i = 1, 2$ there exists an inclusionwise minimal odd circuit cover B_i with $|B_i \setminus (Q_i \cup R \cup \{e\})| \leq \pi - 2$. So B_i contains one edge of $C_3, \ldots, C_\pi$ each, and consists for the rest of edges in $Q_i \cup R \cup \{e\}$. As $C_1 \cup C_2$ contains an odd circuit disjoint from $Q_i \cup R$, we know $e \in B_i$.

Since B_1 and B_2 are minimal odd circuit covers, there exists a subset U of V with

(75.20) $\quad B_1 \triangle B_2 = \delta(U)$

and U disjoint from e (as $e \notin B_1 \triangle B_2$). So U is disjoint from all $x - v_j$ paths and from the $v_{j+1} - y$ path R' in $P_1 \cup P_2$ edge-disjoint from R (since B_1 and B_2 are edge-disjoint from these paths).

As G has no odd-K_4 minor, there is no path contained in U that connects VQ_1 and VQ_2 and that consists only of edges out of B_1. (It creates with Q_1, Q_2, R', e and any $x - v_j$ path in $P_1 \cup P_2$ an odd K_4-subdivision, as B_1 can serve as a signing.) So U has a subset X such that $VQ_1 \cap U \subseteq X$ and $X \cap VQ_2 = \emptyset$ and such that each edge connecting X and $U \setminus X$ belongs to B_1. So $\delta(X) \subseteq B_1 \cup \delta(U) \subseteq B_1 \cup B_2$. Define

(75.21) $\qquad B := B_1 \triangle \delta(X).$

Then B is an odd circuit cover. We show that $|B \setminus (R \cup \{e\})| \leq \pi - 2$, contradicting (75.18).

Since $U \cap VQ_1 \subseteq X \subseteq U$, we know that $B_1 \cap Q_1 \subseteq \delta(U) \cap Q_1 \subseteq \delta(X)$, and hence $B \cap Q_1 = \emptyset$. Also $B \cap Q_2 = \emptyset$, as $\delta(X)$ contains no edge of Q_2, since X is disjoint from VQ_2.

As $\delta(X) \subseteq B_1 \cup B_2$, we know that $B \subseteq B_1 \cup B_2$. As $|B_i \cap C_h| = 1$ for each $h = 3, \ldots, \pi$, this implies that $|B \cap C_h| \leq 2$, and hence $|B \cap C_h| = 1$ (as it is odd). So we have $|B \setminus (R \cup \{e\})| \leq \pi - 2$. This contradicts (75.18). ∎

This theorem implies a characterization of strongly bipartite graphs:

Corollary 75.3a. *A signed graph G is strongly bipartite if and only if G has no odd-K_4 minor.*

Proof. Necessity follows from the fact that odd-K_4 is not strongly bipartite. To see sufficiency, let $G = (V, E, \Sigma)$ be a signed graph without odd-K_4 minor. Let $w : E \to \mathbb{Z}_+$. We must show that minimizing $w^\mathsf{T} x$ over (75.13) has an integer optimum dual solution.

Let G' arise from G by replacing (in E and in Σ) any edge e by $w(e)$ parallel edges. Then the minimum value of $w^\mathsf{T} x$ over integer vectors x satisfying (75.13) is equal to the minimum size of an odd circuit cover in G'. As G' has no odd-K_4 minor, by Theorem 75.3 this is equal to the maximum number of edge-disjoint odd circuits in G'. This gives an integer optimum dual solution to minimizing $w^\mathsf{T} x$ over (75.13). ∎

To interpret this characterization for (nonsigned) undirected graphs, and to get some subtleties straight, it is good to realize that for any undirected graph $G = (V, E)$ one has:

(75.22) $\qquad$ the signed graph (V, E, E) has odd-K_4 as minor $\iff$ the undirected graph (V, E) has K_4 as odd minor $\iff$ the undirected graph (V, E) contains an odd K_4-subdivision.

(Recall that an undirected graph H is an *odd minor* of an undirected graph G if H arises from G by deleting edges and vertices and contracting all edges in some cut. A subdivision of K_4 is called *odd* if each triangle of K_4 becomes an odd circuit.)

Hence:

Corollary 75.3b. *An undirected graph is strongly bipartite if and only if it contains no odd K_4-subdivision as subgraph.*

Proof. See above. ∎

For multiflows, Seymour's theorem implies (where we take $(V, E \setminus R)$ as supply graph and (V, R) as demand graph, and where $c|E \setminus R$ and $c|R$ are the capacity and demand function, respectively):

Corollary 75.3c. *Let $G = (V, E)$ be a graph and let $R \subseteq E$ be such that the signed graph (V, E, R) has no odd-K_4 minor. Then for each $c : E \to \mathbb{Z}_+$, the cut condition implies the existence of an integer multiflow.*

Proof. Let $c : E \to \mathbb{Z}_+$ satisfy the cut condition. So for each cut D we have $c(D \cap R) \leq c(D \setminus R)$. Hence for each cut D:

(75.23) $$c(D \triangle R) = c(D \setminus R) + c(R \setminus D) \geq c(D \cap R) + c(R \setminus D) = c(R).$$

So R minimizes $c(R)$ over all odd circuit covers. Therefore, as (V, E, R) has no odd-K_4 minor, by Corollary 75.3a, there exist odd circuits $C_1, \ldots, C_k$ such that each edge e is in at most $c(e)$ of the C_i and such that $k = c(R)$. Hence

(75.24) $$\sum_{i=1}^{k} |C_i \cap R| \leq c(R) = k.$$

This implies, since each $|C_i \cap R|$ is odd, that $|C_i \cap R| = 1$ for each i, and hence we have equality in (75.24). This gives the required multiflow. ∎

75.5. Characterizing weakly and evenly bipartite signed graphs

Guenin [1998a,2001a] showed that odd-K_5 is the only minor-minimal signed graph that is not weakly bipartite (unique up to resigning). It proves a special case of a hypergraph conjecture of Seymour [1977b] (cf. Section 78.3). We prove Guenin's theorem using shortenings of his proof found by Geelen and Guenin [2001] (yielding a similar characterization of evenly bipartite graphs) and Schrijver [2002a].

We use the following lemma on undirected graphs. (Recall that a K_4-subdivision is called *odd* if each triangle of K_4 has become a circuit with an odd number of edges.)

Lemma 75.4α. *Let $G = (V, E)$ be a graph, let u be a vertex of G, and let v_1, v_2, and v_3 be three of its neighbours. Let S_1, S_2, and S_3 be disjoint stable sets in G, with $v_i \in S_i$ for $i = 1, 2, 3$. Suppose that for all distinct $i, j \in \{1, 2, 3\}$, the subgraph induced by $S_i \cup S_j$ contains a $v_i - v_j$ path. Then G contains an odd K_4-subdivision containing the edges uv_1, uv_2, and uv_3.*

Proof. Consider a counterexample with $|V| + |E|$ minimal. So $V = S_1 \cup S_2 \cup S_3 \cup \{u\}$ and E consists of the edges uv_1, uv_2, and uv_3, and of the edges contained in the paths as described. Hence for distinct i, j, there is a unique path $P_{i,j}$ from v_i to v_j contained in $S_i \cup S_j$. Then

(75.25) for distinct i, j: $S_i \cup S_j = VP_{i,j}$.

For if (say) $v \in S_1 \setminus VP_{1,2}$, then v is only on $P_{1,3}$, and hence has degree 2. Then we can contract the two edges incident with v to obtain a smaller counterexample, a contradiction.

(75.25) implies $|S_1| = |S_2| = |S_3|$. If $|S_1| = 1$, $G = K_4$ and we are done. So we can assume that each $|S_i| \geq 2$. Hence each path $P_{i,j}$ has length at least 3. Let v_2' be the second vertex along $P_{1,2}$, v_3' the second vertex along $P_{2,3}$, and v_1' the second vertex along $P_{3,1}$. Contract the edges incident with u. The new vertex u' is adjacent to v_1', v_2', and v_3'. For $i = 1, 2, 3$, let $S_i' := S_i \setminus \{v_i\}$. So S_i' contains v_i' and is a stable set in the contracted graph G'. Moreover,

(75.26) for distinct i, j, $S_i' \cup S_j'$ contains a $v_i' - v_j'$ path.

To prove this, we can assume $i = 1$, $j = 2$. By (75.25), since $v_1' \in S_1$, we know that v_1' is on $P_{1,2}$. Since also v_2' is on $P_{1,2}$, $S_1 \cup S_2$ contains a $v_1' - v_2'$ path avoiding v_1 and v_2. This proves (75.26).

As G' is smaller than G, G' contains an odd K_4-subdivision containing $u'v_1'$, $u'v_2'$, and $u'v_3'$. By decontracting we obtain an odd K_4-subdivision in G as required. ∎

(The proof implies that the odd K_4-subdivision found in fact is a *bad* K_4-subdivision (cf. Section 68.4).)

This lemma is used in the characterization of Geelen and Guenin [2001] of evenly bipartite signed graphs. The following is the kernel of this characterization (a signed graph is called *Eulerian* if its underlying graph is Eulerian):

Theorem 75.4. *In an Eulerian signed graph without odd-K_5 minor, the maximum number of edge-disjoint odd circuits is equal to the minimum size of an odd circuit cover.*

Proof. For any signed graph $G = (V, E, \Sigma)$, let $\pi(G)$ denote the minimum size of an odd circuit cover and let $\mu(G)$ denote the maximum number of edge-disjoint odd circuits. It suffices to show $\mu(G) = \pi(G)$ for any Eulerian signed graph G without odd-K_5 minor.

Suppose that this is not true. Choose a counterexample $G = (V, E, \Sigma)$, with $\pi(G)$ minimum, $|V|$ minimum, and $|E|$ maximum, in this order of priority. Such a graph exists, since if there are more than $\pi(G)$ parallel edges connecting two vertices, we can contract them to obtain a counterexample with $|V|$ smaller.

Fix an edge $e = xy$ not contained in every minimum-size odd circuit cover. By adding two parallel edges connecting x and y, we do not change $\pi(G)$ or $|V|$, but we increase $|E|$. Hence in the extended graph there exist $\pi(G)$ edge-disjoint odd circuits. This means that in the original graph G

(75.27) there exist odd circuits $C_1, \ldots, C_{\pi(G)}$ with $e \in C_1 \cap C_2 \cap C_3$ and with $C_1 \setminus \{e\}$, $C_2 \setminus \{e\}$, C_3, $C_4, \ldots, C_{\pi(G)}$ disjoint

(describing circuits by edge sets). $G, C_1, \ldots, C_{\pi(G)}$ moreover satisfy:

(75.28) $\pi(G - C) \leq \pi(G) - 3$ for each odd circuit $C \subseteq C_1 \cup C_2 \cup C_3$ such that $((C_1 \cup C_2 \cup C_3) \setminus C) \cup \{e\}$ contains an odd circuit.

Otherwise, by the minimality of $\pi(G)$, $G - C$ contains disjoint odd circuits $C'_1, \ldots, C'_{\pi(G)-2}$. Then $E' := E \setminus (C \cup C'_1 \cup \cdots \cup C'_{\pi(G)-2})$ contains an odd circuit C'', since E is Eulerian and since G has a minimum-size odd circuit cover B of size $\pi(G)$; so, as B is an equivalent signing of G, $|E' \cap B|$ is odd. Hence $C, C'', C'_1, \ldots, C'_{\pi(G)-2}$ form $\pi(G)$ disjoint odd circuits in G, contradicting our assumption. This proves (75.28).

We show that for signed Eulerian graphs G, conditions (75.27) and (75.28) imply that G has an odd-K_5 minor, which finishes the proof.

We delete our earlier minimality assumptions, and now choose a counterexample to this with $|E|$ minimal and (secondly) $|C_1 \cup C_2 \cup C_3|$ minimal. Let P_i be the $x - y$ path $C_i \setminus \{e\}$ for $i = 1, 2, 3$ (describing paths by edge sets). Then:

Claim 1. P_1, P_2, P_3 are internally vertex-disjoint.

Proof of Claim 1. Suppose not. Define $F := P_1 \cup P_2 \cup P_3$. We first show:

(75.29) F contains no odd circuit.

To see this, first observe that any $P_i \cup P_j$ contains no odd circuit, since otherwise, for the third path P_k there exist $\pi(G) - 2$ disjoint odd circuits in $G - (P_k \cup \{e\})$, contradicting (75.28).

Hence there exists an inclusionwise minimal odd circuit cover B disjoint from $P_1 \cup P_2$. Then for each vertex v in VP_3 that is also in $VP_1 \cup VP_2$, the $x - v$ part of P_3 has an even number of edges in B (as it forms with part of P_1 or P_2 an even cycle). Hence between two contacts of P_3 with $VP_1 \cup VP_2$, P_3 has an even number of edges in B. This implies (75.29).

Orient the edges in $C_1 \cup C_2 \cup C_3$ by orienting each P_i from x to y, and by orienting edge e from y to x. Then

(75.30) F contains no directed circuit C, for otherwise $F \setminus C$ contains three edge-disjoint $x-y$ paths. They yield odd circuits C_1', C_2', C_3' avoiding C, with $e \in C_1' \cap C_2' \cap C_3'$ and with $C_1' \setminus \{e\}$, $C_2' \setminus \{e\}$, $C_3' \setminus \{e\}$ disjoint. This contradicts the minimality of $C_1 \cup C_2 \cup C_3$.

So F is acyclic, and hence there exists a total order $\leq$ on V with $s < t$ for each arc (s,t) in F. So all vertices v in $VP_1 \cup VP_2 \cup VP_3$ have $x \leq v \leq y$.

Then for each undirected $x-y$ path P in F:

(75.31) P is a directed path $\iff$ $(C_1 \cup C_2 \cup C_3) \setminus P$ contains an odd circuit.

To prove $\Rightarrow$, let P be a directed path. Then there exists a directed $x-y$ path edge-disjoint from Q. Hence $Q \cup \{e\}$ is an odd circuit disjoint from $(C_1 \cup C_2 \cup C_2) \setminus P$.

To prove $\Leftarrow$, let C be an odd circuit in $(C_1 \cup C_2 \cup C_3) \setminus P$. Then $C \setminus \{e\}$ is an $x-y$ path Q edge-disjoint from P. If P is not directed, there is a vertex v such that P traverses two arcs entering v. Now there exist precisely three arcs (s,t) with $s < v \leq t$. Hence P contains all three, and nothing is left for Q, a contradiction.

This proves (75.31). So any circuit C qualifies for (75.28) if and only if it is a directed circuit.

Let W be the set of vertices that are in at least two of the P_i. Since P_1, P_2, and P_3 are not internally vertex-disjoint by assumption, we know $|W| \geq 3$.

Call a directed path in F a *link* if it connects two distinct vertices in W, while each internal vertex is not in W. Then:

(75.32) there exist vertices u, v and a $u-v$ link Q such that $u \neq x$ and such that there is at least one directed $u-v$ path edge-disjoint from Q and such that each directed $x-u$ path is a link.

To see this, first observe that there is a directed $x-y$ path P traversing all vertices in W. Indeed, for all $s,t \in W$ with $s < t$, there is a directed $s-t$ path. This follows from the fact that at least two of the P_i leave s and at least two of the P_i enter t, and that hence at least one of the P_i leaves s and enters t.

Now to prove (75.32), let u be the smallest vertex in W with $u \neq x$. Then each directed $x-u$ path is a link. Let Q be a link leaving u which is not on P. Taking for v the end vertex of Q, we obtain (75.32).

Let X be the set of edges that are on directed $u-v$ paths $\neq Q$. We may assume that if C_i intersects X, then C_i traverses both u and v. So X consists of one or two $u-v$ paths. Then

(75.33) $(C_1 \cup C_2 \cup C_3) \setminus (Q \cup X)$ contains no arc leaving u or no arc entering v.

Otherwise, by (75.32), F has three arcs leaving u and three arcs entering v. So each C_i contains a $u-v$ path, which hence is in $Q \cup X$. This proves (75.33).

Consider $G' := G/Q$ and $C'_i := C_i \setminus (Q \cup X)$ for $i = 1, 2, 3$. Then (75.27) is maintained for G', C'_1, C'_2, C'_3. Hence, by the minimality of $C_1 \cup C_2 \cup C_3$, there is a directed circuit C' in G' with

$$\text{(75.34)} \qquad \pi(G' - C') \geq \pi(G') - 2.$$

Now $\pi(G') \geq \pi(G)$ (as this is true for any contraction of G). If C' is also a directed circuit in G, we have $\pi(G - C') \leq \pi(G) - 3$ by (75.28), and hence $G - C'$ has an odd circuit cover B of size $\leq \pi(G) - 3$. By (75.27), B does not intersect Q. Hence B is an odd circuit cover of $G - C'/Q = G' - C'$ of size $\leq \pi(G) - 3$, a contradiction.

So C' is not a directed circuit in G. Then $C' \cup Q$ forms a circuit in G, and, by (75.33), it is a directed circuit. Hence C' contains a link R entering u. As $u \in W$, there is another link, S say, entering u.

Consider $G'' := (G - R)/S$ and $C''_i := C_i \setminus (R \cup S)$ for $i = 1, 2, 3$. Then (75.27) is maintained. Moreover, $\pi(G'') \geq \pi(G)$. For suppose that G'' has an odd circuit cover B of size $\pi(G'') \leq \pi(G) - 1$. By (75.27), $|B| = \pi(G) - 2$ (since it intersects each C_i in an odd number of edges), B does not intersect Q, and contains e. Hence $\pi((G - (R \cup \{e\}))/Q) \leq \pi(G) - 3$. This implies (since $R \cup \{e\} \subseteq C'$):

$$\text{(75.35)} \qquad \pi(G' - C') \leq \pi(G' - (R \cup \{e\})) = \pi(G - (R \cup \{e\})/Q) \leq \pi(G) - 3,$$

contradicting (75.34). This proves that $\pi(G'') \geq \pi(G)$.

Now, by the minimality of G, C_1, C_2, C_3, (75.28) is not maintained. So there is a directed circuit C'' in G'' with $\pi(G'' - C'') \geq \pi(G) - 2$. Then $C'' \cup S$ contains an odd circuit of G, hence also $C'' \cup R$ contains an odd circuit of G (since R and S are parallel links). So (by (75.28) for G) $\pi(G - (C'' \cup R)) \leq \pi(G) - 3$. Hence $G - (C'' \cup R)$ has an odd circuit cover B of size $\pi(G) - 3$, which by (75.27) is disjoint from $F \cup \{e\}$. Then B is an odd circuit cover of $G - (C'' \cup R)/S = G'' - C''$, and so $\pi(G'' - C'') \leq \pi(G) - 3$, contradicting our assumption. *End of Proof of Claim 1*

Set $\pi := \pi(G)$. Since by (75.28), for each $i = 1, 2, 3$, $\pi(G - C_i) \leq \pi - 3$, there is an inclusionwise minimal odd circuit cover B_i of G with $|B_i \setminus C_i| \leq \pi - 3$. By (75.27), we know that $B_i \cap P_j = \emptyset$ for $j \leq 3$ with $j \neq i$, and that $|B_i \cap C_j| = 1$ for $j \geq 4$. Since B_i intersects each of C_1, C_2, C_3, we have $e \in B_i$.

By (75.10), there exist $U_1, U_2, U_3 \subseteq V$ such that

$$\text{(75.36)} \qquad B_j \triangle B_k = \delta(U_i)$$

for distinct $i, j, k \in \{1, 2, 3\}$. We can assume that each U_i is disjoint from e, since $e \notin B_j \triangle B_k$ (as $e \in B_j \cap B_k$). Moreover, we can assume that $U_3 = U_1 \triangle U_2$ — otherwise, just reset $U_3 := U_1 \triangle U_2$. (This works, since $\delta(U_1 \triangle U_2) = \delta(U_1) \triangle \delta(U_2) = (B_2 \triangle B_3) \triangle (B_1 \triangle B_3) = B_1 \triangle B_2$.)

Define

$$\text{(75.37)} \qquad S_i := U_j \cap U_k$$

for distinct $i, j, k \in \{1, 2, 3\}$. So S_1, S_2, S_3 are disjoint and

(75.38) $\quad U_i = S_j \cup S_k$

for distinct $i, j, k \in \{1, 2, 3\}$ (since $U_1 \triangle U_2 \triangle U_3 = \emptyset$). Define

(75.39) $\quad S_0 := V \setminus (S_1 \cup S_2 \cup S_3)$.

Then

(75.40) $\quad$ each $f \in E \setminus (B_1 \cup B_2 \cup B_3)$ is spanned by S_0, S_1, S_2, or S_3.

Otherwise, f belongs to some $\delta(U_i)$, and hence to some B_j, by (75.36).

Moreover,

(75.41) $\quad VP_i \subseteq S_0 \cup S_i$

for each $i \in \{1, 2, 3\}$, since $VP_i \cap \delta(U_i) = \emptyset$ by (75.36) and since $x, y \notin U_i$.

We in fact have for each $i \in \{1, 2, 3\}$:

(75.42) $\quad C_i \subseteq B_i$.

For suppose that $f \in C_1 \setminus B_1$. Then G/f again satisfies (75.27) and (75.28), for $C'_1 := C_1 \setminus \{f\}$, $C'_2 := C_2$, $C'_3 := C_3$. Indeed, each odd circuit C of G/f contained in $C'_1 \cup C'_2 \cup C'_3$ is equal to one of the C'_i, and moreover

(75.43) $\quad \pi((G/f) - C'_i) \leq |B_i \setminus C_i| \leq \pi(G) - 3 \leq \pi(G/f) - 3$.

This contradicts the minimality of $|E|$. So we have (75.42).

Similarly,

(75.44) $\quad$ each $f \in E \setminus (B_1 \cup B_2 \cup B_3)$ is spanned by $VP_1 \cup VP_2 \cup VP_3$.

Otherwise, we can contract f to obtain a smaller example satisfying (75.27) and (75.28) (by (75.43) for $C'_i := C_i$).

Now let E' be the set of edges in $B_1 \triangle B_2 \triangle B_3$ that are in $C_1 \cup C_2 \cup C_3$ or connect two distinct sets among S_1, S_2, S_3. So $C_1 \cup C_2 \cup C_3 \subseteq E'$. As $E' \subseteq B_1 \triangle B_2 \triangle B_3$ and as $B_1 \triangle B_2 \triangle B_3$ is a signing equivalent to Σ, it suffices to show that the undirected graph $G' = (V, E')$ has K_5 as odd minor.

By definition of E', for each $i \in \{1, 2, 3\}$:

(75.45) $\quad S_i$ is a stable set of G'.

Moreover, for all distinct $i, j \in \{1, 2, 3\}$,

(75.46) $\quad G'$ has a path contained in $S_i \cup S_j$ and connecting VP_i and VP_j.

To see this, we may assume $i = 1$, $j = 2$. Suppose that no such path exists. Then U_3 ($= S_1 \cup S_2$) has a subset X such that $S_1 \cap VP_1 \subseteq X$ and $X \cap VP_2 = \emptyset$ and such that no edge of G' connects X and $U_3 \setminus X$. So

(75.47) $\quad \delta_{E'}(X) \subseteq \delta(U_3)$.

Then

(75.48) $\quad \delta_E(X) \subseteq B_1 \cup B_2 \cup B_3$.

Indeed, let $f \in \delta_E(X) \setminus (B_1 \cup B_2 \cup B_3)$. By (75.44), f is spanned by $VP_1 \cup VP_2 \cup VP_3$. Moreover, by (75.40), as f is incident with X, f is spanned by S_1 or S_2. So f is spanned by $S_1 \cap VP_1$ or by $S_2 \cap VP_2$, contradicting the fact that f leaves X. This proves (75.48).

Define

(75.49) $$B := B_1 \triangle \delta_E(X).$$

Then B is an odd circuit cover of G. So $|B| \geq \pi$. Since $S_1 \cap VP_1 \subseteq X$ and $P_1 \subseteq B_1$, we know that $P_1 \subseteq \delta(X)$, and so B is disjoint from P_1. For $i = 2, 3$, B is disjoint from P_i, as $\delta(X)$ contains no edge of P_i, since X is disjoint from VP_i. Hence, as $B \subseteq B_1 \cup B_2 \cup B_3$ by (75.48), we know that $|B \cap C_j| \geq 2$ for some $j = 4, \ldots, \pi$. Then $|B \cap C_j| \geq 3$. As $|B_1 \cap C_j| = 1$ and $|B_2 \cap C_j| = 1$, it follows that there exists an edge $f \in B \cap C_j$ with $f \notin B_1 \cup B_2$. So $f \in \delta_E(X)$, hence $f \in B_3$, therefore $f \in \delta(U_1) \cap \delta(U_2)$, and so $f \in E'$. Therefore, $f \in \delta_{E'}(X)$, and hence by (75.47), $f \in \delta(U_3)$, contradicting (75.36). This proves (75.46).

Consider the minor H of G' obtained by contracting, for each $i = 1, 2, 3$, $VC_i \setminus \{x, y\}$ to one vertex, z_i say. By Lemma 75.4α, $H - y$ has an odd K_4-subdivision containing the edges xz_1, xz_2, and xz_3. Since y is adjacent to x, z_1, z_2, and z_3, H has K_5 as odd minor. ∎

A consequence of this is a characterization of weakly and evenly bipartite graphs. (The equivalence of (i) and (iii) is Guenin's theorem (Guenin [1998a,2001a]), and the equivalence with (ii) was found by Geelen and Guenin [2001].)

Corollary 75.4a. *For any signed graph G the following are equivalent:*

(75.50) (i) *G is weakly bipartite;*
(ii) *G is evenly bipartite;*
(iii) *G has no odd-K_5 minor.*

Proof. The implications (ii)⇒(i)⇒(iii) follow from (75.14) and from the facts that weak bipartiteness is closed under taking minors and that odd-K_5 is not weakly bipartite.

The implication (iii)⇒(ii) follows from Theorem 75.4. Let $G = (V, E, \Sigma)$ be a signed graph without odd-K_5 minor and let $c : E \to \mathbb{Z}_+$ be such that $c(\delta(v))$ is even for each $v \in V$. We must show that the dual of minimizing $c^{\mathsf{T}}x$ over (75.13) has an integer optimum dual solution.

Let G' arise from G by replacing (in E and in Σ) any edge e by $c(e)$ parallel edges. So G' is Eulerian. Then the minimum value of $c^{\mathsf{T}}x$ over integer vectors x satisfying (75.13) is equal to the minimum size of an odd circuit cover in G'. As G' has no odd-K_5 minor, by Theorem 75.4 this is equal to the maximum number of edge-disjoint odd circuits in G'. This gives an integer optimum dual solution to minimizing $c^{\mathsf{T}}x$ over (75.13). ∎

For (nonsigned) undirected graphs, this characterization can be described in terms of odd minors as follows. (Recall that an undirected graph H is an *odd minor* of an undirected graph G if H arises from G by deleting edges and vertices and contracting all edges in some cut.) Then for any undirected graph $G = (V, E)$:

(75.51) the signed graph (V, E, E) has odd-K_5 as minor $\iff$ the undirected graph (V, E) has K_5 as odd minor.

(This is a simple exercise.) Hence:

Corollary 75.4b. *An undirected graph G is weakly bipartite if and only if K_5 is not an odd minor of G.*

Proof. See above. ∎

Notes. Special cases of the equivalence of (i) and (iii) in Corollary 75.4a were shown by Barahona [1980] (for planar graphs; cf. Theorem 75.2), Fonlupt, Mahjoub, and Uhry [1992] (for graphs without K_5 minor), Barahona [1983a] (for graphs G such that $G - u - v$ is bipartite for two of its vertices u, v), and Gerards [1992a] (for graphs G such that $G - v$ is planar with at most two odd faces, for some vertex v).

75.6. Applications to multiflows

Geelen and Guenin's theorems also have consequences for multiflows (where again we take $(V, E \setminus R)$ as supply graph and (V, R) as demand graph, and where $c|E \setminus R$ and $c|R$ are the capacity and demand function, respectively):

Corollary 75.4c. *Let $G = (V, E)$ be a graph and let $R \subseteq E$ be such that the signed graph (V, E, R) has no odd-K_5 minor. Then for each $c : E \to \mathbb{R}_+$, the cut condition implies the existence of a fractional multiflow. If moreover c is integer, there is a half-integer multiflow. If moreover the Euler condition holds, there is an integer multiflow.*

Proof. By Corollary 75.4a, (V, E, R) is weakly bipartite. Let c satisfy the cut condition. So for each cut D we have $c(D \cap R) \leq c(D \setminus R)$. Hence for each cut D:

(75.52) $$c(D \triangle R) = c(D \setminus R) + c(R \setminus D) \geq c(D \cap R) + c(R \setminus D) = c(R).$$

So R minimizes $c(R)$ over all odd circuit covers. Therefore, as (V, E, R) is weakly bipartite, there exist odd circuits $C_1, \ldots, C_k$ and $\lambda_1, \ldots, \lambda_k > 0$ with

(75.53) $$\sum_{i=1}^{k} \lambda_i \chi^{C_i} \leq c \text{ and } \sum_{i=1}^{k} \lambda_i = c(R).$$

Hence

(75.54) $$\sum_{i=1}^{k} \lambda_i |C_i \cap R| \leq c(R) = \sum_{i=1}^{k} \lambda_i.$$

This implies, since each $|C_i \cap R|$ is odd, that $|C_i \cap R| = 1$ for each i, and that we have equality in (75.54). This gives the required multiflow.

The integrality results follow from Theorem 75.4. ∎

This implies the following generalization of Theorem 74.3, due to Seymour [1981a] (who derived it from Theorem 74.3 by using Wagner's theorem on the decomposition of K_5-free graphs (Theorem 3.3)):

Corollary 75.4d. *A graph $G = (V, E)$ has no K_5 minor if and only if for each $R \subseteq E$ and each $c : E \to \mathbb{R}_+$, the cut condition implies the existence of a multiflow. Moreover, if G has no K_5 minor and c is integer, the cut condition implies the existence of a half-integer multiflow. If moreover the Euler condition holds, then it implies the existence of an integer multiflow.*

Proof. Directly from Corollary 75.4c. ∎

For planar graphs, these integrality results can be derived also from results on packing T-cuts (Theorem 29.2), using duality like in Theorem 75.2 (cf. Theorem 74.3).

75.7. The cut cone and the cut polytope

Let $G = (V, E)$ be an undirected graph. Recall that a subset C of E is called a *cut* if $C = \delta(U)$ for some $U \subseteq V$. The *cut polytope* $P_{\text{cut}}(G)$ of G is the convex hull of the incidence vectors (in $\mathbb{R}^E$) of cuts in G:

(75.55) $$P_{\text{cut}}(G) := \text{conv.hull}\{\chi^C \mid C \text{ cut in } G\}.$$

As $\emptyset$ is a cut, the cut polytope contains the origin.

Since a set of edges is bipartite if and only if it is contained in a cut, the bipartite subgraph polytope can be expressed in terms of the cut polytope:

(75.56) $$P_{\text{bipartite subgraph}}(G) = \{x \in \mathbb{R}_+^E \mid \exists y \geq x : y \in P_{\text{cut}}(G)\}.$$

Any vector x in the cut polytope of G satisfies

(75.57)
(i) $0 \leq x_e \leq 1$ for each $e \in E$,
(ii) $x(F) - x(C \setminus F) \leq |F| - 1$ for each circuit C and $F \subseteq C$ with $|F|$ odd.

A full characterization is known of those graphs for which (75.57) determines the cut polytope: they are the graphs without K_5 minor (Seymour [1981a], Barahona [1983b]). This can be deduced from the characterization of weakly bipartite graphs.

This characterization can be formulated equivalently in terms of the *cut cone* of a graph $G = (V, E)$, which is the convex cone generated by the incidence vectors of the cuts. Necessary conditions for its elements are:

$$(75.58) \qquad \begin{array}{ll} x_e \geq 0 & \text{for } e \in E, \\ x_f \leq x(C \setminus \{f\}) & \text{for each circuit } C \text{ and } f \in C. \end{array}$$

The graph K_5 shows that these conditions generally are not sufficient: fix distinct $u, v \in VK_5$; then $x := \mathbf{2} - \chi^{\delta(\{u,v\})}$ satisfies (75.58). However, x does not belong to the cut cone of K_5, since the incidence vector z of any cut satisfies $2z(\delta(\{u, v\})) \geq z(EK_5)$.

K_5 is the only minor-minimal example, as Seymour [1981a] showed:

Corollary 75.4e. *The cut cone is determined by* (75.58) *if and only if G has no K_5 minor.*

Proof. Necessity is shown by the example above, and by the closedness of the property under taking minors. If G has the property, and we contract an edge e, then any x satisfying (75.58) for G/e can be extended to a vector x satisfying (75.58) for G by defining $x_e := 0$. Then the extended x is in the cut cone of G, and hence the original x is in the cut cone of G/e.

If we delete e, extend x satisfying (75.58) for $G-e$ by defining x_e to be the distance in $G - e$ between the end vertices of e, taking x as length function. Again, the extended x is in the cut cone of G, and hence the original x is in the cut cone of $G - e$. This shows necessity.

To see sufficiency, let G have no K_5 minor. Let $c^{\mathsf{T}}x \geq 0$ be a valid inequality for the cut cone. Define $R := \{e \in E \mid c(e) < 0\}$. Taking $(V, E \setminus R)$ as supply graph and (V, R) as demand graph, the cut condition holds for capacity function $c|E \setminus R$ and demand function $-c|R$. By Corollary 75.4d, there exists a multiflow subject to $c|E \setminus R$ and of value $-c|R$. It means that c is a nonnegative combination of vectors $-\chi^f + \chi^{C \setminus \{f\}}$ where C is a circuit and $f \in C$, and of vectors χ^e where $e \in E \setminus R$. Hence the inequality $c^{\mathsf{T}}x \geq 0$ is a nonnegative linear combination of the inequalities (75.58). ∎

Using the symmetry of the cut polytope (as observed by Barahona and Grötschel [1986]), Corollary 75.4e has as a consequence (Barahona [1983b]):

Corollary 75.4f. *The cut polytope of a graph $G = (V, E)$ is determined by* (75.57) *if and only if G has no K_5 minor.*

Proof. By Corollary 75.4e, it suffices to show that the cut polytope is determined by (75.57) if and only if the cut cone is determined by (75.58).

First assume that the cut polytope is determined by (75.57). Since the origin belongs to the cut polytope, the cut cone is determined by the inequalities among (75.57) with right-hand side 0 — that is, by (75.58).

Conversely, assume that the cut cone is determined by (75.58). Then (75.58) determines the cut polytope in the neighbourhood of the origin.

Consider now any vertex χ^D of the cut polytope, where D is a cut of G. For each $x \in \mathbb{R}^E$, define $\tilde{x} \in \mathbb{R}^E$ by:

$$(75.59) \qquad \tilde{x}_e := \begin{cases} 1 - x_e & \text{if } e \in D, \\ x_e & \text{if } e \notin D. \end{cases}$$

The function $x \to \tilde{x}$ brings the cut polytope to itself (since $D' \triangle D$ is a cut for any cut D' and $\tilde{x} = \chi^{D' \triangle D}$ if $x = \chi^{D'}$), and χ^D to $\mathbf{0}$. Since the cut cone is determined by (75.58), it implies that in the neighbourhood of χ^D, the cut polytope is determined by the inequalities (75.58) applied to $\tilde{x}$:

$$(75.60) \qquad \begin{array}{lll} \text{(i)} & \tilde{x}_e \geq 0 & \text{for } e \in E, \\ \text{(ii)} & \tilde{x}_f \leq \tilde{x}(C \setminus \{f\}) & \text{for each circuit } C \text{ and } f \in C. \end{array}$$

Now inequality (75.60)(i) follows from (75.57)(i). To see inequality (75.60)(ii), we first consider the case $f \notin D$. Define $F := (C \cap D) \cup \{f\}$. Then, using (75.57)(ii), (75.60)(ii) follows from

$$(75.61) \qquad \begin{aligned} \tilde{x}_f = x_f = x(F) - x(C \cap D) &\leq x(C \setminus F) - x(C \cap D) + |F| - 1 \\ &= \tilde{x}(C \setminus F) + \tilde{x}(C \cap D) = \tilde{x}(C \setminus \{f\}). \end{aligned}$$

If $f \in D$, define $F := (C \cap D) \setminus \{f\}$. Then, again using (75.57)(ii), (75.60)(ii) follows from

$$(75.62) \qquad \begin{aligned} \tilde{x}_f = 1 - x_f = 1 + x(F) - x(C \cap D) &\leq x(C \setminus F) - x(C \cap D) + |F| \\ &= x(C \setminus D) + x_f - x(C \cap D) + |C \cap D| - 1 = \tilde{x}(C \setminus \{f\}). \end{aligned} \qquad \blacksquare$$

Notes. By Corollary 75.4f, the cut polytope of any planar graph is determined by (75.57). As cuts in planar graphs correspond to $\emptyset$-joins ($\equiv$ cycles) in the dual graph (Orlova and Dorfman [1972]), one may also derive this from Corollary 29.2e on the T-join polytope.

Hadlock [1975] showed in a similar way that a maximum-capacity cut in a planar graph can be found in strongly polynomial time. Using the decomposition of graphs without K_5 minors into planar graphs and copies of V_8 (Theorem 3.3), Barahona [1983b] derived from this a combinatorial strongly polynomial-time algorithm to find a maximum-capacity cut in graphs without K_5 minor.

Poljak [1992] showed that for each graph G, the polytope determined by (75.2) is the down hull of the polytope determined by (75.57).

Karzanov [1985b] showed that the separation problem for the cut cone is co-NP-complete.

Barahona and Mahjoub [1986] showed that the separation problem over (75.57) is polynomial-time solvable, hence any linear objective function can be optimized over (75.57) in strongly polynomial time (with the ellipsoid method).

Integer decomposition. What about integer decomposition in the cut cone? A theorem of Chvátal [1980] implies that it is NP-complete to decompose a given metric as a nonnegative integer sum of incidence vectors of cuts. Let $\mathcal{H}$ be the class of graphs such that each integer vector x in the cut cone with $x(C)$ even for each circuit C, is a nonnegative integer combination of incidence vectors of cuts. (Equivalently, the incidence vectors of the cuts form a Hilbert base.)

By (74.34), each planar graph belongs to $\mathcal{H}$. This was extended (using Wagner's theorem (Theorem 3.3)) by Fu and Goddyn [1999] who showed that each graph without K_5 minor belongs to $\mathcal{H}$.

Goddyn [1993] also conjectured that each graph not having the Petersen graph as minor, belongs to $\mathcal{H}$. However, Laurent [1996b] showed that K_6 does not belong to $\mathcal{H}$. She also showed that all proper subgraphs of K_6 belong to $\mathcal{H}$. (More on this can be found in Laburthe [1995] and in the survey by Goddyn [1993].)

Fu and Goddyn [1999] asked: is $\mathcal{H}$ closed under taking minors?

Metrics and hypermetrics. The following *metric inequalities* are valid for the vectors in the cut cone of the complete graph K_V on a vertex set V:

(75.63) (i) $x_{uv} \geq 0$ for distinct $u, v \in V$,
(ii) $x_{uv} + x_{vw} \geq x_{uw}$ for distinct $u, v, w \in V$.

The cone determined by these inequalities is called the *metric cone*.

Tylkin [1960,1962] (= M.M. Deza) introduced a stronger set of valid inequalities, the *hypermetric inequalities*:

(75.64) (i) $x_{uv} \geq 0$ for distinct $u, v \in V$,
(ii) $\displaystyle\sum_{\substack{u,v \in V \\ u \neq v}} c_u c_v x_{uv} \leq 0$ for each $c : V \to \mathbb{Z}$ with $c(V) = 1$.

These inequalities are valid for the vectors in the cut cone, since for each cut $\delta(U)$ one has (setting $x := \chi^{\delta(U)}$):

(75.65)
$$\begin{aligned}\sum_{\substack{u,v \in V \\ u \neq v}} c_u c_v x_{uv} &= 2 \sum_{u\in U} \sum_{v \in V\setminus U} c_u c_v = 2c(U)c(V \setminus U) \\ &= \tfrac{1}{2}(c(U) + c(V \setminus U))^2 - \tfrac{1}{2}(c(U) - c(V \setminus U))^2 \\ &= \tfrac{1}{2} - \tfrac{1}{2}(c(U) - c(V \setminus U))^2 \leq 0,\end{aligned}$$

since $|c(U) - c(V \setminus U)| \geq 1$, as $c(V) = 1$ and c is integer.

Hypermetric inequalities generalize the metric inequalities, since (75.63)(ii) is equivalent to taking $c := \chi^u + \chi^w - \chi^v$ in (75.64)(ii).

The cone determined by (75.64) is called the *hypermetric cone*. Deza, Grishukhin, and Laurent [1993] showed that this cone is polyhedral (despite that there are infinitely many inequalities in (75.64)(ii)).

Avis and Grishukhin [1993] showed that it is co-NP-complete to decide if a given vector is in the hypermetric cone. Relations with the geometry of numbers are given in Deza, Grishukhin, and Laurent [1995]. More on the metric cone can be found in Avis [1980b,1980c], Grishukhin [1992], Laurent and Poljak [1992,1995b], Lomonosov and Sebő [1993], and Laurent [1996a], and on metrics and hypermetrics in the book by Deza and Laurent [1997].

75.8. The maximum cut problem and semidefinite programming

The maximum-capacity cut problem has a natural semidefinite relaxation. Let V be a finite set and denote

(75.66) $\mathcal{M}_V :=$ the set of all symmetric positive semidefinite $V \times V$ matrices M with $M_{v,v} = 1$ for each $v \in V$.

Let $c : V \times V \to \mathbb{R}_+$ be a 'capacity' function, with $c(u,v) = c(v,u)$ for all $u, v \in V$. Consider c as a capacity function on the complete graph K_V on V. Let C be the $V \times V$ matrix with (u,v)th entry equal to $c(u,v)$. The maximum-capacity cut problem asks for the maximum of

(75.67) $$\sum_{u \in U} \sum_{v \in V \setminus U} c(u,v).$$

Theorem 75.1 implies that this is an NP-complete problem.

A relaxation is to maximize

(75.68) $$\tfrac{1}{4}\mathrm{Tr} C(J - M)$$

over $M \in \mathcal{M}_V$. If we restrict M to matrices of rank 1 (so $M = xx^{\mathsf{T}}$ for some $\{-1,+1\}$ vector x in $\mathbb{R}^V$), we have the maximum-capacity cut problem.

Goemans and Williamson [1994,1995b] showed the following surprising bound (surprising also since the proof is very simple). Define

(75.69) $$\alpha := \min_{0 < \phi \leq \pi} \frac{\phi}{1 - \cos\phi} \frac{2}{\pi} = 0.87856....$$

(The latter estimate results from a numerical computation.)

Theorem 75.5. *Let μ be the maximum capacity of a cut and let ν be the maximum value of* (75.68). *Then*

(75.70) $$\alpha\nu \leq \mu \leq \nu.$$

Proof. The inequality $\mu \leq \nu$ was shown above. To see the first inequality, let M maximize (75.68). As M is positive semidefinite, there exist vectors $x_v \in \mathbb{R}^n$ for $v \in V$ such that $x_u^{\mathsf{T}} x_v = M_{u,v}$ for all $u, v \in V$. (Here $n := |V|$.) So $\|x_v\| = 1$ for each $v \in V$.

For any hyperplane H in $\mathbb{R}^n$ with $\mathbf{0} \in H$, let D be the set of edges uv of K_V with u and v at different sides of H. Choosing H at random, the set D is a cut, with probability 1. Any edge uv of K_V is in D with probability

(75.71) $$\frac{\angle(x_u, x_v)}{\pi}.$$

($\angle(a,b)$ is the angle of a and b.) This follows from the fact that (75.71) is the probability that x_u and x_v are at different sides of H.

So the expected value of the capacity of D is equal to

(75.72) $$\sum_{uv \in EK_V} \frac{\angle(x_u, x_v)}{\pi} c(u,v).$$

Now if $\phi = \angle(x_u, x_v)$, then $x_u^{\mathsf{T}} x_v = \cos\phi$. Hence, by definition of α, (75.73) $$\frac{\angle(x_u, x_v)}{\pi} = \frac{\phi}{\pi} \geq \tfrac{1}{2}\alpha(1 - \cos\phi) = \tfrac{1}{2}\alpha(1 - x_u^{\mathsf{T}} x_v).$$

Hence (75.72) is at least

(75.74) $$\sum_{uv \in EK_V} \alpha \cdot \tfrac{1}{2}c(u,v)(1 - x_u^{\mathsf{T}} x_v) = \tfrac{1}{4}\alpha \mathrm{Tr} C(J - M) = \alpha\nu.$$

Concluding, there exists a cut of capacity at least $\alpha\nu$. So $\mu \geq \alpha\nu$. ∎

Since the separation problem over $\mathcal{M}_V$ is solvable in polynomial time, in a certain approximation model (cf. Grötschel, Lovász, and Schrijver [1988]), with the ellipsoid method, one can optimize any linear objective function over $\mathcal{M}_V$ in strongly polynomial time, or rather approximate the optimum. Hence the value of ν can be approximated in polynomial time. As Goemans and Williamson [1994,1995b] pointed out, this gives a randomized polynomial-time algorithm to find a cut of capacity at least $\alpha\nu \geq 0.87856\nu$: choosing a random hyperplane H as above gives a random cut of expected capacity as required. By derandomization, such a cut can in fact be found deterministically in polynomial-time (Mahajan and Ramesh [1995,1999]).

This approach also gives a *relaxation* ($\equiv$ superset) of the cut polytope. Indeed, let $G = (V, E)$ be an undirected graph. For any $M \in \mathcal{M}_V$, define $x_M : E \to \mathbb{R}_+$ by:

(75.75) $$x_M(e) := \tfrac{1}{2}(1 - M_{u,v})$$

for $e = uv \in E$. Then

(75.76) $$P_{\mathrm{cut}}(G) \subseteq K := \{x_M \mid M \in \mathcal{M}_V\},$$

since for each cut $\delta(U)$, the matrix M given by

(75.77) $$M := (\mathbf{1} - 2\chi^U)(\mathbf{1} - 2\chi^U)^{\mathsf{T}}$$

belongs to $\mathcal{M}_V$ and satisfies $x_M = \chi^{\delta(U)}$.

So K is a relaxation of the cut polytope. With the ellipsoid method, one can optimize over $\mathcal{M}_V$, and hence over K in polynomial time. What Goemans and Williamson's theorem tells is that for nonnegative $c : E \to \mathbb{R}_+$, maximizing $c^{\mathsf{T}}x$ over K has only a small relative error compared to maximizing over $P_{\mathrm{cut}}(G)$. In other words:

(75.78) $$K \subseteq \alpha^{-1} \cdot P_{\text{bipartite subgraph}}(G).$$

Here we use that $P_{\text{bipartite subgraph}}(G)$ is the down hull in $\mathbb{R}_+^E$ of $P_{\mathrm{cut}}(G)$.

Feige and Schechtman [2001,2002] showed that for each $\varepsilon > 0$ there is a graph for which the ratio of the semidefinite programming bound ν and the maximum cut-size is no better than $\alpha + \varepsilon$.

Notes. Before Goemans and Williamson found their theorem, only a factor of 2 was known to be achievable in polynomial time, by just taking $c(E)$ as upper bound. This gives a factor 2, since a random cut has expected capacity $\frac{1}{2}c(EK_V)$, as each edge has probability $\frac{1}{2}$ to be in the random cut (Johnson and Lafuente [1970] and Sahni and Gonzalez [1976]).

Håstad [1997,2001] showed that if NP≠P, then there is no polynomial-time algorithm that finds a cut of capacity more than $\frac{16}{17}$ of the maximum cut-capacity (cf. Trevisan, Sorkin, Sudan, and Williamson [1996,2000]).

Related work can be found in Bellare, Goldreich, and Sudan [1995,1998], Karloff [1996,1999], Zwick [1999b], Alon and Sudakov [2000], and Alon, Sudakov, and Zwick [2001,2002].

Earlier eigenvalue methods for the maximum cut problem include Poljak [1992] and Delorme and Poljak [1993a,1993b,1993c].

Surveys on semidefinite methods for the maximum cut problem (and more generally in combinatorial optimization) are given by Goemans [1997], Reed [2001a], and Laurent and Rendl [2002]. Alizadeh [1995] gives a survey of applying interior-point methods to semidefinite programming in combinatorial optimization. More on the semidefinite relaxation of the cut polytope can be found in Laurent and Poljak [1995a,1996a,1996b]. Other approximation algorithms for the maximum cut problem were given by Arora, Karger, and Karpinski [1995,1999], Fernandez de la Vega [1996], Frieze and Kannan [1996,1999], Fernandez de la Vega and Kenyon [1998,2001], Feige and Langberg [2001], and Halperin, Livnat, and Zwick [2002].

An extension of the semidefinite programming bound to 3-cuts was given by Goemans and Williamson [2001]. For extensions to directed graphs, see Feige and Goemans [1995], Matuura and Matsui [2001], and Lewin, Livnat, and Zwick [2002].

For a survey on approximation algorithms, see Shmoys [1995] and the book by Vazirani [2001].

75.9. Further results and notes

75.9a. Cuts and stable sets

The vertex cover polytope of a graph $G = (V, E)$ can be considered as a face of the cut polytope of the graph $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ obtained from G by adding one new vertex u adjacent to all vertices of G. Since the stable set polytope can be expressed in terms of the vertex cover polytope (as S is a stable set if and only if $V \setminus S$ is a vertex cover), this gives a relation between cuts and stable sets.

To see the relation between $P_{\text{vertex cover}}(G)$ and $P_{\text{cut}}(\widetilde{G})$, first note that each $x \in P_{\text{cut}}(\widetilde{G})$ satisfies

(75.79) $\qquad x(T) \leq 2$ for each triangle $T \subseteq \widetilde{E}$.

Therefore, the set of vectors x in $P_{\text{cut}}(\widetilde{G})$ satisfying

(75.80) $\qquad x(T) = 2$ for each triangle $T = \{uv, uw, vw\}$ containing u

(so vw is an edge of G), forms a face F of $P_{\text{cut}}(\widetilde{G})$.

Now we project $\mathbb{R}^{\widetilde{E}}$ on $\mathbb{R}^{\widetilde{E}\setminus E}$ by deleting the coordinates indexed by E. Moreover, we identify any edge uv in $\widetilde{E} \setminus E$ with vertex v of G. This brings F one-to-one to the vertex cover polytope of G.

More precisely, define a projection $\pi : \mathbb{R}^{\widetilde{E}} \to \mathbb{R}^V$ by $\pi(x)_v := x_{uv}$ for $v \in V$ and $x \in \mathbb{R}^{\widetilde{E}}$. Then:

Theorem 75.6. *$\pi|F$ is a bijection between F and $P_{\text{vertex cover}}(G)$.*

Proof. First, $\pi|F$ is injective, since if $\pi(x) = \pi(y)$ for $x, y \in F$, then for each $v \in V$, $x_{uv} = y_{uv}$. Hence, by (75.80), for each $vw \in E$, $x_{vw} = 2 - x_{uv} - x_{uw} = 2 - y_{uv} - y_{uw} = y_{vw}$. So $x = y$.

To see that $\pi(F) \subseteq P_{\text{vertex cover}}(G)$, let C be a cut in $\widetilde{G}$ with $\chi^C \in F$ (that is, χ^C is a vertex of F). Then for each edge vw of G, precisely two of the edges uv, uw, vw belong to C. Hence at least one of uv, uw belongs to C. So $\pi(\chi^C)$ is the incidence vector of a vertex cover of G.

Conversely, to see $P_{\text{vertex cover}}(G) \subseteq \pi(F)$, let U be a vertex cover of G. So $U \subseteq V$. Let C be the cut in $\widetilde{G}$ determined by U. Then χ^C belongs to F, since for each edge vw of G we have that precisely two of uv, uw, vw belong to C. Moreover, $\pi(\chi^C) = \chi^U$, since for each $v \in V$: $v \in U \iff uv \in C$. ∎

The relation given in this theorem can be useful when we have a good description of the cut polytope for certain classes of graphs. The description then can be transferred to the vertex cover polytope, hence to the stable set polytope, for certain derived classes of graphs.

In particular, we can derive from Guenin's theorem the t-perfection of graphs without odd K_4-subdivision (a consequence of Theorem 68.3 (Gerards and Schrijver [1986])):

Theorem 75.7. *A graph G without odd K_4 subdivision as subgraph is t-perfect.*

Proof. Let $G = (V, E)$ be a graph without odd K_4-subdivision as subgraph. By (75.22), G has no K_4 as odd minor. Let $\widetilde{G} = (\widetilde{V}, \widetilde{E})$ be the graph obtained from G by adding a new vertex u, adjacent to all vertices in V.

Then $\widetilde{G}$ has no K_5 as odd minor. For suppose it has. Then by deleting the vertex from the K_5 to which u has been contracted (if any) we obtain a graph being K_4 or K_5. It implies that G has K_4 as odd minor, a contradiction.

Now let $y \in \mathbb{R}^V$ satisfy

$$(75.81) \qquad \begin{array}{ll} 0 \leq y_v \leq 1 & \text{for } v \in V, \\ y_u + y_v \leq 1 & \text{for } uv \in E, \\ y(VC) \leq \lfloor \frac{1}{2}|VC| \rfloor & \text{for each odd circuit } C. \end{array}$$

Define $x \in \mathbb{R}^{\widetilde{E}}$ by

$$(75.82) \qquad \begin{array}{ll} x(vw) := y_v + y_w & \text{for each edge } vw \text{ of } G, \\ x(uv) := 1 - y_v & \text{for each } v \in V. \end{array}$$

Then x satisfies (75.2) with respect to $\widetilde{G}$. Indeed, (75.2)(i) trivially holds. To see (ii), we can restrict ourselves to chordless odd circuits C. If C traverses u, it is a triangle containing u, and we have $x(EC) = 2 = |VC| - 1$. If C does not traverse u, then $x(EC) = 2y(VC) \leq |VC| - 1$.

So by Corollary 75.4a, x is a convex combination of incidence vectors of bipartite subgraphs B:

$$(75.83) \qquad x = \sum_B \lambda_B \chi^B.$$

Since $x(C) = 2$ for each triangle C containing u, those B with $\lambda_B > 0$ intersect each such C in precisely two edges. Hence (since each circuit in $\widetilde{G}$ is a symmetric difference of triangles containing u) B intersects each circuit in an even number of edges. So B is a cut $\delta(U)$ of $\widetilde{G}$. We can assume that $u \notin U$. Then $V \setminus U$ is a stable set of G, and

(75.84) $$y = \sum_U \lambda_{\delta(U)} \chi^{V \setminus U}$$

describes y as a convex combination of incidence vectors of stable sets. ∎

It should be noted that the face F of the cut polytope described above is at the same time a face of the (larger) bipartite subgraph polytope (while the cut polytope need not be a face of the bipartite subgraph polytope). Indeed, also the bipartite subgraph polytope satisfies (75.79). Moreover, any set B of edges having even intersection with the triangle $\{uv, uw, vw\}$ for each edge vw of G, has even intersection with each circuit of $\widetilde{G}$, as it is a binary sum of such triangles. So B is a cut.

Laurent, Poljak, and Rendl [1997] showed how the set TH(G) (defined in Section 67.4a) can be derived as an affine image from the convex body K in Section 75.8.

75.9b. Further notes

Chvátal, Cook, and Hartmann [1989] showed that the Chvátal rank of system (75.2) is at least $\frac{1}{4}|V| - 1$ for complete graphs $G = (V, E)$.

Conforti and Gerards [2000] described (by forbidden odd minors) another class of Eulerian graphs for which the maximum number of edge-disjoint odd circuits is equal to the minimum size of an odd circuit cover.

Barahona [1983b] showed that the maximum-size cut problem is NP-complete for *apex graphs*, that is graphs G having a vertex v with $G - v$ planar. (More strongly, Barahona proved NP-completeness if $G - v$ is cubic and planar.)

Grötschel and Nemhauser [1984] showed that for each fixed k there is a polynomial-time algorithm to solve the maximum-capacity cut problem for graphs without odd circuits of length $\geq k$.

Facets of the bipartite subgraph polytope were studied by Barahona, Grötschel, and Mahjoub [1985] (cf. Gerards [1985]), and facets of the cut polytope and cut cone by Barahona and Mahjoub [1986], De Simone [1989,1990], Deza and Laurent [1990, 1992a,1992b], Deza, Laurent, and Poljak [1992], and Laurent and Poljak [1996a]. Compositions in the bipartite subgraph polytope were given by Fonlupt, Mahjoub, and Uhry [1992].

Conforti and Rao [1987] showed that a minimum-weight odd circuit cover can be found in strongly polynomial time, if its weight is less than the minimum weight of a nonempty cut.

For more geometric background on the cut cone and the cut polytope, see the book by Deza and Laurent [1997]. Gerards [1990] gave a survey on signed graphs without odd K_4-subdivision. For more background on the relations between odd circuits and multicommodity flows, see Sebő [1990a] and Gerards [1993]. For surveys on maximum cut and the cut cone, see Deza, Grishukhin, and Laurent [1995] (hypermetrics) and Poljak and Tuza [1995]. For related work, see Conforti, Rao, and

Sassano [1990a,1990b], Jerrum and Sorkin [1993,1998], Feige and Goemans [1995], Frieze and Jerrum [1995,1997], Ageev and Sviridenko [1999], Ageev, Hassin, and Sviridenko [2001], Feige and Langberg [2001], Halperin and Zwick [2001a,2001b, 2002], Ye [2001], Han, Ye, and Zhang [2002], and Lewin, Livnat, and Zwick [2002].

Chapter 76

Homotopy and graphs on surfaces

As we saw in Chapter 74, disjoint paths and multiflow problems are generally hard even for planar graphs. In some special cases, these problems are polynomial-time solvable.
If we require the paths (or flows) to have certain homotopies, the range of polynomial-time solvable problems can be extended. By enumerating homotopies, it sometimes implies polynomial-time solvability for nonhomotopic versions of the problems.
This can be extended to general surfaces and yield polyhedral characterizations for circulations, flows, and paths of prescribed homotopies.

76.1. Graphs, curves, and their intersections: terminology and notation

Let S be a compact surface. A *closed curve* on S is a continuous function $C : S^1 \to S$, where S^1 is the unit circle in $\mathbb{C}$. It is *simple* if C is one-to-one.

Two closed curves C and C' are called *freely homotopic*, in notation $C \sim C'$, if there exists a continuous function bringing C to C'; that is, a continuous function $\Phi : S^1 \times [0,1] \to S$ with $\Phi(z,0) = C(z)$ and $\Phi(z,1) = C'(z)$ for each $z \in S^1$.

For any pair of closed curves C, D on S, let $\mathrm{cr}(C,D)$ denote the number of intersections of C and D, counting multiplicities:

$$(76.1) \qquad \mathrm{cr}(C,D) := |\{(w,z) \in S^1 \times S^1 \mid C(w) = D(z)\}|.$$

Moreover, $\mathrm{mincr}(C,D)$ denotes the minimum of $\mathrm{cr}(C',D')$ where C' and D' range over closed curves freely homotopic to C and D, respectively:

$$(76.2) \qquad \mathrm{mincr}(C,D) := \min\{\mathrm{cr}(C',D') \mid C' \sim C, D' \sim D\}.$$

Similarly, $\mathrm{cr}(C)$ denotes the number of self-intersections of C:

$$(76.3) \qquad \mathrm{cr}(C) := \tfrac{1}{2}|\{(w,z) \in S^1 \times S^1 \mid C(w) = C(z), w \neq z\}|,$$

and $\mathrm{mincr}(C)$ denotes the minimum of $\mathrm{cr}(C')$ where C' ranges over all closed curves freely homotopic to C:

(76.4) $\quad \text{mincr}(C) := \min\{\text{cr}(C') \mid C' \sim C\}.$

As is well-known, mincr(C, D) and mincr(C) are finite numbers.

Let $G = (V, E)$ be an undirected graph embedded in S. We identify G with its topological graph, and with its embedding in S.

For any closed curve D on S, cr(G, D) denotes the number of intersections of G and D (counting multiplicities):

(76.5) $\quad \text{cr}(G, D) := |\{z \in S^1 \mid D(z) \in G\}|.$

Moreover, mincr(G, D) denotes the minimum of cr(G, D') where D' ranges over all closed curves freely homotopic to D and not intersecting V:

(76.6) $\quad \text{mincr}(G, D) := \min\{\text{cr}(G, D') \mid D'$ is a closed curve in $S \setminus V$ freely homotopic to $D\}$.

(It would seem more consistent with definition (76.2) if we would also allow to shift G over S so as to obtain G' and minimize cr(G', D'), where G' is possibly not one-to-one mapped in S. However, Theorem 76.1 below implies that this would not change the minimum value.)

We say that a closed curve C is *in* a graph G if $C : S^1 \to G$.

76.2. Making curves minimally crossing by Reidemeister moves

The proof of Theorem 76.1 below is based on the following result of de Graaf and Schrijver [1997b]. Let $C_1, \ldots, C_k$ be closed curves on S. Call $C_1, \ldots, C_k$ *minimally crossing* if

(76.7) (i) cr(C_i) = mincr(C_i) for each $i = 1, \ldots, k$;
(ii) cr(C_i, C_j) = mincr(C_i, C_j) for all $i, j = 1, \ldots, k$ with $i \neq j$.

Call $C_1, \ldots, C_k$ *regular* if $C_1, \ldots, C_k$ have only a finite number of (self-)intersections, each being a crossing of only two curve parts. (That is, each point of S traversed twice by the $C_1, \ldots, C_k$ has a disk-neighbourhood on which the curve parts are topologically homeomorphic to two crossing straight lines.)

In de Graaf and Schrijver [1997b] the following was shown:

(76.8) Any regular system of closed curves on a compact surface S can be transformed to a minimally crossing system by a series of *Reidemeister moves*: replacing  by  (*type 0*); replacing  by (*type I*); replacing  by (*type II*); replacing  by  (*type III*).

The pictures in (76.8) represent the intersection of the union of $C_1, \ldots, C_k$ with a closed disk on S — no other curve parts than those shown intersect this disk.

It is important to note that in (76.8) we do not allow to apply the operations in the reverse direction — otherwise the result would follow quite straightforwardly with the techniques of simplicial approximation, and would not be powerful enough for our purposes. The Reidemeister moves given in (76.8) do not increase the number of intersections.

76.3. Decomposing the edges of an Eulerian graph on a surface

We first show a homotopic analogue of the theorems in previous chapters relating distances and cut packings. It will be used to derive that the cut condition is sufficient for the existence of a fractional packing of circuits of prescribed homotopies in a graph on a surface (analogous to the line of proof developed in Section 70.12).

A graph is called *Eulerian* if each vertex has even degree. (We do not assume connectedness of the graph.) Moreover, *decomposing* the edges into closed curves $C_1, \ldots, C_k$ means that $C_1, \ldots, C_k$ are closed curves in G such that each edge is traversed by exactly one C_i, and by that C_i exactly once.

We now give the theorem, due to de Graaf and Schrijver [1997a], which was proved for the projective plane by Lins [1981] (Corollary 74.1b above) and for compact orientable surfaces by Schrijver [1991a].

Theorem 76.1. *Let $G = (V, E)$ be an Eulerian graph embedded in a compact surface S. Then the edges of G can be decomposed into closed curves $C_1, \ldots, C_k$ such that*

$$\text{(76.9)} \qquad \text{mincr}(G, D) = \sum_{i=1}^{k} \text{mincr}(C_i, D)$$

for each closed curve D on S.

Proof. First note that the inequality $\geq$ in (76.9) trivially holds, for *any* decomposition of the edges into closed curves $C_1, \ldots, C_k$: by definition of $\text{mincr}(G, D)$, there exists a closed curve $D' \sim D$ in $S \setminus V$ with $\text{mincr}(G, D) = \text{cr}(G, D')$, and hence

$$\text{(76.10)} \qquad \text{mincr}(G, D) = \text{cr}(G, D') = \sum_{i=1}^{k} \text{cr}(C_i, D') \geq \sum_{i=1}^{k} \text{mincr}(C_i, D).$$

The content of the theorem is that there exists a decomposition attaining equality.

To prove this, we may assume that each vertex v of G has degree at most 4. If v would have a degree larger than 4, we can replace G in a neighbourhood of v like

 by  .

This modification does not change the value of $\text{mincr}(G, D)$ for any D. Moreover, closed curves decomposing the edges of the modified graph satisfying (76.9), directly yield closed curves decomposing the edges of the original graph satisfying (76.9).

For any graph G embedded in S with each vertex having degree 2 or 4, we define the *straight decomposition* of G as the regular system of closed curves $C_1, \ldots, C_k$ such that $G = C_1 \cup \cdots \cup C_k$. So each vertex of G of degree 4 represents a (self-)crossing of $C_1, \ldots, C_k$.

Up to some trivial operations, such a decomposition is unique, and conversely, it uniquely describes G. Moreover, any Reidemeister move applied to $C_1, \ldots, C_k$ carries over a modification of G. So we can speak of Reidemeister moves applied to G. Then straightforwardly:

(76.11) if G' arises from G by one Reidemeister move of type III, then $\text{mincr}(G', D) = \text{mincr}(G, D)$ for each closed curve D.

Call any graph $G = (V, E)$ that is a counterexample to the theorem such that each vertex has degree at most 4 and such that it has a minimum number of faces, a *minimal counterexample.* (A *face* is a connected component of $S \setminus G$.)

From (76.11) it directly follows that:

(76.12) if G' arises from a minimal counterexample G by one Reidemeister move of type III, then G' is a minimal counterexample again.

Moreover:

(76.13) if G is a minimal counterexample, then no Reidemeister move of type 0, I or II can be applied to G.

For suppose that a Reidemeister move of type II can be applied to G. Then G contains the following subconfiguration: . Replacing this by  would give a smaller counterexample (since the function $\text{mincr}(G, D)$ does not change by this operation), contradicting the minimality of G. One similarly sees that no Reidemeister move of type I can be applied. No Reidemeister move of type 0 can be applied, as otherwise we can delete the circuit to obtain a smaller counterexample. This proves (76.13).

The proof now is finished by showing that the straight decomposition $C_1, \ldots, C_k$ of any minimal counterexample G satisfies (76.9) — contradicting the fact that G is a counterexample.

Choose a closed curve D. We may assume that $D, C_1, \ldots, C_k$ form a regular system. By (76.8) we can apply Reidemeister moves so as to obtain a minimally crossing system $D', C_1', \ldots, C_k'$. Let G' be the graph formed by $C_1', \ldots, C_k'$.

By (76.12) and (76.13) we did not apply Reidemeister moves of type 0, I or II to $C_1, \ldots, C_k$. Hence, by (76.11), $\text{mincr}(G', D) = \text{mincr}(G, D)$. So

(76.14) $$\begin{aligned}\text{mincr}(G, D) &= \text{mincr}(G', D) = \text{mincr}(G', D') \leq \text{cr}(G', D') \\ &= \sum_{i=1}^{k} \text{cr}(C_i', D') = \sum_{i=1}^{k} \text{mincr}(C_i', D') = \sum_{i=1}^{k} \text{mincr}(C_i, D).\end{aligned}$$

Since the converse inequality holds by (76.10), we have (76.9). ∎

The theorem can be sharpened to include compact surfaces with holes, just by replacing holes by handles.

76.4. A corollary on lengths of closed curves

Using surface duality we derive the following consequence of Theorem 76.1 (Schrijver [1991a], de Graaf and Schrijver [1997a]). If G is a graph embedded in a surface S and C is a closed curve in G, then $\text{minlength}_G(C)$ denotes the minimum length of any closed curve $C' \sim C$ in G. Here the *length* $\text{length}_G(C')$ of C' is the number of edges traversed by C', counting multiplicities. So

(76.15) $$\text{minlength}_G(C) = \min\{\text{length}_G(C') \mid C' \sim C, C' \text{ in } G\}.$$

Corollary 76.1a. *Let $G = (V, E)$ be a bipartite graph embedded in a compact surface S and let $C_1, \ldots, C_k$ be closed curves in G. Then there exist closed curves $D_1, \ldots, D_t$ in $S \setminus V$ such that each edge of G is crossed by exactly one D_j and by this D_j only once, and such that*

(76.16) $$\text{minlength}_G(C_i) = \sum_{j=1}^{t} \text{mincr}(C_i, D_j)$$

for each $i = 1, \ldots, k$.

Proof. Let

(76.17) $$d := \max\{\text{minlength}_G(C_i) \mid i = 1, \ldots, k\}.$$

We can extend G to a bipartite graph L embedded in S, such that each face of L is an open disk. By inserting d new vertices on each edge of L not occurring in G, we obtain a bipartite graph H satisfying $\text{minlength}_H(C_i) = \text{minlength}_G(C_i)$ for each $i = 1, \ldots, k$ (since the new edges cannot be used to obtain a closed curve shorter than $\text{minlength}_G(C_i)$).

Consider a surface dual graph H^* of H. Then for each $i = 1, \ldots, k$,

(76.18) $$\text{mincr}(H^*, C_i) = \text{minlength}_H(C_i) = \text{minlength}_G(C_i).$$

Since H is bipartite, H^* is Eulerian. Hence by Theorem 76.1, the edges of H^* can be decomposed into closed curves $D_1, \ldots, D_t$ such that

(76.19) $$\text{mincr}(H^*, C) = \sum_{j=1}^{t} \text{mincr}(D_j, C)$$

for each closed curve C. With (76.18), this gives (76.16). ∎

Notes. This proof also implies that we can replace $C_1, \ldots, C_k$ by the set of *all* closed curves on S if G is *cellularly embedded* (i.e., each face is an open disk) — in that case we need not extend G to L and H.

It is not difficult to see that this also holds for not-cellularly embedded bipartite graphs in the torus, since then there is essentially only one closed curve C in G to consider.

This is not true for the double torus (a surface with two handles), as is shown by the example of Figure 76.1 (from Schrijver [1991a]).

76.5. A homotopic circulation theorem

By linear programming duality (Farkas' lemma) we derive from Corollary 76.1a the following 'homotopic circulation theorem' — a fractional packing theorem for closed curves of given homotopies in a graph on a compact surface.

Let $G = (V, E)$ be a graph embedded in a compact surface S. For any closed curve C in G define the vector tr^C in $\mathbb{Z}_+^E$ by:

(76.20) $$\text{tr}^C(e) := \text{number of times } C \text{ traverses } e,$$

for $e \in E$.

Let C_0 be a closed curve on S. Call a function $f : E \to \mathbb{R}$ a *circulation freely homotopic to* C_0 (of *value* 1) if f is a convex combination of functions tr^C, where the C are closed curves in G freely homotopic to C_0.

Corollary 76.1b (homotopic circulation theorem)**.** *Let $G = (V, E)$ be an undirected graph embedded in a compact surface S and let $C_1, \ldots, C_k$ be closed curves on S. Then there exist circulations $f_1, \ldots, f_k$ freely homotopic to $C_1, \ldots, C_k$ respectively, such that*

(76.21) $$f_1(e) + \cdots + f_k(e) \leq 1$$

for each edge e, if and only if

(76.22) $$\text{cr}(G, D) \geq \sum_{i=1}^{k} \text{mincr}(C_i, D)$$

for each closed curve D in $S \setminus V$.

Proof. *Necessity.* First note that if f is a circulation freely homotopic to a closed curve C_0, then

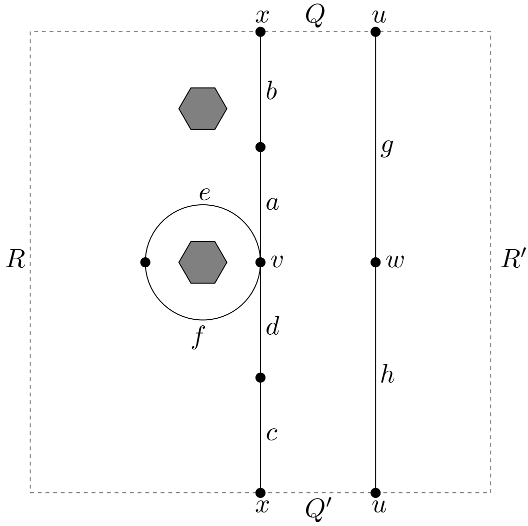

Figure 76.1
A not-cellularly embedded bipartite graph G in the double torus S for which Corollary 76.1a is not true if we replace $C_1, \ldots, C_k$ by all closed curves on S. The double torus is obtained from the square by identifying R and R' and identifying Q and Q' (so as to obtain the torus) and next deleting the interiors of the two hexagons and identifying their boundaries (so as to obtain the double torus).
For $i = 0, 1, 2, \ldots$ let C_i be the closed curve in G which, starting at v, follows e and f once, and next follows i times the closed curve a, b, c, d. Then $\text{minlength}_G(C_i) = 4i+2$. Suppose now that $D_1, \ldots, D_t$ are closed curves as described in Corollary 76.1a. Choose an arbitrary curve P from v to w. Then C_i is homotopic to the closed curve $\widetilde{C}_i$ obtained by, starting at v, first following e and f, next following P, then following i times the closed curve g, h, and finally following P back from w to v. Hence for each i (where B is the closed curve from w to w following g and h):

$$
\begin{aligned}
&4i + 2 = \text{minlength}_G(C_i) = \sum_{j=1}^{t} \text{mincr}(C_i, D_j) \\
&\leq \sum_{j=1}^{t} \text{cr}(\widetilde{C}_i, D_j) = \sum_{j=1}^{t} (\text{cr}(C_0, D_j) + 2 \cdot \text{cr}(P, D_j) + i \cdot \text{cr}(B, D_j)) \\
&= \sum_{j=1}^{t} (\text{cr}(C_0, D_j) + 2 \cdot \text{cr}(P, D_j)) + 2i.
\end{aligned}
$$

As the first term in the last sum is independent of i, this is a contradiction.

$$\sum_{e\in E} f(e)\mathrm{cr}(e,D) \geq \mathrm{mincr}(C_0,D). \tag{76.23}$$

for each closed curve D in $S\setminus V$ (denoting by $\mathrm{cr}(e,D)$ the number of times D intersects edge e). This follows from the fact that (76.23) holds for $f := \mathrm{tr}^C$ for each C freely homotopic to C_0 as

$$\sum_{e\in E} \mathrm{tr}^C(e)\mathrm{cr}(e,D) = \mathrm{cr}(C,D) \geq \mathrm{mincr}(C_0,D), \tag{76.24}$$

and hence also for any convex combination of such functions.

Suppose now that there exist circulations $f_1,\ldots,f_k$ as required. Let D be a closed curve in $S\setminus V$. Then, using (76.23):

$$\begin{aligned} \mathrm{cr}(G,D) &= \sum_{e\in E}\mathrm{cr}(e,D) \geq \sum_{e\in E}\mathrm{cr}(e,D)\sum_{i=1}^k f_i(e) \\ &= \sum_{i=1}^k\sum_{e\in E} f_i(e)\mathrm{cr}(e,D) \geq \sum_{i=1}^k \mathrm{mincr}(C_i,D). \end{aligned} \tag{76.25}$$

Sufficiency. Suppose that (76.22) is satisfied for each closed curve D in $S\setminus V$. Let $I := \{1,\ldots,k\}$ and let K be the convex cone in $\mathbb{R}^I\times\mathbb{R}^E$ generated by the vectors[23]

$$\begin{array}{ll} (\chi^i;\mathrm{tr}^C) & (i\in I; C \text{ closed curve in } G \text{ with } C\sim C_i), \\ (\mathbf{0}_I;\chi^e) & (e\in E). \end{array} \tag{76.26}$$

Here χ^i denotes the ith unit base vector in $\mathbb{R}^I$ and χ^e denotes the eth unit base vector in $\mathbb{R}^E$. Moreover, $\mathbf{0}_I$ denotes the all-zero vector in $\mathbb{R}^I$.

Although generally there are infinitely many vectors (76.26), K is finitely generated. This can be seen by observing that, for each $i\in I$, we can restrict the vectors $(\chi^i;\mathrm{tr}^C)$ in the first line of (76.26) to those that are minimal with respect to the usual partial order $\leq$ on $\mathbb{Z}_+^I\times\mathbb{Z}_+^E$ (with $(x;y)\leq(x';y') \iff x_i\leq x_i'$ for all $i\in I$ and $y_e\leq y_e'$ for all $e\in E$). They form an 'antichain' in $\mathbb{Z}_+^I\times\mathbb{Z}_+^E$ (i.e., a set of pairwise incomparable vectors). Since each antichain in $\mathbb{Z}_+^I\times\mathbb{Z}_+^E$ is finite, K is finitely generated.

We must show that the vector $(\mathbf{1}_I;\mathbf{1}_E)$ belongs to K. Here $\mathbf{1}_I$ and $\mathbf{1}_E$ denote the all-one vectors in $\mathbb{R}^I$ and $\mathbb{R}^E$, respectively. By Farkas' lemma, it suffices to show that each vector $(d;l)\in\mathbb{Q}^I\times\mathbb{Q}^E$ having nonnegative inner product with each of the vectors (76.26), also has nonnegative inner product with $(\mathbf{1}_I;\mathbf{1}_E)$. Thus let $(d;l)\in\mathbb{Q}^I\times\mathbb{Q}^E$ have nonnegative inner product with each vector among (76.26). This is equivalent to:

$$\begin{array}{lll} \text{(i)} & d_i + \sum_{e\in E} l(e)\mathrm{tr}^C(e) \geq 0 & (i\in I; C \text{ closed curve in } G \\ & & \text{with } C\sim C_i), \\ \text{(ii)} & l(e)\geq 0 & (e\in E). \end{array} \tag{76.27}$$

[23] We write $(x;y)$ for $\binom{x}{y}$.

Suppose now that $(d;l)^{\mathsf{T}}(\mathbf{1}_I;\mathbf{1}_E) < 0$. By increasing l slightly, we may assume that $l(e) > 0$ for each $e \in E$. Next, by multiplying $(d;l)$ appropriately, we may assume that each entry in $(d;l)$ is an even integer.

Let G' be the graph arising from G by replacing each edge e of G by a path of length $l(e)$. That is, we insert $l(e)-1$ new vertices on e. Then by (76.27)(i),

$$(76.28) \qquad -d_i \leq \operatorname{minlength}_{G'}(C_i)$$

for each $i \in I$. Since G' is bipartite, by Corollary 76.1a there exist closed curves $D_1, \ldots, D_t$ intersecting no vertex of G' such that each edge of G' is intersected by exactly one D_j and only once by that D_j and such that

$$(76.29) \qquad \operatorname{minlength}_{G'}(C_i) = \sum_{j=1}^{t} \operatorname{mincr}(C_i, D_j)$$

for each $i \in I$. So

$$(76.30) \qquad l(e) = \sum_{j=1}^{t} \operatorname{cr}(e, D_j)$$

for each edge e of G. Hence (76.22), (76.28) and (76.29) give

$$(76.31) \qquad \begin{aligned} \sum_{e \in E} l(e) &= \sum_{j=1}^{t} \sum_{e \in E} \operatorname{cr}(e, D_j) = \sum_{j=1}^{t} \operatorname{cr}(G, D_j) \\ &\geq \sum_{j=1}^{t} \sum_{i=1}^{k} \operatorname{mincr}(C_i, D_j) = \sum_{i=1}^{k} \sum_{j=1}^{t} \operatorname{mincr}(C_i, D_j) \\ &= \sum_{i=1}^{k} \operatorname{minlength}_{G'}(C_i) \geq -\sum_{i=1}^{k} d_i. \end{aligned}$$

So $(d;l)^{\mathsf{T}}(\mathbf{1}_I;\mathbf{1}_E) \geq 0$. ∎

This corollary has an equivalent capacitated version. Let C_0 be a closed curve on S. Call a function $f : E \to \mathbb{R}$ a *circulation freely homotopic to* C_0 of *value* d if f is a nonnegative linear combination of functions tr^C, where the C are closed curves in G freely homotopic to C_0 and where the scalars add up to d.

Corollary 76.1c. *Let $G = (V, E)$ be an undirected graph embedded in a compact surface S and let $C_1, \ldots, C_k$ be closed curves on S. Let $c : E \to \mathbb{R}_+$ and $d_1, \ldots, d_k \in \mathbb{R}_+$. Then there exist circulations $f_1, \ldots, f_k$ freely homotopic to $C_1, \ldots, C_k$ respectively and of values $d_1, \ldots, d_k$ respectively, such that*

$$(76.32) \qquad \sum_{i=1}^{k} f_i(e) \leq c(e)$$

for each edge e *if and only if*

$$(76.33) \qquad \sum_{e\in E} c(e)\mathrm{cr}(e,D) \geq \sum_{i=1}^{k} d_i \cdot \mathrm{mincr}(C_i,D)$$

for each closed curve D *in* $S \setminus V$.

Proof. Using the argument on the finite generation of the convex cone K in the proof of Corollary 76.1b, we can assume that c and the d_i are rational, and hence integer. Replace each edge e of G by $c(e)$ parallel edges, and replace any C_i by d_i copies of C_i. Then the present corollary follows from Corollary 76.1b. ∎

Notes. Frank and Schrijver [1992] showed that if S is the torus and each C_i is a simple closed curve, then there exist half-integer circulations in Corollary 76.1b — that is, where the scalars of the tr^C are $\frac{1}{2}$ (similarly, in Corollary 76.1c if c and the d_i are integer). More generally, it is shown that there are integer circulations if the following Euler condition holds:

(76.34) for each closed curve D in $S \setminus V$, the number of crossings of D with G has the same parity as the number of crossings with $C_1, \ldots, C_k$.

This condition in particular implies that each vertex of G has even degree. This result can be formulated equivalently as:

(76.35) Let $G = (V,E)$ be a graph embedded in the torus S and let $C_1, \ldots, C_k$ be simple closed curves on S such that the Euler condition (76.34) holds. Then G has edge-disjoint closed walks $C'_1, \ldots, C'_k$ (each traversing no edge more than once) with C'_i freely homotopic to C_i for $i = 1, \ldots, k$, if and only if condition (76.22) holds.

The C'_i need not be simple; they may have self-intersections at vertices. (See Schrijver [1992] for a survey on disjoint circuits in graphs on the torus.)

Figures 76.2 and 76.3 show that we cannot delete in (76.35) the Euler condition or the condition that the C_i are simple. Moreover, Figure 76.4 shows that (76.35) does not extend to the double torus (a surface with two handles).

76.6. Homotopic paths in planar graphs with holes

As was shown in Schrijver [1991a], Corollary 76.1b gives a 'homotopic flow-cut theorem', stating that a homotopic cut condition implies the existence of a fractional solution for the planar edge-disjoint paths problem, if the paths have prescribed homotopies in the surface obtained from the plane by deleting the interiors of certain faces covering all terminals. (This answers a question of C.St.J.A. Nash-Williams.)

Before formulating the result, we introduce some notation and terminology. Fix some subset T of $\mathbb{R}^2$. A *curve* in T is a continuous function $D : [0,1] \to T$. The points $D(0)$ and $D(1)$ are the *end points* of D.

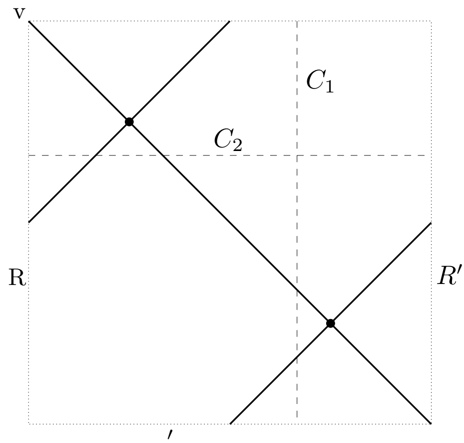

Figure 76.2

A graph G and curves C_1, C_2 on the torus satisfying the cut condition (76.22) (but not the Euler condition (76.34)), where G has no edge-disjoint circuits C_1' and C_2' with C_i' freely homotopic to C_i ($i = 1, 2$).

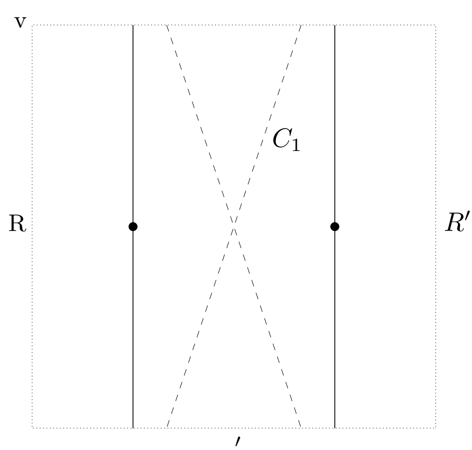

Figure 76.3

A graph G and a *nonsimple* curve C_1 on the torus satisfying the cut condition (76.22) and the Euler condition (76.34), where G has no closed curve C_1' freely homotopic to C_1 such that C_1' traverses any edge of G at most once.

Two curves D, D' are called *homotopic* (*in* T), denoted by $D \sim D'$, if there exists a continuous function $\Phi : [0,1] \times [0,1] \to T$ with $\Phi(x, 0) = D(x)$,

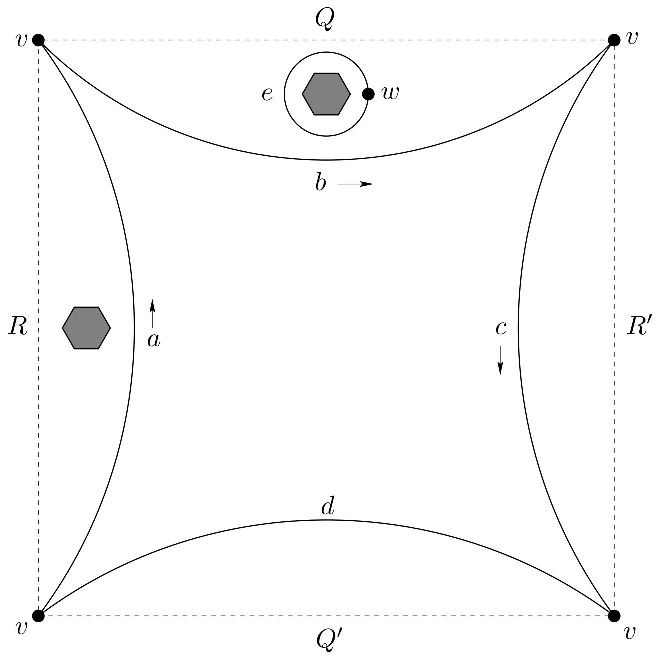

Figure 76.4

A graph G and curves C_1, C_2 on the double torus satisfying the cut condition (76.22) and Euler condition (76.34), but where no integer feasible circulations exist. The double torus is obtained from the square by identifying R and R' and identifying Q and Q' (so as to obtain the torus) and next deleting the interiors of the two hexagons and identifying their boundaries (so as to obtain the double torus). The graph G has two vertices, v and w, and four loops, a, b, c, d, at v, and one loop, e, at w. Curve C_1 follows the edges a and b, and curve C_2 follows the edges b and c — in the directions indicated. The cut condition (76.22) and the Euler condition (76.34) hold, but G has no edge-disjoint closed walks freely homotopic to C_1 and C_2 respectively. (The cut condition follows from the existence of a fractional solution.)

$\Phi(x,1) = D'(x)$, $\Phi(0,x) = D(0)$, $\Phi(1,x) = D(1)$ for each $x \in [0,1]$. (It follows that $D(0) = D'(0)$ and $D(1) = D'(1)$.)

If C and D are curves in T, then we denote:

(76.36) $$\mathrm{cr}(C,D) := |\{(x,y) \in [0,1] \times [0,1] \mid C(x) = D(y)\}|,$$
$$\mathrm{mincr}(C,D) := \min\{\mathrm{cr}(C',D') \mid C' \sim C, D' \sim D\}.$$

Let $G = (V,E)$ be a graph embedded in T. For any curve D in T and any $e \in E$, let

(76.37) $$\mathrm{cr}(e,D) := |\{x \in [0,1] \mid D(x) \in e\}|,$$

and

$$(76.38) \qquad \mathrm{cr}(G, D) = \sum_{e \in E} \mathrm{cr}(e, D).$$

For any walk P in G, let tr^P be the vector in $\mathbb{Z}_+^E$ defined by

$$(76.39) \qquad \mathrm{tr}^P(e) := \text{number of times } P \text{ traverses } e,$$

for $e \in E$. For any curve C in T, a *flow homotopic to* C (*of value* 1) is a convex combination of functions tr^P where P is a walk in G being (as a curve) homotopic to C in T.

Corollary 76.1d. *Let $G = (V, E)$ be a planar graph embedded in $\mathbb{R}^2$. Let $F_1, \ldots, F_p$ be (the interiors of) some of the faces of G, including the unbounded face. Let $T := \mathbb{R}^2 \setminus (F_1 \cup \cdots \cup F_p)$. Let $C_1, \ldots, C_k$ be curves in T with ends points being vertices of G on the boundary of T. Then there exist flows $f_1, \ldots, f_k$ homotopic to $C_1, \ldots, C_k$ respectively, each of value* 1*, such that*

$$(76.40) \qquad f_1(e) + \cdots + f_k(e) \leq 1$$

for each edge e of G if and only if

$$(76.41) \qquad \mathrm{cr}(G, D) \geq \sum_{i=1}^{k} \mathrm{mincr}(C_i, D)$$

for each curve D in $T \setminus V$ with end points on the boundary of T.

Proof. Necessity is shown similarly as in the proof of Corollary 76.1b. To see sufficiency, let the condition hold. We construct a compact orientable surface S. First embed $\mathbb{R}^2$ in the 2-dimensional sphere S^2. Next for each $i = 1, \ldots, k$ make a handle H_i between the faces among $F_1, \ldots, F_k$ incident with the end points of C_i. This yields S.

Let G' be the graph obtained from G by adding, for each $i = 1, \ldots, k$, an edge f_i between the end points of C_i, by routing f_i over H_i. This can be done in such a way that the new edges do not intersect each other, and do no intersect the edges of G. Each curve C_i now can be extended to a closed curve C_i' by adding f_i.

We apply Corollary 76.1b to G' and S. The circulations described in Corollary 76.1b give flows as required in the present corollary. So it suffices to check condition (76.22) for G' and S. That is, for any closed curve D in $S \setminus V$ we must show

$$(76.42) \qquad \mathrm{cr}(G', D) \geq \sum_{i=1}^{k} \mathrm{mincr}'(C_i', D).$$

Here mincr' denotes the function mincr with respect to S. To show (76.42), we distinguish three cases.

Case 1: D is contained in T. Let y be some point on D, let z be some point on the boundary of T with $z \notin V$, and let R be some curve in T connecting z and y, such that R does not intersect V, and intersects G only a finite number of times. For $n \in \mathbb{Z}_+$, let Q_n be the curve from z to z which follows R from z to y, then follows n times the closed curve D, and next returns from y to z over R. Let $r := \mathrm{cr}(G, R)$. Let D^n be the closed curve that follows n times D. Then for all $n \in \mathbb{Z}_+$,

$$\begin{aligned}(76.43)\qquad n \cdot \sum_{i=1}^{k} \mathrm{mincr}'(C'_i, D) &= \sum_{i=1}^{k} \mathrm{mincr}'(C'_i, D^n) \leq \sum_{i=1}^{k} \mathrm{mincr}(C_i, Q_n)\\ &\leq \mathrm{cr}(G, Q_n) = 2r + n \cdot \mathrm{cr}(G', D).\end{aligned}$$

Here the first equality is a general relation for curves on compact orientable surfaces (see Proposition 5 in Schrijver [1991a]). The first inequality holds as any curve homotopic to Q_n is equal to a *closed* curve *freely* homotopic to D^n. The second inequality follows from (76.41). The last equality follows from the definition of Q_n. Since (76.43) holds for each n, while r is fixed, we have (76.42).

Case 2: D does not intersect T. Then

$$(76.44)\qquad \mathrm{cr}(G', D) = \sum_{i=1}^{k} \mathrm{cr}(C'_i, D) \geq \sum_{i=1}^{k} \mathrm{mincr}'(C'_i, D).$$

Case 3: D intersects both T and $S \setminus T$. Set $H := S \setminus T$. Then we can split D into curves $D_1, D_2, \ldots, D_{2q}$, such that for odd i, D_i is contained in T and connects two points on the boundary of T, while for even i, D_i is contained in H, except for its end points. Then we have:

$$\begin{aligned}(76.45)\qquad \mathrm{cr}(G', D) &= \sum_{j=1}^{q} \mathrm{cr}(G, D_{2j-1}) + \sum_{j=1}^{q}\sum_{i=1}^{k} \mathrm{cr}(f_i, D_{2j})\\ &\geq \sum_{j=1}^{q}\sum_{i=1}^{k} \mathrm{mincr}(C_i, D_{2j-1}) + \sum_{j=1}^{q}\sum_{i=1}^{k} \mathrm{cr}(f_i, D_{2j})\\ &= \sum_{i=1}^{k}\sum_{j=1}^{q} (\mathrm{mincr}(C_i, D_{2j-1}) + \mathrm{cr}(f_i, D_{2j})) \geq \sum_{i=1}^{k} \mathrm{mincr}'(C'_i, D).\end{aligned}$$

The first inequality follows from (76.41). The last inequality can be derived as follows. Fix $i = 1, \ldots, k$. Then there exist curves $\widetilde{C}_i \sim C_i$ and $\widetilde{D}_{2j-1} \sim D_{2j-1}$ ($j = 1, \ldots, q$) with $\mathrm{mincr}(C_i, D_{2j-1}) = \mathrm{cr}(\widetilde{C}_i, \widetilde{D}_{2j-1})$ for $j = 1, \ldots, q$. (This can be derived, for instance, from (76.8).) Hence $\widetilde{C}_i$ attains the minimum simultaneously for all D_{2j-1}. So

$$(76.46)\qquad \sum_{j=1}^{q} \mathrm{mincr}(C_i, D_{2j-1}) = \sum_{j=1}^{q} \mathrm{cr}(\widetilde{C}_i, \widetilde{D}_{2j-1}).$$

Hence, where $\widetilde{D}$ is the concatenation of $\widetilde{D}_1, D_2, \widetilde{D}_3, D_4, \ldots, \widetilde{D}_{2q-1}, D_{2q}$, and $\widetilde{C}_i'$ is the concatenation of $\widetilde{C}_i$ and f_i,

$$(76.47) \qquad \sum_{j=1}^{q}(\text{mincr}(C_i, D_{2j-1}) + \text{cr}(f_i, D_{2j})) \\ = \sum_{j=1}^{q}(\text{cr}(\widetilde{C}_i, \widetilde{D}_{2j-1}) + \text{cr}(f_i, D_{2j})) = \text{cr}(\widetilde{C}_i', \widetilde{D}) \geq \text{mincr}'(C_i', D),$$

proving the last inequality in (76.45). ∎

Notes. Related is the following *homotopic edge-disjoint paths problem*:

(76.48) given: a planar graph $G = (V, E)$, a subcollection $F_1, \ldots, F_p$ of the faces of G (including the unbounded face), curves $C_1, \ldots, C_k$ in $T := \mathbb{R}^2 \setminus (F_1 \cup \cdots \cup F_p)$, with end points in vertices of G on the boundary of T,
find: edge-disjoint walks $P_1, \ldots, P_k$, such that P_i traverses any edge at most once and is homotopic to C_i in T ($i = 1, \ldots, k$).

In this context, the faces $F_1, \ldots, F_p$ are called the *holes*.

Clearly, the *homotopic cut condition* (76.41) is a necessary condition for the feasibility of (76.48), while Figure 70.3 shows that it is generally not sufficient. By Corollary 76.1d, it is equivalent to the existence of a *fractional* solution of (76.48).

We can add the following *Euler condition* (or *local Euler condition*):

(76.49) for each vertex $v \in V$, the degree of v in G has the same parity as the number of times v is end point of the C_i (counting for 2 if C_i begins and ends at v).

By the Okamura-Seymour theorem, if $p = 1$ the homotopic cut and local Euler conditions are sufficient for the feasibility of (76.48). This was extended to $p = 2$ by van Hoesel and Schrijver [1990]:

(76.50) if $p = 2$ and the local Euler condition (76.49) holds, then the homotopic edge-disjoint paths problem (76.48) has a solution if and only if the homotopic cut condition (76.41) holds.

It implies that if $p = 2$, we can take the flows in Corollary 76.1d half-integer.

(76.50) cannot be extended to $p = 3$, as is shown by Figure 76.5. In fact, Kaufmann and Maley [1993] showed that it is NP-complete to solve the homotopic edge-disjoint paths problem even if the local Euler condition (76.49) holds and the graph is a grid graph (with as holes all faces enclosed by more than four edges).

We can consider a stronger parity condition, the *global Euler condition*:

(76.51) $\text{cr}(G, D) \equiv \sum_{i=1}^{k} \text{mincr}(C_i, D) \pmod 2$ for each curve D in $T \setminus V$ with end points on $\text{bd}(T)$ and having no touchings with G.

Kaufmann and Mehlhorn [1992] showed that if G is a grid graph and the holes are those faces enclosed by more than four edges, and if the global Euler condition holds, then the homotopic edge-disjoint paths problem has a solution if and only if

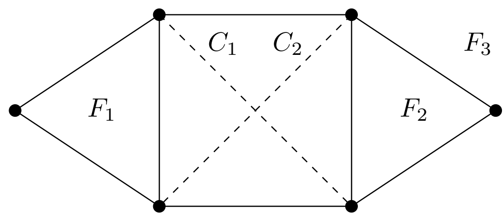

Figure 76.5
This graph G with curves C_1 and C_2 satisfies the cut condition (76.41) (as there is a fractional solution) and the (local) Euler condition, but G has no edge-disjoint walks $P_1 \sim C_1$ and $P_2 \sim C_2$ (in $\mathbb{R}^2 \setminus (F_1 \cup F_2 \cup F_3)$).

the homotopic cut condition holds. Kaufmann and Mehlhorn also gave an $O(n^2)$-time algorithm to find the paths. This was improved to a linear-time algorithm by Kaufmann [1987] and Kaufmann and Mehlhorn [1994].

Other types of grids, like the hexagonal and the octo-square grid, were considered by Kaufmann [1987]. A generalization to 'straight-line planar graphs' was given by Schrijver [1991d]. A *straight-line planar graph* is a planar graph G such that each edge is a straight line segment, where $F_1, \ldots, F_p$ are such that for each edge e of G and each vertex v on e, when extending the line segment forming e slightly at v we arrive either in another edge of G or in one of the faces F_i. In this case, if the global Euler condition holds, then the homotopic edge-disjoint paths problem has a solution if and only if the homotopic cut condition holds. Moreover, the problem is solvable in polynomial time in this case.

76.7. Vertex-disjoint paths and circuits of prescribed homotopies

76.7a. Vertex-disjoint circuits of prescribed homotopies

As for the vertex-disjoint analogue of the results studied above, the existence of vertex-disjoint circuits of prescribed homotopies in a graph on a compact surface can be fully characterized.

Let $G = (V, E)$ be a graph embedded in a compact surface S and let $C_1, \ldots, C_k$ be pairwise disjoint simple closed curves on S. We say that a closed curve D on a surface S is *doubly odd* (with respect to G, $C_1, \ldots, C_k$), if D is the concatenation of two closed curves D_1 and D_2, with common end point not on G, such that

(76.52) $$\operatorname{cr}(G, D_j) \not\equiv \sum_{i=1}^{k} \operatorname{mincr}(C_i, D_j) \pmod 2 \text{ for } j = 1, 2.$$

Then the following was shown in Schrijver [1991b] (conjectured by L. Lovász and P.D. Seymour):

Theorem 76.2. *There exist disjoint circuits $C'_1, \ldots, C'_k$ in G where C'_i is freely homotopic to C_i $(i = 1, \ldots, k)$ if and only if for each closed curve D on S one has*

(76.53) $$\mathrm{cr}(G,D) \geq \sum_{i=1}^{k} \mathrm{mincr}(C_i, D),$$

with strict inequality if D is doubly odd.

We only show necessity of the condition. To that end, we can assume that $C_1, \ldots, C_k$ are disjoint circuits in G. Then the inequality follows from

(76.54) $$\mathrm{cr}(G,D) \geq \sum_{i=1}^{k} \mathrm{cr}(C_i, D) \geq \sum_{i=1}^{k} \mathrm{mincr}(C_i, D).$$

Moreover, if D is doubly odd, let D_1 and D_2 be as above. Then:

(76.55) $$\begin{aligned}\mathrm{cr}(G,D) = \mathrm{cr}(G,D_1) + \mathrm{cr}(G,D_2) &> \sum_{i=1}^{k} (\mathrm{cr}'(C_i, D_1) + \mathrm{cr}'(C_i, D_2)) \\ = \sum_{i=1}^{k} \mathrm{cr}'(C_i, D) &\geq \sum_{i=1}^{k} \mathrm{mincr}(C_i, D).\end{aligned}$$

Here $\mathrm{cr}'(C,D)$ counts the number of crossing (and not touchings) of C and D. The strict inequality holds as

(76.56) $$\mathrm{cr}(G,D_j) \not\equiv \sum_{i=1}^{k} \mathrm{mincr}(C_i, D_j) \equiv \sum_{i=1}^{k} \mathrm{cr}'(C_i, D_j) \pmod 2$$

for $j = 1, 2$.

For the proof of sufficiency, based on solving a system of linear inequalities in integers, we refer to Schrijver [1991b]. The proof also implies a polynomial-time algorithm to find disjoint circuits as required in Theorem 76.2.

For the torus, the condition in Theorem 76.2 on the strictness of the inequality is superfluous, and the characterization can be formulated as:

(76.57) Let G be a graph embedded in the torus T, and let C be a simple closed curve on T. Then G contains k disjoint circuits each freely homotopic to C if and only if

$$\mathrm{cr}(G,D) \geq k \cdot \mathrm{mincr}(C,D)$$

for each closed curve D on T.

This was extended to directed graphs by Seymour [1991] (including polynomial-time solvability). A shorter proof of this, together with an extension to the Klein bottle, was given by Ding, Schrijver, and Seymour [1993]. A survey is given in Schrijver [1992].

76.7b. Vertex-disjoint homotopic paths in planar graphs with holes

In a similar way one can prove (or derive from Theorem 76.2 as in the proof of Corollary 76.1d for the fractional edge-disjoint case) results on vertex-disjoint homotopic paths in a planar graph with holes.

Consider the following *disjoint homotopic paths problem*:

(76.58) given: A planar graph $G = (V, E)$, faces $F_1, \ldots, F_p$ of G, including the unbounded face, disjoint curves $C_1, \ldots, C_k$ in $T := \mathbb{R}^2 \setminus (F_1 \cup \cdots \cup F_p)$, each with end points in vertices of G on the boundary of T,
find: disjoint paths $P_1, \ldots, P_k$ in G, where P_i is homotopic to C_i in T $(i = 1, \ldots, k)$.

Frank and Schrijver [1990] and Schrijver [1991c] gave polynomial-time algorithms for this problem, and gave the following characterization (the first paper gives an algorithm using the ellipsoid method, the second paper a combinatorial algorithm):

Theorem 76.3. *Problem* (76.58) *has a solution if and only if for each curve D in T with end points on* $\mathrm{bd}(T)$ *we have*

(76.59) $$\mathrm{cr}(G, D) \geq \sum_{i=1}^{k} \mathrm{mincr}(C_i, D),$$

and for each doubly odd closed curve D in T traversing no fixed point of any C_i we have

(76.60) $$\mathrm{cr}(G, D) > \sum_{i=1}^{k} \mathrm{mincr}(C_i, D).$$

Here a point p is called a *fixed point of* C if each curve homotopic to C traverses p. (In particular, the ends points of C are fixed points of C.)

Figure 76.6 (due to L. Lovász, cf. Robertson and Seymour [1986]) shows that condition (76.60) cannot be deleted in Theorem 76.3.

Theorem 76.3 was proved by Cole and Siegel [1984] for the special case where G is a grid graph (a subgraph of the rectangular grid), and the F_i are precisely the faces that are not surrounded by exactly four edges of the grid, and the boundary of each face F_i is a rectangle. In this case, condition (76.60) is superfluous. Cole and Siegel [1984] also gave a polynomial-time ($O(n \log n)$) algorithm for this case (answering a question of Pinter [1983]), using an oracle to test homotopy of curves. A polynomial-time algorithm for such graphs, not using a homotopy testing oracle, was given by Leiserson and Maley [1985]. Maley [1987] gave an $O(n^2 \log n)$-time algorithm (where the solution has the additional property that each of the paths found is shortest among all possible solutions), while Maley [1996] gave an $O(n \log n)$-time algorithm to test routability (not constructing the solution), under some mild conditions on the routing rules and the input layout.

Theorem 76.3 and the polynomial-time solvability of (76.58) was proved for $p \leq 2$ by Robertson and Seymour [1986], where again condition (76.60) is superfluous. (A linear-time algorithm for $p = 2$ was given by Ripphausen-Lipa, Wagner, and Weihe [1993a], if at least one of the curves C_i connects F_1 and F_2.) A short proof for the case $p = 2$ was given by Frank [1990c], which also extends to the directed case, implying a result of Seymour [1991].

The polynomial-time solvability of (76.58) implies the following for *nonhomotopic* disjoint paths (Schrijver [1991c]):

(76.61) for each fixed p, the vertex-disjoint paths problem is polynomial-time solvable for planar graphs if the terminals can be covered by the boundaries of at most p faces.

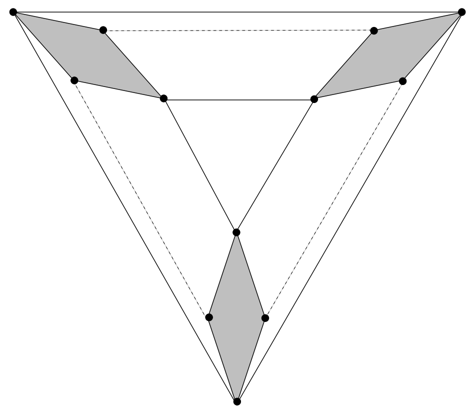

Figure 76.6
The three holes are indicated by grey regions, and the curves by dashed lines. We assume that the graph is embedded in the 2-sphere, such that there is no unbounded face.
The cut condition (76.59) holds, as there is a fractional solution, but no vertex-disjoint paths homotopic to the given curves exist.

(This was conjectured by Robertson and Seymour [1986], who proved it for $p \leq 2$ (see Section 74.4c for $p = 1$). For $p \leq 2$, Suzuki, Akama, and Nishizeki [1988a, 1988b,1988c,1990] gave an $O(n \log n)$-time algorithm, improved to linear-time by Ripphausen-Lipa, Wagner, and Weihe [1993a,1993b]. (The algorithm of Suzuki, Akama, Nishizeki is linear-time if each net is spanned by F_1 or by F_2.) For $p = 3$, a linear-time algorithm if each net is spanned by F_1, F_2, or F_3 was announced by H. Suzuki, T. Kumagai, and T. Nishizeki (1993; cf. Ripphausen-Lipa, Wagner, and Weihe [1995]).)

The idea of proof of (76.61) is that for each net r we choose a curve C_r connecting the points in r such that the C_r are disjoint, and next try to find paths as in (76.58); it can be proved that we need to consider only a polynomially bounded number of homotopy classes of curves C_r (for fixed p), which gives the required result.

In Schrijver [1993] this was extended, by similar methods, to the directed case:

(76.62) for each fixed p, the disjoint paths problem is polynomial-time solvable for directed planar graphs if the terminals can be covered by the boundaries of at most p faces.

This remains the case if we prescribe for each net (s_i, t_i) a subset A_i of the arc set that path P_i is allowed to use.

For a sketch of the method for (76.58), see Schrijver [1990b].

Robertson and Seymour [1995] proved that if the number of terminals is fixed, the vertex-disjoint paths problem in undirected graphs is $O(n^3)$-time solvable, also for nonplanar graphs. If moreover the graph is planar, Reed, Robertson, Schrijver, and Seymour [1993] gave a *linear*-time algorithm. This connects to the results described in Section 70.13a.

76.7c. Disjoint trees

The polynomial-time solvability of finding paths (76.58) can be generalized to disjoint trees (Schrijver [1991c]). The following problem is solvable in polynomial time:

(76.63) given: a planar graph G, faces $F_1, \ldots, F_p$ of G (including the unbounded face), curves $C_{1,1}, \ldots, C_{1,t_1}, \ldots, C_{k,1}, \ldots, C_{k,t_k}$ in the space $S := \mathbb{R}^2 \setminus (F_1 \cup \cdots \cup F_p)$, with end points in vertices of G on $\mathrm{bd}(S)$, such that for each $i = 1, \ldots, k$, $C_{i,1}, \ldots, C_{i,t_i}$ have the same starting vertex;
find: disjoint subtrees $T_1, \ldots, T_k$ of G such that for each $i = 1, \ldots, k$ and $j = 1, \ldots, t_i$, T_i contains a path homotopic to $C_{i,j}$ in S.

Again, by enumerating homotopy classes, it can be derived that, for each fixed p, the problem

(76.64) given: a graph $G = (V, E)$ and disjoint subsets $W_1, \ldots, W_k$ of V;
find: disjoint subtrees $T_1, \ldots, T_k$ of G such that T_i spans W_i for $i = 1, \ldots, k$,

is polynomial-time solvable if G is planar and $W_1, \ldots, W_k$ can be covered by the boundaries of at most p faces of G. (For $p \leq 2$, Suzuki, Akama, and Nishizeki [1988a, 1988b,1988c,1990] gave an $O(n \log n)$-time algorithm, improved to linear-time by Ripphausen-Lipa, Wagner, and Weihe [1993a,1993b].)

Robertson and Seymour [1995] showed that for each fixed p, (76.64) is $O(n^3)$-time solvable for any graph if $|W_1 \cup \cdots \cup W_k| \leq p$. If moreover the graph is planar, Reed, Robertson, Schrijver, and Seymour [1993] gave a *linear*-time algorithm.

For minimum-length homotopic routing in grid graphs, see Ho, Suzuki, and Sarrafzadeh [1993]. Surveys of homotopic routing methods are given by Schrijver [1990b,1994b], and of applications of polyhedral combinatorics to multiflows on surfaces by Schrijver [1990a]. 'Gridless' homotopic routing (that is, routing in the plane (not in a graph), observing mutual distances between curves) was studied by Tompa [1981] and Maley [1988].

Part VIII

Hypergraphs

Part VIII: Hypergraphs

Hypergraphs form a framework in which many of the min-max relations discussed before can be formulated. This is not to say that they all can be *derived* from general hypergraph theory. Rather, hypergraph theory yields relations between different min-max relations, for instance through the blocking and antiblocking relations of hypergraphs and of polyhedra. Moreover, certain hereditary min-max relations can be characterized by equivalent but weaker conditions. This can be helpful in proving min-max relations for special classes of hypergraphs.

The material in this part is grouped by the hypergraph generalizations of four notions that also played a central role in the earlier parts on graphs: matching, vertex cover, edge cover, and stable set. Among the landmarks of this part are theorems of Lehman on minimally nonideal hypergraphs and of Seymour characterizing binary Mengerian hypergraphs.

Chapters:

Chapter 77

Packing and blocking in hypergraphs: elementary notions

Packing in hypergraphs asks for a maximum number of disjoint edges. *Blocking* concerns the minimum number of vertices intersecting each edge. In this chapter we give basic concepts of hypergraphs, in particular those related to packing and blocking.

77.1. Elementary hypergraph terminology and notation

We start with some elementary definitions and notation on hypergraphs. A *hypergraph*[1] is a pair $H = (V, \mathcal{E})$, where V is a finite set and $\mathcal{E}$ is a family of subsets of V. Any element of V is called a *vertex* of H and any set in $\mathcal{E}$ an *edge* of H. We sometimes denote the vertex set and the edge set of H by VH and EH respectively. In our discussions, we can assume without loss of generality that $\mathcal{E}$ is a collection of subsets (rather than a family, with multiplicities).

Graphs are special cases of hypergraphs: they are the hypergraphs that have all its edges of size 2.

The $\mathcal{E} \times V$ *incidence matrix* of H is the $\mathcal{E} \times V$ matrix M with $M_{F,v} = 1$ if $v \in F$ and $M_{F,v} = 0$ if $v \notin F$ (for $v \in V$, $F \in \mathcal{E}$). For most of our purposes, studying a hypergraph is equivalent to studying its incidence matrix. Any result on hypergraphs is simultaneously a result on $0, 1$ matrices, and conversely. We will go back and forth between both interpretations and often choose the most appropriate one.

The *dual hypergraph* H^* of a hypergraph $H = (V, \mathcal{E})$ is the hypergraph with vertex set $\mathcal{E}$ and edges all sets $\{E \in \mathcal{E} \mid v \in E\}$ for $v \in V$. So the incidence matrix of H^* is the transpose of the incidence matrix of H.

For any hypergraph $H = (V, \mathcal{E})$ we denote

$$r_{\min}(H) := \min\{|E| \bigm| E \in \mathcal{E}\} \text{ and } r_{\max}(H) := \max\{|E| \bigm| E \in \mathcal{E}\}. \tag{77.1}$$

[1] Berge [1996] said that the name 'hypergraph' was invented in 1969 by J.-M. Pla, after earlier attempts to call it 'graphoid' (e.g. Berge [1969]).

77.2. Deletion, restriction, and contraction

We describe two operations on a hypergraph $H = (V, \mathcal{E})$, deletion and contraction. Let $v \in V$, and define:

(77.2) $$\mathcal{E} \setminus v := \{E \in \mathcal{E} \mid v \notin E\}, \quad H \setminus v := (V \setminus \{v\}, \mathcal{E} \setminus v),$$
$$\mathcal{E}/v := \{E \setminus \{v\} \mid E \in \mathcal{E}\}, \quad H/v := (V \setminus \{v\}, \mathcal{E}/v).$$

Replacing H by $H \setminus v$ is called *deleting* v and replacing H by H/v is called *contracting* v. We say that H' is a *restriction* of H if it arises by a series of deletions, and a *contraction* of H if it arises by a series of contractions. The *restriction to* $U \subseteq V$ is $H \setminus (V \setminus U)$.

Deletions and contractions commute in the ways one may expect: for distinct $u, v \in V$ one has

(77.3) $(H/u)/v = (H/v)/u$, $(H \setminus u) \setminus v = (H \setminus v) \setminus u$, and $(H/u) \setminus v = (H \setminus v)/u$.

Deletion of an edge E means replacing $\mathcal{E}$ by $\mathcal{E} \setminus \{E\}$. A hypergraph H' is called a *minor* of H, if H' arises from H by a series of deletions and contractions of vertices, and deletions of edges that are not inclusionwise minimal edges.

77.3. Duplication and parallelization

Let $H = (V, \mathcal{E})$ be a hypergraph and let $v \in V$. *Duplicating* v means extending V by a new vertex, v' say, and replacing $\mathcal{E}$ by

(77.4) $$\mathcal{E} \cup \{(E \setminus \{v\}) \cup \{v'\} \mid v \in E \in \mathcal{E}\}.$$

A hypergraph obtained from H by a sequence of deletions and duplications of vertices, is called a *parallelization* of H. If $w : V \to \mathbb{Z}_+$, we denote by H^w the result of deleting any vertex v with $w(v) = 0$, and duplicating any vertex v $w(v) - 1$ times, if $w(v) \geq 2$. So restrictions correspond to functions $w : V \to \{0, 1\}$. In a certain sense, contractions correspond to functions $w : V \to \{1, \infty\}$.

77.4. Clutters

For any hypergraph $H = (V, \mathcal{E})$, define

(77.5) $$H^{\min} := (V, \{F \in \mathcal{E} \mid \text{there is no } E \in \mathcal{E} \text{ with } E \subset F\}) \text{ and}$$
$$H^{\uparrow} := (V, \{F \subseteq V \mid \text{there is an } E \in \mathcal{E} \text{ with } E \subseteq F\}).$$

A hypergraph $H = (V, \mathcal{E})$ is called a *clutter* if no two sets in $\mathcal{E}$ are contained in each other[2]. So for any hypergraph, $H^{\min}$ is a clutter.

[2] The term 'clutter' was introduced by Edmonds and Fulkerson [1970].

77.5. Packing and blocking

Let $H = (V, \mathcal{E})$ be a hypergraph. The following notions generalize the corresponding notions defined for graphs.

A *vertex cover* is a set of vertices intersecting each edge of H. A *matching* is a collection of pairwise disjoint edges of H. Define

(77.6) $\tau(H) :=$ the minimum size of a vertex cover in H,
$\nu(H) :=$ the maximum size of a matching in H.

Determining these numbers is NP-complete, since determining $\tau(G)$ and (the stability number) $\alpha(G)$ of a graph $G = (V, E)$ is NP-complete (cf. Theorem 64.1), and since $\alpha(G) = \nu(G^*)$.

We should note that replacing H by $H^{\min}$ or $H^{\uparrow}$ does not change the value of $\tau(H)$ or $\nu(H)$. So $\tau(H) = \tau(H^{\uparrow}) = \tau(H^{\min})$ and $\nu(H) = \nu(H^{\uparrow}) = \nu(H^{\min})$.

There is the following straightforward inequality:

(77.7) $\nu(H) \leq \tau(H)$.

In the previous parts we met several classes of hypergraphs where equality holds in (77.7), and the purpose of this and the coming chapters is to treat them in a unifying and clarifying framework.

77.6. The blocker

For any hypergraph $H = (V, \mathcal{E})$, the *blocking hypergraph*, or *blocker*, of H is the hypergraph $b(H) = (V, \mathcal{B})$ where $\mathcal{B}$ is the collection of all inclusionwise minimal vertex covers of H. So $b(H)$ is a clutter and

(77.8) $\tau(H) = r_{\min}(b(H))$.

Moreover, $b(H)^{\uparrow}$ is the collection of vertex covers.

The following important duality relation was noticed by Lawler [1966] (also by Edmonds and Fulkerson [1970]):

Theorem 77.1. *For any hypergraph $H = (V, \mathcal{E})$, $b(b(H)) = H^{\min}$. In particular, if H is a clutter, then $b(b(H)) = H$.*

Proof. It suffices to show $b(b(H))^{\uparrow} = H^{\uparrow}$. If $U \in H^{\uparrow}$, then U intersects each set in $b(H)$. Hence U is a vertex cover of $b(H)$, and so $U \in b(b(H))^{\uparrow}$.

Conversely, if $U \notin H^{\uparrow}$, then $V \setminus U$ is a vertex cover of H. So $V \setminus U \in b(H)$. Hence U is not a vertex cover of $b(H)$. So $U \notin b(b(H))^{\uparrow}$. ∎

One may check that the operations of deletion and contraction interchange when passing to the blocker. More precisely, for any vertex v of a hypergraph H one has:

(77.9) $b(H/v) = b(H) \setminus v$ and $b(H \setminus v) = (b(H)/v)^{\min}$.

77.7. Fractional matchings and vertex covers

Let $H = (V, \mathcal{E})$ be a hypergraph. A *fractional vertex cover* is a function $x : V \to \mathbb{R}_+$ satisfying

(77.10) $$\sum_{v \in F} x_v \geq 1 \text{ for each } F \in \mathcal{E}.$$

A *fractional matching* is a function $y : \mathcal{E} \to \mathbb{R}_+$ satisfying

(77.11) $$\sum_{F \ni v} y_F \leq 1 \text{ for each } v \in V.$$

(Here and below, F ranges over the edges of H.) Let $\tau^*(H)$ denote the minimum size of a fractional vertex cover and let $\nu^*(H)$ denote the maximum size of a fractional matching (where the *size* of a vector is the sum of its components).

We can describe $\tau^*(H)$ and $\nu^*(H)$ by linear programs[3]:

(77.12) $$\tau^*(H) = \min\{\mathbf{1}^{\mathsf{T}} x \mid x \in \mathbb{R}^V_+, Mx \geq \mathbf{1}\},$$

where M is the $\mathcal{E} \times V$ incidence matrix of H. Similarly,

(77.13) $$\nu^*(H) = \max\{y^{\mathsf{T}}\mathbf{1} \mid y \in \mathbb{R}^{\mathcal{E}}_+, y^{\mathsf{T}} M \leq \mathbf{1}^{\mathsf{T}}\}.$$

As these linear programs are each others dual, this gives:

(77.14) $$\nu^*(H) = \tau^*(H).$$

77.8. k-matchings and k-vertex covers

There is an alternative interpretation of the parameters $\nu^*(H)$ and $\tau^*(H)$, in terms of 'k-vertex covers' and 'k-matchings'.

A *k-vertex cover* is a function $x : V \to \mathbb{Z}_+$ such that

(77.15) $$\sum_{v \in F} x_v \geq k \text{ for each } F \in \mathcal{F}.$$

Let $\tau_k(H)$ denote the minimum size of a k-vertex cover. Since (minimal) 1-vertex covers are precisely the incidence vectors of the vertex covers, we have $\tau_1(H) = \tau(H)$.

A *k-matching* is a function $y : \mathcal{E} \to \mathbb{Z}_+$ such that

(77.16) $$\sum_{F \ni v} y_F \leq k \text{ for each } v \in V.$$

Let $\nu_k(H)$ denote the maximum size of a k-matching in H. As 1-matchings are the incidence vectors of the matchings, we have $\nu_1(H) = \nu(H)$.

Then for any $k \in \mathbb{Z}_+$:

[3] $\mathbf{1}$ stands for all-one column vectors of appropriate sizes.

(77.17) $\nu_k(H) \leq \tau_k(H)$,

since for any k-vertex cover x and any k-matching y:

(77.18) $$\sum_F y_F \leq \frac{1}{k}\sum_F y_F \sum_{v\in F} x_v = \frac{1}{k}\sum_v x_v \sum_{F\ni v} y_F \leq \sum_v x_v.$$

More extensively, one has for each $k \geq 1$:

(77.19) $$\nu(H) \leq \frac{\nu_k(H)}{k} \leq \nu^*(H) = \tau^*(H) \leq \frac{\tau_k(H)}{k} \leq \tau(H).$$

The first two inequalities follow from the facts that if y is a 1-matching, then $k \cdot y$ is a k-matching, and that if y is a k-matching, then $k^{-1} \cdot y$ is a fractional matching. The last two inequalities are shown similarly.

We will investigate classes of hypergraphs where some or all of the inequalities in (77.19) are satisfied with equality. Obviously, if $\nu(H) = \tau(H)$, then all terms in (77.19) are equal.

$\nu^*(H)$ can be described in terms of the $\nu_k(H)$ (Lovász [1974]):

(77.20) $$\nu^*(H) = \max_k \frac{\nu_k(H)}{k} = \lim_{k\to\infty} \frac{\nu_k(H)}{k}.$$

Here the left-hand side equality holds as the maximum in (77.13) is attained by a rational optimum solution y. If k is the common denominator of the components of y, then $k \cdot y$ is a k-matching, and hence $k \cdot \nu^*(H) \leq \nu_k(H)$; so equality follows by (77.19).

The right-hand side equality follows from Fekete's lemma (Theorem 2.2), using the fact that for all $k, l \geq 1$:

(77.21) $\nu_{k+l}(H) \geq \nu_k(H) + \nu_l(H)$,

since if y' and y'' are a k- and an l-matching respectively, then $y' + y''$ is a $k + l$-matching.

Similarly we have:

(77.22) $$\tau^*(H) = \min_k \frac{\tau_k(H)}{k} = \lim_{k\to\infty} \frac{\tau_k(H)}{k},$$

using (77.12) and the fact that for all $k, l \geq 1$:

(77.23) $\tau_{k+l}(H) \leq \tau_k(H) + \tau_l(H)$.

77.9. Further results and notes

77.9a. Bottleneck extrema

Edmonds and Fulkerson [1970] showed that for any clutter $H = (V, \mathcal{E})$, its blocker $(V, \mathcal{B})$ is the unique clutter with the property that for each $f : V \to \mathbb{R}$ the following equality holds:

(77.24) $$\min_{E\in\mathcal{E}} \max_{x\in E} f(x) = \max_{B\in\mathcal{B}} \min_{y\in B} f(y).$$

(These extrema are called *bottleneck extrema.*) To see that the collection $\mathcal{B}$ of minimal vertex covers of H has this property, let $E \in \mathcal{E}$ and $x \in E$ attain the first minimum and first maximum. Then each $F \in \mathcal{E}$ contains a vertex z with $f(z) \geq f(x)$. Hence $\{z \in V \mid f(z) \geq f(x)\}$ contains a set B in $\mathcal{B}$. So $f(x) \leq \min_{y \in B} f(y)$. This shows $\leq$ in (77.24). Moreover, for any $B \in \mathcal{B}$, as E intersects B, we have $f(x) \geq \min_{y \in B} f(y)$. This gives $\geq$ in (77.24).

To see that this property characterizes the blocker, let $\mathcal{B}$ be any clutter satisfying (77.24) for each $f : V \to \mathbb{R}$. Then for each $B \in \mathcal{B}$ and $E \in \mathcal{E}$ we have $B \cap E \neq \emptyset$, since otherwise we can define f such that $f(x) < 0$ for all $x \in E$ and $f(y) > 0$ for each $y \in B$, giving $<$ in (77.24), a contradiction.

Finally, each vertex cover B of $\mathcal{E}$ contains a set in $\mathcal{B}$. If not, we can define f such that $f(x) > 0$ for each $x \in B$ and $f(y) < 0$ for each $y \in V \setminus B$. Then we have $>$ in (77.24), again a contradiction.

77.9b. The ratio of τ and τ^*

The following theorem of Johnson [1974a] and Lovász [1975c] bounds $\tau(H)$ in terms of $\tau^*(H)$ and the maximum degree of H. (The *degree* of a vertex v is the number of edges containing v. The *maximum degree* of H is the maximum of the degrees of its vertices.) The method is similar to that of Theorem 64.13.

Theorem 77.2. *For any hypergraph $H = (V, \mathcal{E})$ of maximum degree d one has:*

(77.25) $$\tau(H) \leq (1 + \ln d)\tau^*(H).$$

Proof. Iteratively choose vertices $v_1, v_2, \ldots$, where, for each $i = 1, 2, \ldots$, vertex v_i is chosen such that it is contained in a maximum number of edges not intersecting $\{v_1, \ldots, v_{i-1}\}$. We stop if the set $\{v_1, \ldots, v_k\}$ of chosen vertices is a vertex cover. So $\tau(H) \leq k$.

For each $i = 1, \ldots, k$, let d_i be the number of edges containing v_i but not intersecting $\{v_1, \ldots, v_{i-1}\}$. For each $F \in \mathcal{E}$, define

(77.26) $$y_F := \frac{1}{d_i},$$

where i is the smallest index with $v_i \in F$. Then

(77.27) $$\sum_{F \in \mathcal{E}} y_F = \sum_{i=1}^{k} d_i \frac{1}{d_i} = k,$$

and hence

(77.28) $$\tau(H) \leq \sum_{F \in \mathcal{E}} y_F.$$

We next show that $(1 + \ln d)^{-1} \cdot y$ is a fractional matching. To this end, consider any vertex v. Let $F_1, \ldots, F_t$ be the edges of H containing v, in the order by which they are intersected by $v_1, \ldots, v_k$. Then for each $j = 1, \ldots, t$, we have

(77.29) $$y_{F_j} \leq \frac{1}{t - j + 1}.$$

For let i be the smallest index with $v_i \in F_j$. So $y_{F_j} = 1/d_i$. Moreover, $d_i \geq t-j+1$, since v is contained in at least $t-j+1$ edges not intersected by $\{v_1, \ldots, v_{i-1}\}$. This proves (77.29).

Hence

(77.30) $$\sum_{j=1}^{t} y_{F_j} \leq \sum_{j=1}^{t} \frac{1}{t-j+1} = \sum_{j=1}^{t} \frac{1}{j} \leq 1 + \ln t \leq 1 + \ln d.$$

As this holds for each vertex v, $(1+\ln d)^{-1} \cdot y$ is a fractional matching.

This implies

(77.31) $$\tau(H) \leq \sum_{F \in \mathcal{E}} y_F \leq (1+\ln d)\nu^*(H) = (1+\ln d)\tau^*(H),$$

as required. ∎

(Related work can be found in Balas [1984].)

The proof shows that one can find a vertex cover of size less than $(1+\ln d)\tau^*$, by iteratively selecting a vertex of maximum degree and deleting it.

The proof method of Theorem 67.17 gives that for any hypergraph $H = (V, \mathcal{E})$:

(77.32) $$\tau^*(H) = \lim_{k \to \infty} \sqrt[k]{\tau(H^k)},$$

where H^k is the hypergraph on V^k with edges all sets $E_1 \times \cdots \times E_k$ with $E_1, \ldots, E_k \in \mathcal{E}$.

77.9c. Further notes

Füredi, Kahn, and Seymour [1993] showed that each hypergraph $H = (V, \mathcal{E})$ has a matching $\mathcal{M} \subseteq \mathcal{E}$ such that

(77.33) $$\sum_{F \in \mathcal{M}} (|F| - 1 + \frac{1}{|F|}) \geq \nu^*(H).$$

In particular, for any hypergraph H:

(77.34) $$\nu(H) \geq \frac{r_{\max}}{r_{\max}^2 - r_{\max} + 1} \nu^*(H),$$

where $r_{\max} := r_{\max}(H)$ (the maximum edge size of H). (For *uniform* hypergraphs H (that is, all edges of H have the same size), this was proved by Füredi [1981] (confirming a conjecture of L. Lovász (cf. Füredi [1988])).)

Füredi, Kahn, and Seymour [1993] conjecture the following weighted extension of (77.33):

(77.35) (?) For each hypergraph $H = (V, \mathcal{E})$ and each $w : \mathcal{E} \to \mathbb{R}_+$, there exists a matching $\mathcal{M} \subseteq \mathcal{E}$ such that

$$\sum_{F \in \mathcal{M}} \big(|F| - 1 + \frac{1}{|F|}\big) w(F) \geq \nu_w^*(H),$$

where $\nu_w^*(H)$ is the maximum weight $w^\mathsf{T} y$ of a fractional matching $y : \mathcal{E} \to \mathbb{R}_+$. Füredi, Kahn, and Seymour [1993] proved this conjecture for uniform hypergraphs, and also for hypergraphs H with $\nu(H) = 1$.

Related work on the relations between fractional and integer packing and covering was reported by Chvátal [1979], Dobson [1982], Fisher and Wolsey [1982], Aharoni, Erdős, and Linial [1985,1988], Raghavan [1988], Feige [1996,1998], and Slavík [1996,1997].

Lovász [1975b] showed that for each choice of $\nu, \tau \in \mathbb{Z}_+$ and $r \in \mathbb{Q}_+$ satisfying $1 \leq \nu \leq r \leq \tau$ and $r > 1$, there exists a hypergraph H with $\nu(H) = \nu$, $\tau^*(H) = r$, and $\nu(H) = \nu$. Chung, Füredi, Garey, and Graham [1988] showed that for each rational number r, there exists a 3-uniform hypergraph H with $\tau^*(H) \equiv r \pmod 1$. (For each 2-uniform hypergraph (= graph) H, $\tau^*(H)$ belongs to $\frac{1}{2}\mathbb{Z}$ (cf. Section 64.6).)

Saks [1986] studied the behaviour of the parameters τ and ν under taking unions of edges and vertex covers.

The hypergraph analogue of matching augmenting paths in graphs was studied by Edmonds [1962].

Seymour [1977a] gave a forbidden minor characterization of those clutters H that come from an undirected graph $G = (V, E)$ and $s, t \in V$, by taking as edges of H all edge sets of $s - t$ paths. (Related work can be found in Novick and Sebő [1995].)

Determining the vertex cover number $\tau(H)$ of a hypergraph H is equivalent to the set covering problem. In Section 82.6b we give further references for this problem. Determining the matching number $\nu(H)$ of H is equivalent to the vertex packing (equivalently, the set packing) problem. In Section 64.9e we gave further references for this problem.

Connectivity augmentation for hypergraphs was studied by Bang-Jensen and Jackson [1999], Benczúr [1999], Benczúr and Frank [1999], Cheng [1999], and Szigeti [1999].

The problems of finding a maximum-size matching and a minimum-size vertex cover in a hypergraph are equivalent to finding a maximum-size stable set in a graph and a minimum-size edge cover in a hypergraph. For references to general methods for these problems, we refer to Sections 64.9e and 82.6b, respectively.

Extensions of Gallai's theorem (Theorem 19.1) to hypergraphs were given by Tuza [1991], and generalizations of Kőnig's and Hall's theorems to hypergraphs by Aharoni and Haxell [2000] and Aharoni, Berger, and Ziv [2002].

Surveys on packing and covering in hypergraphs were given by Berge [1973b, 1973c,1978a,1979b,1989a], Schrijver [1979b], Füredi [1988], and Cornuéjols [2001].

Chapter 78

Ideal hypergraphs

Ideal hypergraphs are those hypergraphs for which the convex hull of the vertex covers is given by the edge inequalities. They therefore form a class of hypergraphs where polyhedral methods apply. Since the relations of blocking hypergraphs and of blocking polyhedra coincide in this case, the class of ideal hypergraphs is closed under taking blockers.
The class of ideal hypergraphs is also closed under taking minors. A characterization of ideal hypergraphs in terms of forbidden minors is not known, but a theorem of Lehman gives powerful properties of minimally nonideal hypergraphs.

78.1. Ideal hypergraphs

For any hypergraph $H = (V, \mathcal{E})$, let P_H be the set of all fractional vertex covers; that is, P_H is the solution set of

(78.1) (i) $x_v \geq 0$ for $v \in V$,
(ii) $x(F) \geq 1$ for $F \in \mathcal{E}$.

A hypergraph $H = (V, \mathcal{E})$ is called *ideal* if P_H is integer[4]. Obviously, H is ideal $\iff$ $H^{\min}$ is ideal $\iff$ $H^{\uparrow}$ is ideal.

Note that each integer vertex of P_H is a 0,1 vector, and hence the incidence vector of some vertex cover of H. So H is ideal if and only if (78.1) determines the up hull of the incidence vectors of the vertex covers of H. By Theorem 5.19, H is ideal if and only if the convex hull of the incidence vectors of the vertex covers of H is determined by

(78.2) (i) $0 \leq x_v \leq 1$ for $v \in V$,
(ii) $x(F) \geq 1$ for $F \in \mathcal{E}$.

By the theory of blocking polyhedra (cf. Theorem 5.8), H is ideal if and only if each vertex of the polyhedron determined by

[4] Alternatively, such hypergraphs are called *Fulkersonian*, or said to satisfy the *length-width inequality* or the *width-length inequality*, or to have the *max-flow min-cut property*, the $\mathbb{Q}_+$-*max-flow min-cut property*, shortly the *MFMC property* or the $\mathbb{Q}_+$-*MFMC property*. Sakarovitch [1975,1976] used the term *quasi-balanced*.

(78.3) (i) $x_v \geq 0$ for $v \in V$,
(ii) $x(B) \geq 1$ for $B \in b(H)$

is integer — that is, is the incidence vector of an edge of H. This gives the following important theorem of Fulkerson [1970b,1971a]:

Theorem 78.1. *A hypergraph H is ideal $\iff$ its blocker $b(H)$ is ideal.*

Proof. See above. ∎

The class of ideal hypergraphs is also closed under taking minors (Lehman [1965,1979]):

Theorem 78.2. *Any minor of an ideal hypergraph is ideal again.*

Proof. Let $H = (V, \mathcal{E})$ be ideal and let $v \in V$. Choose $x \in P_{H/v}$. Let $\tilde{x} \in \mathbb{R}^V$ be defined by $\tilde{x}_u := x_u$ for $u \in V \setminus \{v\}$ and $\tilde{x}_v := 0$. Then $\tilde{x} \in P_H$. Hence $\tilde{x}$ is a convex combination of integer vectors z in P_H. Each of these vectors z satisfies $z_v = 0$. Hence we obtain x as a convex combination of integer vectors in $P_{H/v}$.

Next choose $x \in P_{H\backslash v}$. Now let $\tilde{x} \in \mathbb{R}^V$ be defined by $\tilde{x}_u := x_u$ for $u \in V \setminus \{v\}$ and $\tilde{x}_v := 1$. Then $\tilde{x} \in P_H$. Hence $\tilde{x}$ is a convex combination of integer vectors z in P_H. Now deleting the vth component from any such z, we obtain an integer vector in $P_{H\backslash v}$. Hence we obtain x as a convex combination of integer vectors in $P_{H\backslash v}$. ∎

78.2. Characterizations of ideal hypergraphs

We will give several characterizations of ideal hypergraphs — albeit not by forbidden minors, since such a characterization is not known.

In the present section we discuss some equivalent properties each characterizing ideality. In Section 78.4, we show Lehman's theorem, which gives properties of minimally nonideal hypergraphs. From this, some further characterizations of ideality will be derived.

The definition of ideal hypergraph can be stated equivalently as:

(78.4) H is ideal if and only if for each $w : V \to \mathbb{R}_+$, the minimum of $w^{\mathsf{T}}x$ over (78.1) is attained by an integer vector x.

As we can restrict ourselves to rational-valued w, and hence to integer-valued w, we have equivalently:

(78.5) H is ideal if and only if for each $w : V \to \mathbb{Z}_+$, the minimum of $w^{\mathsf{T}}x$ over (78.1) is attained by an integer vector x.

We can formulate this in terms of the 'parallelization' H^w (defined in Section 77.3). To this end, it is good to observe that, for any 'weight' function $w : V \to \mathbb{Z}_+$:

(78.6) $\tau(H^w) =$ the minimum weight of a vertex cover of H

and

(78.7) $\nu(H^w) =$ the maximum number t of edges $E_1, \ldots, E_t$ of H such that each $v \in V$ is in at most $w(v)$ of the E_i.

The values of $\tau^*(H^w)$ and $\nu^*(H^w)$ can be described by dual linear programs:

(78.8)
$$\tau^*(H^w) = \min\{w^\mathsf{T} x \mid x \in \mathbb{R}_+^V, Mx \geq \mathbf{1}\}$$
$$= \min\{y^\mathsf{T}\mathbf{1} \mid y \in \mathbb{R}_+^{\mathcal{E}}, y^\mathsf{T} M \leq w^\mathsf{T}\} = \nu^*(H^w),$$

where M is the $\mathcal{E} \times V$ incidence matrix of H. So we have:

(78.9) H is ideal if and only if $\tau^*(H^w) = \tau(H^w)$ for each $w : V \to \mathbb{Z}_+$.

The following further characterizations were found[5]:

Theorem 78.3. *For any hypergraph $H = (V, \mathcal{E})$ the following are equivalent:*

(78.10)
(i) *H is ideal, that is $\tau^*(H') = \tau(H')$ for each parallelization H' of H;*
(ii) *$\tau^*(H')$ is an integer for each parallelization H' of H;*
(iii) *$b(H)$ is ideal;*
(iv) *$\tau^*(b(H)')$ is an integer for each parallelization $b(H)'$ of $b(H)$;*
(v) *P_H and $P_{b(H)}$ form a pair of blocking polyhedra;*
(vi) *$\tau(H^w)\tau(b(H)^l) \leq w^\mathsf{T} l$ for all $w, l : V \to \mathbb{Z}_+$.*

Proof. The implications (i)⇒(ii) and (iii)⇒(iv) are trivial. The equivalences (i) $\iff$ (iii) $\iff$ (v) were shown above.

The implication (ii)⇒(i) is shown as follows[6]. We must show that (ii) implies that each vertex x^* of the polyhedron P_H defined by (78.1) is integer. Suppose not. Choose $v \in V$ with x_v^* not integer. As x^* is a vertex, there is a weight function $w : V \to \mathbb{R}_+$ such that the minimum of $w^\mathsf{T} x$ over P_H is attained uniquely by x^*. By scaling, we can assume that w is integer and that for $\tilde{w} := w + \chi^v$, also the minimum of $\tilde{w}^\mathsf{T} x$ over P_H is attained at x^*. So $w^\mathsf{T} x^*$ and $\tilde{w}^\mathsf{T} x^*$ are integers (by (ii)), and hence $x_v^* = \tilde{w}^\mathsf{T} x^* - w^\mathsf{T} x^*$ is an integer, contradicting our assumption.

This proves (ii)⇒(i) and similarly (iv)⇒(iii). So conditions (i), (ii), (iii), (iv), and (v) are equivalent. We finally consider condition (vi).

Necessity of (vi) can be seen as follows. Choose $w, l : V \to \mathbb{Z}_+$. Let $\alpha := \tau(H^w) = \tau^*(H^w)$ and $\beta := \tau(b(H)^l) = \tau^*(b(H)^l)$. So $w(B) \geq \alpha$ for each edge B of $b(H)$ (= minimal vertex cover of H), and hence $\alpha^{-1} \cdot w(B) \geq 1$

[5] (i)⇔(vi)⇔(iii) was shown by Lehman [1965,1979], (i)⇔(v) by Fulkerson [1970b,1971a], and (i)⇔(ii) and (iii)⇔(iv) by Lovász [1977b].

Lehman called condition (i) the *max-flow min-cut property*, and condition (vi) the *width-length inequality* (motivated by work of Moore and Shannon [1956] who proved this inequality for the width (minimum cut-capacity) and length (shortest path) of a network).

[6] It also follows directly from general polyhedral theory (Theorem 5.18).

for each edge of $b(H)$. So $\alpha^{-1} \cdot w \in P_{b(H)}$. Similarly, $\beta^{-1} \cdot l$ belongs to P_H. As $P_{b(H)}$ is the blocking polyhedron of P_H, we have $(\alpha^{-1} \cdot w)^{\mathsf{T}}(\beta^{-1} \cdot l) \geq 1$, that is $w^{\mathsf{T}} l \geq \alpha\beta$, as required.

To see sufficiency of (vi), suppose that P_H has a noninteger vertex x^*. Then there is a hyperplane separating x^* from the integer vectors in P_H. So there is a $y \in \mathbb{Q}_+^V$ with $y^{\mathsf{T}} x^* < 1$ while $y^{\mathsf{T}} x \geq 1$ for each integer vector x in P_H. Let $\alpha > 0$ and $\beta > 0$ be such that $w := \alpha \cdot y$ and $l := \beta \cdot x^*$ are integer vectors. As $y^{\mathsf{T}} x \geq 1$ for each integer vector x in P_H, we have $w^{\mathsf{T}} x \geq \alpha$ for each integer vector x in P_H, and so $w(B) \geq \alpha$ for each vertex cover B of H; that is $\tau(H^w) \geq \alpha$. Since x^* belongs to P_H, we have that $x^*(F) \geq 1$ for each $F \in \mathcal{E}$, and hence $l(F) \geq \beta$ for each $F \in \mathcal{E}$; that is $\tau(b(H)^l) \geq \beta$. This implies

(78.11) $$\tau(H^w)\tau(b(H)^l) \geq \alpha\beta > \alpha\beta \cdot y^{\mathsf{T}} x^* = w^{\mathsf{T}} l,$$

contradicting (vi). ∎

78.3. Minimally nonideal hypergraphs

A hypergraph $H = (V, \mathcal{E})$ is called *minimally nonideal* if H is nonideal and each proper minor of H is ideal. In particular, H is a clutter.

So being ideal can be characterized by not having a minimally nonideal hypergraph as a minor. Since the class of ideal hypergraphs is closed under taking the blocker, the blocker of any minimally nonideal hypergraph is minimally nonideal again.

There turn out to be infinitely many minimally nonideal hypergraphs. Known examples are[7]:

(78.12)
- (i) for each $n \geq 3$: $J_n :=$ the hypergraph with vertex set $\{1, \ldots, n\}$ and edges $\{2, \ldots, n\}$, $\{1, 2\}, \ldots, \{1, n\}$;
- (ii) the odd circuits C_{2k+1} and their blockers $b(C_{2k+1})$ $(k \geq 1)$;
- (iii) $F_7 :=$ the hypergraph with vertex set the points of the projective plane of order 2, and edges all lines (the *Fano hypergraph*)[8];
- (iv) $\mathcal{O}(K_5) :=$ the hypergraph with vertex set EK_5 and edges all odd circuits of K_5, and its blocker $b(\mathcal{O}(K_5))$ (having edges the complements of the nonempty cuts of K_5);
- (v) the hypergraph with vertex set EK_5 and edges all triangles of K_5, and its blocker;

[7] Examples (i), (ii), (iii) were given by Lehman [1965,1979], example (iv) by Seymour [1977b], examples (v) and (vi) by Cornuéjols and Novick [1994], example (vii) by P.D. Seymour (cf. Ding [1993]), $\mathcal{C}_5^3$ and $\mathcal{C}_7^4$ by Lehman [1965,1979] (they are the blockers of the circuits C_5 and C_7), $\mathcal{C}_8^3$ by Cornuéjols and Novick [1994] and Ding [1993], $\mathcal{C}_9^5$ and $\mathcal{C}_{11}^6$ by Qi [1989], and the other $\mathcal{C}_n^k$ by Cornuéjols and Novick [1994].

[8] Equivalently, $VF_7 = \{1, \ldots, 7\}$ and $EF_7 = \{\{i, i+1, i+3\} \mid i = 1, \ldots, 7\}$, taking addition mod 7.

(vi) the hypergraph with vertex set EK_5 and edges the complements of maximum-size cuts, and its blocker;

(vii) the hypergraph $\mathcal{D}_8$ with vertex set $\{1,\ldots,8\}$ and edges $\{1,2,6\}$, $\{2,3,5\}$, $\{3,4,8\}$, $\{4,5,7\}$, $\{2,5,6\}$, $\{1,6,7\}$, $\{4,7,8\}$, and $\{1,3,8\}$, and its blocker $b(\mathcal{D}_8)$;

(viii) the hypergraphs $\mathcal{C}_5^3$, $\mathcal{C}_8^3$, $\mathcal{C}_{11}^3$, $\mathcal{C}_{14}^3$, $\mathcal{C}_{17}^3$, $\mathcal{C}_7^4$, $\mathcal{C}_{11}^4$, $\mathcal{C}_9^5$, $\mathcal{C}_{11}^6$, $\mathcal{C}_{13}^7$ (where $\mathcal{C}_n^k$ has vertex set VC_n and edges all consecutive k-tuples from VC_n), and their blockers.

Note that $b(F_7) = F_7$ and $b(J_n) = J_n$ for each n. The hypergraphs given in (viii) are all the minimally nonideal hypergraphs of the form $\mathcal{C}_n^k$ with $k \geq 3$. This was proved by Cornuéjols and Novick [1994], who also gave several thousands of other minimally nonideal hypergraphs. A 'catalogue' of minimally nonideal hypergraphs was given by Lütolf and Margot [1998].

Seymour [1981a][9] conjectures that $\mathcal{O}(K_5)$, $b(\mathcal{O}(K_5))$, and F_7 are the only *binary* minimally nonideal hypergraphs (see Chapter 80).

We saw in Section 75.5 that $\mathcal{O}(K_5)$ is the unique minimally nonideal hypergraph among the hypergraphs obtained from a signed graph $G = (V, E, \Sigma)$ by taking EG as vertex set and the circuits C in G with $|C \cap \Sigma|$ odd as edges.

To see that F_7 is nonideal, the vector $x : VF_7 \to \mathbb{R}_+$ defined by $x_v := \frac{1}{3}$ for each $v \in VF_7$, is a fractional vertex cover of size $\frac{7}{3}$, but F_7 has no vertex cover of size $\leq \frac{7}{3}$. Moreover, F_7 is minimally nonideal: if we contract any vertex $v \in VF_7$, we obtain the hypergraph Q_6 isomorphic to the hypergraph $\mathcal{O}(K_4)$ (the hypergraph with vertex set EK_4 and edges all triangles). As this is a proper minor of $\mathcal{O}(K_5)$, it is ideal. Since $b(F_7) = F_7$, also deleting any vertex of F_7 results in an ideal hypergraph.

78.4. Properties of minimally nonideal hypergraphs: Lehman's theorem

A full list of minimally nonideal hypergraphs is not known, but the following theorems of Lehman [1990] show that minimally nonideal hypergraphs different from J_n ($n \geq 3$) are remarkably regular (shorter proofs were given by Padberg [1993] and Seymour [1990b] — we follow the latter):

Theorem 78.4. *Let $H = (V, \mathcal{E})$ be a minimally nonideal hypergraph with $H \neq J_n$ for $n := |V|$. Then P_H has a unique noninteger vertex, namely $r^{-1} \cdot \mathbf{1}$, where $r := r_{\min}(H)$. Moreover, H has precisely n edges of size r, and each vertex of H is contained in precisely r of them.*

Proof. Let x be a noninteger vertex of P_H. Then

(78.13) $\quad 0 < x_v < 1$ for each $v \in V$.

[9] Seymour [1981a] said that this conjecture was presented in Seymour [1977b], but the latter paper presents the three hypergraphs only as minimally nonideal hypergraphs.

For suppose first that $x_v = 0$. Then $x|V \setminus \{v\}$ is a noninteger vertex of $P_{H/v}$, contradicting the minimality of H. Similarly, if $x_v = 1$, then $x|V \setminus \{v\}$ is a noninteger vertex of $P_{H \setminus v}$, again contradicting the minimality of H. This proves (78.13).

Let $\mathcal{F}$ be the collection of sets $F \in \mathcal{E}$ having equality for x in (78.1)(ii). As x is a vertex, $\mathcal{F}$ has dimension n. (Here and below, the *dimension* of a collection of subsets of V, is the dimension of the collection of incidence vectors of these subsets.) Let $\mathcal{F}_v$ and $\mathcal{F} \setminus v$ be the collections of sets in $\mathcal{F}$ containing v and not containing v, respectively. Then

(78.14) (i) For each $F \in \mathcal{F}$ and $v \in V \setminus F$: $\dim(\mathcal{F} \setminus v) \leq n - |F|$;
(ii) for each $F \in \mathcal{F}$ and $v \in F$: $\dim(\mathcal{F}_v) \leq n - |F| + 1$.

To see (i), choose $F \in \mathcal{F}$ and $v \in V \setminus F$. Since $H \setminus v$ is ideal, $x|V \setminus \{v\}$ is a convex combination of incidence vectors of vertex covers of $H \setminus v$. For each $u \in F$, since $x_u > 0$, there is a vertex cover B_u of $H \setminus v$ having positive scalar in this convex decomposition and with $u \in B_u$. So $B_u \cap F = \{u\}$ (as $x(F) = 1$). Hence the incidence vectors χ^{B_u} for $u \in F$ are linearly independent. This implies that the vectors $\chi^{B_u} - x$ for $u \in F$ have dimension at least $|F| - 1$. As each of these vectors is orthogonal to $\chi^{F'}$ for each $F' \in \mathcal{F} \setminus v$, we have $\dim(\mathcal{F} \setminus v) \leq (n-1) - (|F| - 1) = n - |F|$, proving (78.14)(i).

We prove (ii) similarly. Choose $F \in \mathcal{F}$ and $v \in F$. Define $z := (1 - x_v)^{-1} \cdot x|V \setminus \{v\}$. Then $z \in P_{H/v}$, since $x(F' \setminus \{v\}) \geq 1 - x_v$ for each $F' \in \mathcal{F}$. Hence, since H/v is ideal, z is a convex combination of incidence vectors of vertex covers of H/v. For each $u \in F \setminus \{v\}$, since $z_u > 0$, there is a vertex cover B_u of H/v having positive scalar in this convex decomposition and with $u \in B_u$. So $B_u \cap F = \{u\}$ (since $z(F \setminus \{v\}) = 1$). Hence the incidence vectors χ^{B_u} for $u \in F \setminus \{v\}$ are linearly independent. This implies that the vectors $\chi^{B_u} - x$ for $u \in F$ have affine dimension at least $|F| - 1$. As each of these vectors is orthogonal to $\chi^{F'}$ for each $F' \in \mathcal{F}_v$, we have $\dim(\mathcal{F}_v) \leq (n-1) - (|F \setminus \{v\}| - 1) = n - |F| + 1$, proving (78.14)(ii).

Now (78.14)(i) implies:

(78.15) $|\mathcal{F}| = n$ and $|\mathcal{F} \setminus v| = n - |F|$ for each $v \in V$ and $F \in \mathcal{F} \setminus v$.

Indeed, let $\mathcal{F}'$ be a subcollection of $\mathcal{F}$ of dimension and size n. By (78.14)(i), $|\mathcal{F}' \setminus v| \leq n - |F|$ for each $v \in V$ and each $F \in \mathcal{F} \setminus v$. Let U be the set of $v \in V$ not covered by all sets in $\mathcal{F}'$. Then:

(78.16)
$$n = \sum_{F \in \mathcal{F}'} 1 = \sum_{F \in \mathcal{F}'} \sum_{v \in V \setminus F} \frac{1}{n - |F|} = \sum_{v \in U} \sum_{F \in \mathcal{F}' \setminus v} \frac{1}{n - |F|}$$
$$\leq \sum_{v \in U} \sum_{F \in \mathcal{F}' \setminus v} \frac{1}{|\mathcal{F}' \setminus v|} = \sum_{v \in U} 1 = |U| \leq n.$$

So we have equality throughout; that is, $U = V$ and $|\mathcal{F}' \setminus v| = n - |F|$ for each $v \in V$ and each $F \in \mathcal{F}' \setminus v$.

We deduce that $\mathcal{F}' = \mathcal{F}$. For suppose that there exists an $F \in \mathcal{F} \setminus \mathcal{F}'$. Then there is an $F' \in \mathcal{F}'$ such that $\mathcal{F}'' := (\mathcal{F}' \setminus \{F'\}) \cup \{F\}$ has dimension n. Choose $v \in F \setminus F'$ and $F'' \in \mathcal{F}'' \setminus v$. So $F'' \neq F$ and hence $F'' \in \mathcal{F}' \setminus v$. Hence $|\mathcal{F}'' \setminus v| = n - |F''| = |\mathcal{F}' \setminus v|$, contradicting the fact that $v \in F \setminus F'$. Concluding, $\mathcal{F}' = \mathcal{F}$ and we have (78.15).

(78.15) and (78.14)(ii) imply:

(78.17) $\quad |F| + |F'| \leq n + 1$ for any two distinct $F, F' \in \mathcal{F}$.

For choose $v \in F' \setminus F$. Then

(78.18) $$n = |\mathcal{F}| = |\mathcal{F}\setminus v| + |\mathcal{F}_v| \leq n - |F| + n - |F'| + 1 = 2n - |F| - |F'| + 1,$$

implying (78.17).

Let G be the graph on V where distinct $u, v \in V$ are adjacent if there is an $F \in \mathcal{F}$ with $u, v \notin F$. So by (78.15), $|\mathcal{F} \setminus u| = |\mathcal{F} \setminus v|$ for adjacent u, v. Hence, if G is connected, then $|\mathcal{F} \setminus v|$ is independent of v, and hence by (78.15), all sets in $\mathcal{F}$ have the same size, p say. Hence $x = p^{-1} \cdot \mathbf{1}$ and $p \geq r$ (as r is the minimum size of the sets in $\mathcal{E}$). On the other hand, the inequality $x(E) \geq 1$ for any minimum-size $E \in \mathcal{E}$, gives that $r \geq p$. So $p = r$, and the theorem follows.

So we can assume that G is not connected. Then there exists a partition of V into nonempty sets V_1, V_2 with $V_1 \subseteq F$ or $V_2 \subseteq F$ for each $F \in \mathcal{F}$. Let $\mathcal{F}_i$ be the collection of sets $F \in \mathcal{F}$ with $V_i \subseteq F$ (for $i = 1, 2$). So $\mathcal{F}_1, \mathcal{F}_2$ partition $\mathcal{F}$. By (78.17) we can assume that $\mathcal{F}_1 \subseteq \{V_1\}$ (since $|V_1| + |V_2| = n$). Then (78.17) gives moreover that $\mathcal{F}_2 \subseteq \{V_2 \cup \{v\} \mid v \in V_1\}$ (as $|\mathcal{F}| = n \geq 3$, so $\mathcal{F} \neq \{V_1, V_2\}$). Since $|\mathcal{F}_1| + |\mathcal{F}_2| = n$, it follows that $|V_1| = n - 1$, and $(V, \mathcal{F}) = J_n$. Since any subset of V is contained in or contains one of the sets in $\mathcal{F}$, we know that $H = J_n$, a contradiction. ∎

This theorem implies:

Corollary 78.4a. *Let H be a minimally nonideal hypergraph. Define $n := |VH|$, $r := r_{\max}(H)$, and $s := \tau(H)$. Then $\tau(H) - 1 < \tau^*(H) < \tau(H)$. If moreover $H \neq J_n$, then $rs > n$ and $\tau^*(H) = n/r$.*

Proof. First assume that $H = J_n$. Then $\tau(H) = 2$ and $\tau^*(H) = (2n - 3)/(n-1) = 2 - \frac{1}{n-1}$ as one easily checks. So we can assume that $H \neq J_n$.

Consider a pair $x \in P_H$ and $y \in P_{b(H)}$ minimizing $x^{\mathsf{T}}y$. So $x^{\mathsf{T}}y < 1$ (since P_H and $P_{b(H)}$ form no blocking pair of polyhedra). We can assume that x and y are vertices of P_H and $P_{b(H)}$ respectively. Moreover, x and y are noninteger, for if, say, x is integer, it is the incidence vector of a vertex cover of H, and hence $x^{\mathsf{T}}y \geq 1$, since $y \in P_{b(H)}$.

As H and $b(H)$ are minimally nonideal, we know by Theorem 78.4 that $x = r^{-1} \cdot \mathbf{1}$ and $y = s^{-1} \cdot \mathbf{1}$. Then $x^{\mathsf{T}}y < 1$ implies $rs > n$.

Let z minimize $\mathbf{1}^T z$ over $z \in P_H$, where z is a vertex of P_H. So z is a minimum-size vertex cover, and hence $\mathbf{1}^{\mathsf{T}}z = \tau^*(H)$. If z is integer, then

$\mathbf{1}^{\mathsf{T}}z \geq s > n/r$. If z is noninteger, then $z = r^{-1} \cdot \mathbf{1}$ by Theorem 78.4, and hence $\mathbf{1}^{\mathsf{T}}z = n/r$. So $\tau^*(H) = n/r$.

As $rs > n$, we have $n/r < s$ and so $\tau^*(H) < \tau(H)$. Moreover, for any $v \in VH$ we have $\tau^*(H \setminus v) \leq (n-1)/r$, since $r^{-1} \cdot \mathbf{1}_{V \setminus \{v\}}$ is a fractional vertex cover of H. Hence

$$(78.19) \qquad \tau^*(H) = \frac{n}{r} > \frac{n-1}{r} \geq \tau^*(H \setminus v) = \tau(H \setminus v) \geq \tau(H) - 1,$$

as required. ∎

Corollary 78.4a implies a number of further characterizations of ideal hypergraphs, partly sharpening Theorem 78.3 (Lehman [1990], Padberg [1993], Seymour [1990b]; the equivalence (i)⇔(iv) answers a question of P.D. Seymour (personal communication 1976)):

Corollary 78.4b. *For any hypergraph $H = (V, \mathcal{E})$, the following are equivalent:*

(78.20)
- (i) *H is ideal, that is, $\tau(H^w) = \tau^*(H^w)$ for each $w : V \to \mathbb{Z}_+$;*
- (ii) *$H' \neq J_n$ (for all $n \geq 3$) and $\tau(H')r_{\min}(H') \leq |VH'|$, for each minor H' of H;*
- (iii) *$\tau^*(H') \in \mathbb{Z}$ for each minor H' of H;*
- (iv) *$\tau(H') = \tau^*(H')$ for each minor H' of H;*
- (v) *$\tau(H^w) = \tau^*(H^w)$ for each $w : V \to \{0, 1, |V|\}$.*

Proof. Condition (i) implies each of (ii)-(v), since ideality is closed under taking minors and parallelization. The implication (iv)⇒(iii) is direct. The implications (ii)⇒(i) and (iii)⇒(i) follow from Corollary 78.4a: if H is not ideal, it has a minor H' that is minimally nonideal; then Corollary 78.4a contradicts (ii) and (iii). So it suffices to show (v)⇒(iv).

Let (v) hold. Let H' be a minor obtained from H by contracting the vertices in a set U and deleting the vertices in a set W. Define $w(v) := 0$ if $v \in W$, $w(v) := |V|$ if $v \in U$, and $w(v) := 1$ otherwise. We assume that $\tau(H')$ is finite (so $\emptyset \in EH'$). We show

$$(78.21) \qquad \tau(H') \leq \tau(H^w) = \tau^*(H^w) \leq \tau^*(H'),$$

which implies (iv).

We first show the first inequality in (78.21). If $\tau(H') \geq |V|$, then $\tau(H') \geq |VH'|$, and hence each singleton is an edge of H'. So $\tau(H') = |VH'|$, and hence $\tau(H^w) \geq |VH'| = \tau(H')$. So we can assume that $\tau(H') < |V|$. Then $\tau(H') \leq \tau(H^w)$, since otherwise $\tau(H^w) < |V|$, and hence H has a vertex cover B contained in $V \setminus U$ with $|B \setminus W| = \tau(H^w)$. So $\tau(H') \leq |B \setminus W| = \tau(H^w)$. This proves the first inequality in (78.21).

To see the second inequality, let $x \in \mathbb{R}^{V \setminus (U \cup W)}$ be a minimum-size fractional vertex cover of H'. We can extend x to a fractional vertex cover $\tilde{x} \in \mathbb{R}^V$ of H by defining $\tilde{x}_v := 0$ if $v \in U$ and $\tilde{x}_v := 1$ if $v \in W$. Then

(78.22) $$\tau^*(H^w) \leq w^\mathsf{T}\tilde{x} = \mathbf{1}^\mathsf{T}x = \tau^*(H').$$

Hence $\tau^*(H^w) \leq \tau^*(H')$, proving (78.21). ∎

With Theorem 78.4 some more properties of minimally nonideal hypergraphs can be derived (Lehman [1990]), where J denotes an all-one matrix:

Theorem 78.5. *Let $H = (V, \mathcal{E})$ be a minimally nonideal hypergraph with $H \neq J_n$ where $n := |V|$. Let $r := r_{\min}(H)$ and $s = \tau(H)$. Let $\mathcal{F}$ and $\mathcal{C}$ be the collections of minimum-size edges of H and $b(H)$ respectively. Let M and N be the $\mathcal{F} \times V$ and $\mathcal{C} \times V$ incidence matrices of $\mathcal{F}$ and $\mathcal{C}$ respectively. Then the rows of M can be ordered such that*

(78.23) $$MN^\mathsf{T} = J + (rs - n)I = N^\mathsf{T}M.$$

Proof. For each $B \in \mathcal{C}$ we have:

(78.24) $$\sum_{F \in \mathcal{F}} |F \cap B| = rs,$$

since $|B| = s$ and since each $v \in V$ is in exactly r sets in $\mathcal{F}$ (by Theorem 78.4).

As $|F \cap B| \geq 1$ for each $F \in \mathcal{F}$, (78.24) gives:

(78.25) $|F \cap B| \leq rs - n + 1$ for each $F \in \mathcal{F}$, and $|F \cap B| \geq 2$ for at least one $F \in \mathcal{F}$.

Choose for each $B \in \mathcal{C}$ a set $F_B \in \mathcal{F}$ with $|B \cap F_B| \geq 2$. Then

(78.26) for each $v \in V$ there are at least $rs - n + 1$ sets $B \in \mathcal{C}$ with $v \in B \cap F_B$.

To see this, consider $H \setminus v$ and the vector $x := r^{-1} \cdot \mathbf{1}$ in $\mathbb{R}^{V \setminus \{v\}}$. Then x satisfies (78.1) for $H \setminus v$. As $H \setminus v$ is ideal, there exist distinct $B_1, \ldots, B_m \in b(H)$ and $\lambda_1, \ldots, \lambda_m > 0$ with

(78.27) $$x \geq \sum_{i=1}^{m} \lambda_i \chi^{B_i \setminus \{v\}} \text{ and } \sum_{i=1}^{m} \lambda_i = 1.$$

We can assume that $v \in B_i \in \mathcal{C}$ holds for $i = 1, \ldots, k$, and $v \notin B_i$ or $B_i \notin \mathcal{C}$ for $i > k$. So $|B_i \setminus \{v\}| \geq s$ for $i > k$. Then (78.27) implies

(78.28) $$\begin{aligned} \frac{n-1}{r} &= x^\mathsf{T}\mathbf{1} \geq \sum_{i=1}^{m} \lambda_i |B_i \setminus \{v\}| \geq \sum_{i=1}^{k} \lambda_i (s-1) + \sum_{i=k+1}^{m} \lambda_i s \\ &= s - \sum_{i=1}^{k} \lambda_i \geq s - \frac{k}{r}, \end{aligned}$$

since $\lambda_i \leq 1/r$ for each i, by (78.27). (78.28) implies $k \geq rs - n + 1$. Now for each $i \leq k$, we have $v \in F_{B_i}$, since otherwise $x(F_{B_i}) = 1$, implying $|B_i \cap F_{B_i}| = 1$ (by (78.27)), a contradiction. So we have (78.26).

This implies

$$(78.29)\qquad \begin{aligned} n(rs-n+1) &\geq \sum_{B\in\mathcal{C}} |B\cap F_B| \\ &= \sum_{v\in V}(\text{number of } B\in\mathcal{C} \text{ with } v\in B\cap F_B) \geq n(rs-n+1), \end{aligned}$$

and hence we have equality throughout. So for each $B\in\mathcal{C}$ we have $|B\cap F_B| = rs-n+1$ and $|B\cap F|=1$ for each $F\in\mathcal{F}$ with $F\neq F_B$. By symmetry we have, for each $F\in\mathcal{F}$, that $|B\cap F|=1$ for all but one $B\in\mathcal{C}$, which has $|B\cap F| = rs-n+1$. So the set of pairs (B,F) with $|B\cap F| = rs-n+1$ forms a perfect matching covering $\mathcal{C}$ and $\mathcal{F}$. Hence we can reorder the rows of M such that $MN^\mathsf{T} = J+(rs-n)I$. In particular, M and N are nonsingular.

This implies

$$(78.30)\qquad \begin{aligned} MN^\mathsf{T}MN^\mathsf{T} &= (J+(rs-n)I)(J+(rs-n)I) \\ &= (n+2(rs-n))J+(rs-n)^2I = rsJ+(rs-n)(J+(rs-n)I) \\ &= MJN^\mathsf{T}+(rs-n)MN^\mathsf{T} = M(J+(rs-n)I)N^\mathsf{T}. \end{aligned}$$

So $N^\mathsf{T}M = J+(rs-n)I$ (as M and N are nonsingular). ∎

Notes. Seymour [1990b] asked the following related questions. Suppose that $H = (V,\mathcal{E})$ is a hypergraph without J_n minor ($n\geq 3$). Let $l,w : V\to\mathbb{Z}_+$ be such that

$$(78.31)\qquad \tau(H^w)\cdot\tau(b(H)^l) > l^\mathsf{T}w.$$

Is there a minor H' of H and $l',w' : VH' \to \{0,1\}$ such that

$$(78.32)\qquad \tau((H')^{w'})\cdot\tau(b(H')^{l'}) > l'^\mathsf{T}w'$$

and such that $\tau((H')^{w'}) \leq \tau(H^w)$ and $\tau(b(H')^{l'}) \leq \tau(b(H)^l)$?

A second question of Seymour is: Let $H=(V,\mathcal{E})$ be a nonideal hypergraph. Is the minimum of $\tau(H')$ over all parallelizations and minors H' of H with $\tau^*(H') < \tau(H')$ attained by a minor of H?

78.4a. Application of Lehman's theorem: Guenin's theorem

Lehman's theorem can be used as a tool in proving the characterization of Guenin [1998a,2001a] of weakly bipartite graphs (Corollary 75.4a). We follow the derivation as given in Schrijver [2002a].

Recall that a signed graph $G=(V,E,\Sigma)$ is called *weakly bipartite* if each vertex of the polyhedron (in $\mathbb{R}^E$) determined by:

$$(78.33)\qquad \begin{array}{lll} \text{(i)} & x_e \geq 0 & \text{for each edge } e, \\ \text{(ii)} & x(C)\geq 1 & \text{for each odd circuit } C, \end{array}$$

is integer, that is, the incidence vector of an odd circuit cover. Equivalently, if the hypergraph with vertex set E and edge set all odd circuits of G, is ideal.

Again, let odd-K_5 be the signed graph (VK_5, EK_5, EK_5). Then:

Theorem 78.6 (Guenin's theorem)**.** *A signed graph is weakly bipartite if and only if it has no odd-K_5 minor.*

Proof. Necessity follows from the fact that weak bipartition is closed under taking minors and that odd-K_5 is not weakly bipartite.

To see sufficiency, let $G = (V, E, \Sigma)$ be a minimally non-weakly bipartite signed graph (minimal under taking minors). We show that $G = (V, E, \Sigma)$ contains an odd-K_5 minor. Note that the operations of deletion and contraction in the signed graph G correspond to deletion and contraction in the hypergraph defined above.

Let $n := |E|$, let r be the minimum size of an odd circuit, and let s be the minimum size of an odd circuit cover. Let M (N, respectively) be the matrix whose rows are the incidence vectors of the minimum-size odd circuits (minimum-size odd circuit covers, respectively). By Lehman's theorem (Theorem 78.5), we know that both M and N have precisely n rows, that $rs > n$, and that the rows of M can be ordered such that

(78.34) $$MN^{\mathsf{T}} = J + (rs - n)I = N^{\mathsf{T}}M.$$

This implies that we can index the minimum-size odd circuits as $C_1, \ldots, C_n$ and the minimum-size odd circuit covers as $B_1, \ldots, B_n$ in such a way that for all $i, j = 1, \ldots, n$:

(78.35) $$|C_i \cap B_j| = 1 \text{ if } i \neq j \text{ and } |C_i \cap B_j| = q \text{ if } i = j,$$

where $q := rs - n + 1$. Since $q = |C_1 \cap B_1|$ is odd and ≥ 2 (as $rs > n$), we have $q \geq 3$.

The fact that $N^{\mathsf{T}}M = J + (rs - n)I$ is equivalent to:

(78.36)
(i) for each $e \in E$ there are precisely q indices i with $e \in C_i \cap B_i$,

(ii) for all distinct $e, f \in E$ there is precisely one index i with $e \in B_i$ and $f \in C_i$.

Then for all distinct $i, j = 1, \ldots, n$:

(78.37) the only odd circuits contained in $C_i \cup C_j$ are C_i and C_j; the only odd circuit covers contained in $B_i \cup B_j$ are B_i and B_j.

For let C be an odd circuit contained in $C_i \cup C_j$. Then $C_i \triangle C_j \triangle C$ contains an odd circuit, C' say. This implies that $C \cup C' \subseteq C_i \cup C_j$ and $C \cap C' \subseteq C_i \cap C_j$ (for if $e \in C \cap C'$, then $e \notin C_i \triangle C_j$). Hence $|C| + |C'| \leq |C_i| + |C_j|$. So also C and C' are minimum-size odd circuits and $C \cup C' = C_i \cup C_j$. As $|C_i \cap B_i| \geq 3$ we have $|C \cap B_i| \geq 2$ or $|C' \cap B_i| \geq 2$. Therefore, C or C' is equal to C_i, and the other is equal to C_j. The proof for odd circuit covers is analogous. This shows (78.37).

We now construct an odd-K_5 minor. Fix an edge $e \in E$, with ends v_1 and v_2, say. By (78.36)(i) we can assume that e is contained in $C_i \cap B_i$ for $i = 1, \ldots, q$. Then, by (78.36):

(78.38) any two sets among $C_1 \setminus \{e\}, \ldots, C_q \setminus \{e\}, B_1 \setminus \{e\}, \ldots, B_q \setminus \{e\}$ are disjoint, except that $|(C_i \setminus \{e\}) \cap (B_i \setminus \{e\})| = q - 1$ for $i = 1, \ldots, q$.

To see this, choose distinct $i, j = 1, \ldots, q$. Then $C_i \cap B_j = \{e\}$, as $|C_i \cap B_j| = 1$. Moreover, $C_i \cap C_j = \{e\}$, for suppose $f \in C_i \cap C_j$ with $f \neq e$. Then $f \in C_i \cap C_j$ and $e \in B_i \cap B_j$, contradicting (78.36)(ii). One similarly shows that $B_i \cap B_j = \{e\}$. This proves (78.38).

(78.37) implies:

(78.39) $VC_i \cap VC_j = \{v_1, v_2\}$ for distinct $i, j = 1, \ldots, q$.

Otherwise $(C_i \cup C_j) \setminus \{e\}$ contains a path P from v_1 to v_2 different from $C_i \setminus \{e\}$ and $C_j \setminus \{e\}$. By (78.37), $(C_i \cup C_j) \setminus \{e\}$ contains no odd circuit. Hence P and $C_i \setminus \{e\}$ have the same parity (with respect to Σ), and so $P \cup \{e\}$ is an odd circuit in $C_i \cup C_j$, contradicting (78.37). This proves (78.39).

Since $B_i \triangle \Sigma$ is a cut for each $i = 1, 2, 3$, there exist $U_1, U_2, U_3 \subseteq V$ such that

(78.40) $\delta(U_i) = B_j \triangle B_k = (B_j \cup B_k) \setminus \{e\}$

for all distinct $i, j, k \in \{1, 2, 3\}$. As $e \notin B_j \triangle B_k$, we can assume $v_1, v_2 \notin U_i$. Also

(78.41) U_i induces a connected subgraph of G.

If not, there is a $K \subseteq U_i$ such that $\delta(K)$ is a nonempty proper subset of $\delta(U_i)$. Then $B_j \triangle \delta(K)$ is an odd circuit cover contained in $B_j \cup B_k$, distinct from B_j and B_k, contradicting (78.37).

By (78.40), $\delta(U_1 \triangle U_2 \triangle U_3) = \delta(U_1) \triangle \delta(U_2) \triangle \delta(U_3) = \emptyset$, and hence $U_1 \triangle U_2 \triangle U_3$ $=\emptyset$ (as G is connected). So there exist pairwise disjoint sets V_1, V_2, V_3 of vertices with $U_i = V_j \cup V_k$ for all distinct $i, j, k \in \{1, 2, 3\}$. Define $V_0 := V \setminus (V_1 \cup V_2 \cup V_3)$.

(78.38) and (78.40) imply that $\delta(U_j) \cap \delta(U_k) = B_i \setminus \{e\}$ for distinct i, j, k. Hence $B_i \setminus \{e\}$ is the set of edges connecting either V_i and V_0, or V_j and V_k. So any edge not in $(B_1 \cup B_2 \cup B_3) \setminus \{e\}$ is spanned by one of the sets V_0, V_1, V_2, V_3.

Let $\{i, j, k\} = \{1, 2, 3\}$. Since C_i contains no edge in $(B_j \cup B_k) \setminus \{e\} = \delta(U_i)$, the set VC_i is disjoint from $U_i = V_j \cup V_k$. As $|C_i \cap B_i| \geq 3$ we know that VC_i intersects V_i.

We can reset Σ to an equivalent signing

(78.42) $\Sigma := B_1 \triangle B_2 \triangle B_3 \triangle \delta(V_0)$.

So Σ consists of e and all edges connecting distinct sets among V_1, V_2, V_3. For each $i = 1, 2, 3$ and $k = 1, 2$, let $e_{i,k}$ be the first edge along the path $C_i \setminus \{e\}$ that belongs to B_i, when starting from vertex v_k. So both $e_{i,1}$ and $e_{i,2}$ connect V_0 and V_i.

Let H be the minor of G obtained by deleting all edges except those in $C_1 \cup C_2 \cup C_3$ and those spanned by $V_1 \cup V_2 \cup V_3$, and contracting all remaining edges that are not in $\Sigma \cup \{e_{i,k} \mid i = 1, 2, 3; k = 1, 2\}$.

H can be described as follows. H contains the edge e, connecting the vertices $\overline{v}_1$ and $\overline{v}_2$ to which v_1 and v_2 are contracted (we have $\overline{v}_1 \neq \overline{v}_2$ by (78.39)). For each $i = 1, 2, 3$, the part of the path $C_i \setminus \{e\}$ that is between $e_{i,1}$ and $e_{i,2}$ belongs to one contracted vertex of H, call it z_i. This vertex z_i is adjacent to $\overline{v}_1$ and $\overline{v}_2$ by the edges $e_{i,1}$ and $e_{i,2}$. For each $i = 1, 2, 3$, V_i has been contracted to z_i and a number of other vertices, together forming the stable set S_i (say) in H. Any further edge of H connects S_i and S_j for some distinct $i, j \in \{1, 2, 3\}$.

By (78.41), the subgraph of H induced by $S_i \cup S_j$ is connected (for all distinct $i, j = 1, 2, 3$). So by Lemma 75.4α, the graph $H - \overline{v}_2$ has an odd K_4-subdivision as subgraph, containing the edges $\overline{v}_1 z_1$, $\overline{v}_1 z_2$, and $\overline{v}_1 z_3$. As $\overline{v}_2$ is adjacent to $\overline{v}_1$, z_1, z_2, and z_3, it follows that H has an odd-K_5 minor. ∎

78.4b. Ideality is in co-NP

Seymour [1990b] showed (upon a suggestion of J. Edmonds) that Lehman's theorem (Theorem 78.5) implies that the question 'Given a hypergraph, is it ideal?' belongs to co-NP.

In this, we should be careful in the way the hypergraph $(V, \mathcal{E})$ is given. In most classes of examples, the number of edges is exponential in the number of vertices, and we have no full list of all edges at hand. We can however assume that we have an oracle telling us, for any subset U of V, if U contains an edge of H; that is, if $U \in H^{\uparrow}$. This gives us a polynomial-time test if a subset belongs to $H^{\min}$, and also a polynomial-time test if a subset B is a vertex cover (since B is a vertex cover if and only if $V \setminus B \notin H^{\uparrow}$). So if we have such an oracle for H, we can derive one for its blocker $b(H)$, and conversely.

Moreover, for any $v \in V$, an oracle for H gives oracles for H/v and $H \backslash v$. Indeed, for any $U \subseteq V \setminus \{v\}$: $U \in (H/v)^{\uparrow} \iff U \cup \{v\} \in H^{\uparrow}$ and $U \in (H \setminus v)^{\uparrow} \iff U \in H^{\uparrow}$.

Now to certify that a hypergraph is nonideal, it is sufficient and possible to specify *either* a minor H with $H = J_n$ for $n := |VH|$, *or* a minor H together with numbers r, s, edges $F_1, \ldots, F_n$, and vertex covers $B_1, \ldots, B_n$ (where $n := |VH|$) of H such that

(78.43) (i) $rs > n$,
(ii) $|F_i| = r$, $|B_i| = s$, and $|B_i \cap F_i| = rs - n + 1$ for each $i = 1, \ldots, n$;
(iii) each $v \in VH$ is in precisely r of the F_i and in precisely s of the B_i.

This is possible by Theorem 65.2. If $H = J_n$, this can be tested easily with the oracle. If $H \neq J_n$, then the sets F_i (B_i respectively) can be taken to be minimal edges of H ($b(H)$ respectively); the oracle can tell us that they belong to H ($b(H)$ respectively).

It is also sufficient to certify nonideality: (78.43) implies that $\tau(H) \geq s$: a vertex cover B of H intersects at most $r|B|$ of the F_i, and hence $r|B| \geq n$, implying $|B| \geq s$ (since otherwise $(s-1)r \geq n$ and hence $rs - n + 1 > r$, contradicting (78.43)(ii)). Similarly, (78.43) implies that $r_{\min}(H) \geq r$. As $rs > n$, this implies that H is nonideal.

78.5. Further results and notes

78.5a. Composition of clutters

Billera [1971] described the following composition of hypergraphs. Let $H' = (V', \mathcal{E}')$ and $H'' = (V'', \mathcal{E}'')$ be hypergraphs with V' and V'' disjoint, and choose $v \in V'$. Let $V := (V' \setminus \{v\}) \cup V''$, and define $\mathcal{E}$ by:

(78.44) $$\mathcal{E} := \{E' \in \mathcal{E}' \mid v \notin E'\} \cup \{(E' \setminus \{v\}) \cup E'' \mid E' \in \mathcal{E}', v \in E', E'' \in \mathcal{E}''\}.$$

Let $H = (V, \mathcal{E})$. Then H is ideal if and only if H' and H'' are ideal. (The 'only if' part was shown by Billera [1971] and the 'if' part by Bixby [1971].)

Related results were reported by Chopra [1995]. An extension of these results to *clutter amalgam* was given by Nobili and Sassano [1993a] (cf. Nobili and Sassano [1993b]).

78.5b. Further notes

Cornuéjols and Novick [1994] conjecture that there are only finitely many minimally nonideal hypergraphs H with $r_{\min}(H) > 2$ and $\tau(H) > 2$. This would confirm the question of Ding [1993] whether there exists a number t such that each minimally nonideal hypergraph H satisfies $r_{\min}(H) \leq t$ or $\tau(H) \leq t$.

Since by Lehman's theorem, each minimally nonideal hypergraph $H \neq J_n$ satisfies $\tau^*(H) = r^{-1}\tau_r(H) < \tau(H)$, where $r := r_{\min}(H)$, the existence of such a t would imply that the following property characterizes ideality of a hypergraph H:

(78.45) H contains no J_n minor ($n \geq 3$) and satisfies $\tau_k(H') = k \cdot \tau(H')$ and $\tau_k(b(H')) = k \cdot \tau(b(H'))$ for each minor H' of H and each $k \leq t$.

Ding wondered if $t = 3$ would do.

Ding [1993] conjectures that for each fixed $k \geq 2$, each minor-minimal hypergraph H with $\tau_k(H) < k \cdot \tau(H)$, contains some J_n minor ($n \geq 3$) or satisfies the regularity conditions of Lehman's theorems (Theorem 78.4 and 78.5). Ding [1993] proved this for $k = 2$: if H is minor-minimal with the property $\tau_2 < 2\tau$ and if H has no J_n minor ($n \geq 3$), then the minimum-size vertex covers form an odd circuit on VH.

A $\{0, \pm 1\}$ matrix M is called *ideal* if the polytope

(78.46) $$\{x \mid \mathbf{0} \leq x \leq \mathbf{1}, Mx \geq \mathbf{1} - b\}$$

is integer, where b is the vector with b_i equal to the number of -1's in the ith row of M. These matrices generalize the incidence matrices of ideal hypergraphs. Guenin [1998b] and Nobili and Sassano [1995,1998] showed that they can be characterized in terms of ideal hypergraphs.

Related work on ideal hypergraphs was reported by Novick and Sebő [1996]. A survey on ideal hypergraphs was given by Cornuéjols and Guenin [2002b].

Chapter 79

Mengerian hypergraphs

Mengerian hypergraphs form a subclass of the ideal hypergraphs. They are characterized by the total dual integrality of the edge inequalities (where ideal hypergraphs require only totally *primal* integrality). So Mengerian hypergraphs satisfy min-max relations that are combinatorial at both optima.

This chapter gives a few characterizations of Mengerity. No characterization in terms of forbidden minors is known. In Chapter 80 we will give Seymour's forbidden minor characterization of *binary* Mengerian hypergraphs.

79.1. Mengerian hypergraphs

A hypergraph $H = (V, \mathcal{E})$ is called *Mengerian* if $\nu(H') = \tau(H')$ for each parallelization H' of H.[10] Equivalently:

(79.1) $\quad H$ is Mengerian $\iff$ system (78.1) is totally dual integral.

By (77.19) (or by the theory of total dual integrality), each Mengerian hypergraph is ideal. Like ideal hypergraphs, the class of Mengerian hypergraphs is closed under taking minors:

Theorem 79.1. *Any minor of a Mengerian hypergraph is Mengerian again.*

Proof. As restriction is a special case of parallelization, any restriction of a Mengerian hypergraph is again Mengerian. As for contraction, let $H = (V, \mathcal{E})$ be a Mengerian hypergraph and let $v \in V$ and $w : V \setminus \{v\} \to \mathbb{Z}_+$. Define $w' : V \to \mathbb{Z}_+$ by $w'(u) := w(u)$ if $u \in V \setminus \{v\}$ and $w'(v) := \tau((H/v)^w)$. Then

(79.2) $$\tau((H/v)^w) \leq \tau(H^{w'}) = \nu(H^{w'}) \leq \nu((H/v)^w).$$

So $\tau((H/v)^w) = \nu((H/v)^w)$. Concluding, H/v is Mengerian. ∎

Unlike ideal hypergraphs, the class of Mengerian hypergraphs is not closed under taking blockers, as we shall see in Section 79.2.

---

[10] Alternatively, such hypergraphs are said to have the $\mathbb{Z}_+$-*max-flow min-cut property*, shortly the $\mathbb{Z}_+$-*MFMC property*.

Theorem 78.3 implies some characterizations of Mengerian hypergraphs (Lovász [1975a] showed (i)⇔(ii), and Lovász [1976c] (i)⇔(iii); the equivalence (i)⇔(ii) also follows from a more general theorem of Hoffman [1974]):

Theorem 79.2. *For any hypergraph $H = (V, \mathcal{E})$, the following are equivalent:*

(79.3)
(i) *H is Mengerian, that is, $\nu(H') = \tau(H')$ for each parallelization H' of H;*
(ii) *$\nu^*(H') = \nu(H')$ for each parallelization H' of H;*
(iii) *$\nu_2(H') = 2\nu(H')$ for each parallelization H' of H.*

Proof. The equivalence (i) $\iff$ (ii) follows from Theorem 78.3, since (79.3)(ii) implies that $\nu^*(H')$ is an integer and since $\nu^*(H') = \tau^*(H')$. The implications (ii)⇒(iii) follows from (77.19), since $\nu^*(H') \geq \frac{1}{2}\nu_2(H') \geq \nu(H')$. So it suffices to prove (iii)⇒(ii).

First observe that for each $w : V \to \mathbb{Z}_+$ and all $j, k \in \mathbb{Z}_+$ we have $\nu_{jk}(H^w) = \nu_k(H^{jw})$. Hence, if (79.3)(iii) holds, then for each $w : V \to \mathbb{Z}_+$ and each i:

(79.4) $$\nu_{2^{i+1}}(H^w) = \nu_2(H^{2^i w}) = 2\nu(H^{2^i w}) = 2\nu_{2^i}(H^w).$$

So by induction on i we find that for all i:

(79.5) $$\nu_{2^i}(H^w) = 2^i \nu(H^w), \text{ that is, } \frac{\nu_{2^i}(H^w)}{2^i} = \nu(H^w).$$

As

(79.6) $$\nu^*(H^w) = \lim_{k\to\infty} \frac{\nu_k(H^w)}{k}$$

(by (77.20)), this gives (79.3)(ii). ∎

Another characterization, in terms of the blocker, is:

Theorem 79.3. *Let $H = (V, \mathcal{E})$ be a hypergraph. Then the blocker $b(H)$ of H is Mengerian if and only if for each natural number k, each k-vertex cover is the sum of k 1-vertex covers.*

Proof. By definition, $b(H)$ is Mengerian if and only if $\nu(b(H)^l) = \tau(b(H)^l)$ for each $l : V \to \mathbb{Z}_+$. Now $\tau(b(H)^l)$ is equal to the minimum value of $l(E)$ for $E \in \mathcal{E}$ (by Theorem 77.1). In other words, $\tau(b(H)^l)$ is equal to the maximum number k for which l is a k-vertex cover.

Moreover, $\nu(b(H)^l)$ is equal to the maximum number k of vertex covers $B_1, \ldots, B_k$ with

(79.7) $$\chi^{B_1} + \cdots + \chi^{B_k} \leq l.$$

So $\nu(b(H)^l) = \tau(b(H)^l)$ for each $l : V \to \mathbb{Z}_+$ if and only if for each k, each k-vertex cover l is the sum of k 1-vertex covers. ∎

Note that the right-hand side of the equivalence in this theorem directly implies, by definition of τ_k, that $\tau_k(H) = k \cdot \tau(H)$ for each k; that is, $\tau^*(H) = \tau(H)$.

79.1a. Examples of Mengerian hypergraphs

Bipartite graphs. Let $G = (V, E)$ be a bipartite graph. It is very easy to show that $\nu_2(G) = 2\nu(G)$. (It amounts to the fact that each bipartite graph G of maximum degree at most 2 has a matching of size at least $\frac{1}{2}|EG|$.)

Since the class of bipartite graphs is closed under parallelization, Theorem 79.2 gives $\nu(G) = \tau(G)$; that is, the matching number of G is equal to the vertex cover number of G. This is Kőnig's matching theorem (Theorem 16.2).

Network flows. Let $D = (V, A)$ be a directed graph and let $s, t \in V$. Let $\mathcal{P}$ be the collection of arc sets of $s-t$ paths. Consider the hypergraph $H = (A, \mathcal{P})$. Then $b(H)$ is the hypergraph with edge set all inclusionwise minimal $s-t$ cuts.

Now $\nu(b(H)) = \tau(b(H))$, since the minimum size k of an $s-t$ path is equal to the maximum number of pairwise disjoint $s-t$ cuts. This is an easy result, by considering the cuts $\delta^{\text{out}}(V_i)$ for $i = 1, \ldots, k$, where V_i is the set of vertices at distance $< i$ from s.

Since the class of hypergraphs $b(H)$ obtained in this way is closed under parallelization (it corresponds to replacing arcs by paths), $b(H)$ is Mengerian. Hence $b(H)$ is ideal, and hence H is ideal. That is, for each weight function $w : A \to \mathbb{Z}_+$ we have $\tau(H^w) = \tau^*(H^w) = \nu^*(H^w)$. This gives that the minimum weight of an $s-t$ cut is equal to the maximum of $\sum_{P \in \mathcal{P}} \lambda_P$ where $\lambda : \mathcal{P} \to \mathbb{R}_+$ with $\sum_{P \in \mathcal{P}} \lambda_P \chi^P \leq w$. That is, we have the max-flow min-cut theorem.

By Menger's theorem, we even know that $\nu(H) = \tau(H)$. As the class of these hypergraphs is closed under parallelization (it corresponds to adding parallel arcs to arcs), we know that H is Mengerian. By Theorem 79.2, to prove the existence of an integer maximum flow, it suffices to show that $\nu_2(H) = 2\nu(H)$, since this class of hypergraphs is closed under parallelization.

Arborescences. Let $D = (V, A)$ be a directed graph and let $r \in V$. Recall that a subset B of A is called an *r-arborescence* if (V, B) is a rooted tree with root r. An r-cut is a set $\delta^{\text{in}}(U)$ of arcs, where U is a nonempty subset of $V \setminus \{r\}$. Let H be the hypergraph with vertex set A and edges all r-arborescences. So the blocker $b(H)$ of H has edges all inclusionwise minimal r-cuts.

Since this class of hypergraphs is closed under parallelization, Edmonds' disjoint arborescences theorem (Theorem 53.1b) implies that H is Mengerian. By the optimum arborescence theorem (Theorem 52.3) also $b(H)$ is Mengerian.

Directed cuts. Let $D = (V, A)$ be a directed graph. Recall that a *directed cut* is a set of arcs of the form $\delta^{\text{in}}(U)$ where U is a nonempty proper subset of V with $\delta^{\text{out}}(U) = \emptyset$. A *directed cut cover* is a set of arcs intersecting all directed cuts. Let H be the hypergraph with vertex set A and edges all directed cuts. So the blocker $b(H)$ of H has edges all inclusionwise minimal directed cut covers.

One may show that $\nu_2(H) = 2\nu(H)$, as was done in the proof of the Lucchesi-Younger theorem (Theorem 55.2). Since again this class of hypergraphs is closed under parallelization, Theorem 79.2 implies that H is Mengerian. This is the Lucchesi-Younger theorem.

So H is ideal, and hence also $b(H)$ is ideal. The example of Figure 56.1 in Section 56.1 shows that $b(H)$ in general is not Mengerian.

79.2. Minimally non-Mengerian hypergraphs

By Theorem 79.1, the class of Mengerian hypergraphs is closed under taking minors. It is not closed under taking blockers, since the hypergraph

(79.8) $$Q_6 := \mathcal{O}(K_4)$$

(the hypergraph with vertex set EK_4 and edges all triangles of K_4) is non-Mengerian, while its blocker is Mengerian: Q_6 is non-Mengerian, since $\nu(Q_6) = 1$ (K_4 has no two edge-disjoint triangles), while $\tau(Q_6) = 2$ (no edge is contained in all triangles). Its blocker $H := b(Q_6)$ has edges all complements of nonempty cuts of K_4. To see that it is Mengerian, we show that $\nu(H^l) = \tau(H^l)$ for each 'length' function $l : EK_4 \to \mathbb{Z}_+$. Then $\tau(H^l)$ is the minimum length of a triangle in K_4. To calculate $\nu(H^l)$, observe that the edges of H are the triangles and the perfect matchings of K_4. Consider any perfect matching M of K_4 with $l(e) > 0$ for both edges $e \in M$. Then replacing l by $l - \chi^M$ reduces $\tau(H^l)$ by 1 and $\nu(H^l)$ by at least 1. So inductively we can assume that each perfect matching of K_4 contains an edge e with $l(e) = 0$. So l is 0 on all edges of a triangle, in which case $\tau(H^l) = 0 \leq \nu(H^l)$, or on all edges of a star, in which case both $\tau(H^l)$ and $\nu(H^l)$ are equal to the minimum length of the edges of the complementary triangle.

Call a hypergraph $H = (V, \mathcal{E})$ *minimally non-Mengerian* if H is a non-Mengerian hypergraph and each proper minor of H is Mengerian.

The hypergraph Q_6 is minimally non-Mengerian. Indeed, choose a vertex e of Q_6. The restriction $Q_6 \setminus e$ has only two edges, and hence is trivially Mengerian. The contraction Q_6/e is isomorphic to $b(Q_6) \setminus e$, and hence is Mengerian, as we saw above.

In Section 80.5 we will see that Q_6 is the only *binary* minimally nonideal hypergraph (binary is defined in Chapter 80). We list this and other examples of minimally non-Mengerian hypergraphs ((i) was given by Lovász [1974], and (ii)-(vi) by Seymour [1977b]):

(79.9)
- (i) $Q_6 = \mathcal{O}(K_4)$, the hypergraph with vertex set EK_4, and edges all triangles;
- (ii) any odd circuit;
- (iii) the blocker of any odd circuit;
- (iv) J_n for $n \geq 3$ (cf. (78.12));
- (v) the circuit on $1, 2, 3, 4, 5, 6, 7, 9$ (in order) added with the edge $\{3, 6, 9\}$;
- (vi) the blocker of the hypergraph in (v);

(vii) the hypergraph with vertex set $\{0,1,2,3\}$ and edges $\{0,1,2\}$, $\{0,1,3\}$, $\{0,2,3\}$, and its blocker.

Example (vii) shows that a minimally non-Mengerian hypergraph H can satisfy $\nu(H) = \tau(H)$.

Notes. Seymour [1977b] conjectured that Q_6 is the only minimally non-Mengerian hypergraph with Mengerian blocker. However, the example of Figure 56.1 gives a minimally non-Mengerian hypergraph on 9 vertices. Its blocker is Mengerian (by the Lucchesi-Younger theorem). Two other examples of hypergraphs consisting of directed cut covers in a directed graph were given by Cornuéjols and Guenin [2002c] and yield two more minimally non-Mengerian hypergraphs with Mengerian blockers.

Seymour [1977b] indicated by a construction that it might be hard to characterize all minimally non-Mengerian hypergraphs.

79.3. Further results and notes

79.3a. Packing hypergraphs

A hypergraph $H = (V, \mathcal{E})$ is called *packing* if $\nu(H') = \tau(H')$ for each minor H' of H. So we have for any hypergraph H (using Theorem 79.1 and Corollary 78.4b):

(79.10) $\qquad H$ Mengerian $\Rightarrow$ H packing $\Rightarrow$ H ideal.

Q_6 is an example which is ideal but not packing, but no example is known of a non-Mengerian packing hypergraph. In fact, Conforti and Cornuéjols [1993] conjecture that both concepts coincide. Cornuéjols, Guenin, and Margot [1998,2000] proved this for *dyadic hypergraphs*, that is, hypergraphs H with $|E \cap B| \leq 2$ for each edge E of $H^{\min}$ and each edge B of $b(H)$.

The definition of packing implies that it is closed under taking minors. Call a hypergraph *minimally nonpacking* if it is nonpacking, but each proper minor is packing. So it is a minor-minimal hypergraph satisfying $\nu < \tau$.

Cornuéjols, Guenin, and Margot [1998,2000] showed that if a hypergraph is both minimally nonideal and minimally nonpacking, then $H = J_n$ for some $n \geq 3$ or $r_{\min}(H)\tau(H) = |VH| + 1$. They conjecture that, conversely, each minimally nonideal hypergraph H with $r_{\min}(H)\tau(H) = |VH| + 1$ is minimally nonpacking. By a computer program, this conjecture was verified for all hypergraphs with ≤ 14 vertices.

Another conjecture of Cornuéjols, Guenin, and Margot [1998,2000] is that $\tau(H) = 2$ for each ideal minimally nonpacking hypergraph H. This implies the above conjecture of Conforti and Cornuéjols that each packing hypergraph is Mengerian. For suppose that $H = (V, \mathcal{E})$ is packing and minimally non-Mengerian. Since H is non-Mengerian, there is a $w : V \to \mathbb{Z}_+$ with H^w nonpacking. Choose w with $w(V)$ minimal. Then H^w is minimally nonpacking. So by the second conjecture, $\tau(H^w) = 2$. As H is packing, $w(v) \geq 2$ for some $v \in V$. Now $\tau(H^w/v) \geq \tau(H^w) = 2$. Hence $\nu(H^w/v) \geq 2$. So there exist edges E_1, E_2 of H with $\chi^{E_1 \setminus \{v\}} + \chi^{E_2 \setminus \{v\}} \leq w$. Since $w(v) \geq 2$, this implies $\chi^{E_1} + \chi^{E_2} \leq w$, and hence $\nu(H^w) \geq 2$. This contradicts the fact that H^w is minimally nonpacking.

For a survey, see Cornuéjols and Guenin [2002b].

79.3b. Restrictions instead of parallelizations

It is tempting to conjecture that a hypergraph H is Mengerian if and only if $\nu(H') = \tau(H')$ for each restriction H' of H (instead of for each parallelization H' of H). Similarly, one may speculate that H is ideal if and only if $\tau^*(H') = \tau(H)$ for each restriction H' of H. But these characterizations are not valid, as is shown by the hypergraph of (79.9)(vii): then $\nu(H') = \tau(H')$ for each restriction H' of H (as soon as we delete any vertex we obtain a hypergraph with at most one edge); but H is nonideal, since if we duplicate vertex 0, we obtain a hypergraph with $\tau = 2$ and $\tau^* = \frac{3}{2}$.

So in Theorem 78.3, we cannot restrict H' to restrictions of H instead of parallelizations. But the equivalence of (78.10)(i) and (ii) is maintained if we restrict H' to restrictions of H:

Theorem 79.4. *For any hypergraph, $H = (V, \mathcal{E})$, the following are equivalent:*

(79.11) (i) $\tau(H') = \tau^*(H')$ *for each restriction H' of H;*
(ii) $\tau^*(H')$ *is an integer for each restriction H' of H.*

Proof. Since obviously (i)⇒(ii), we prove (ii)⇒(i). Choose a counterexample with $|V|$ smallest. Let x be a fractional vertex cover of size $\tau^*(H)$. Choose a vertex v with $x_v > 0$. As $x|V \setminus \{v\}$ is a fractional vertex cover of $H \setminus v$, we know:

(79.12) $$\tau^*(H \setminus v) \leq x(V \setminus \{v\}) < x(V) = \tau^*(H).$$

As $\tau^*(H)$ and $\tau^*(H \setminus v)$ are integer, this implies that $\tau^*(H \setminus v) \leq \tau^*(H) - 1$. By the minimality of V we know $\tau^*(H \setminus v) = \tau(H \setminus v)$. Therefore,

(79.13) $$\tau(H) \leq 1 + \tau(H \setminus v) = 1 + \tau^*(H \setminus v) \leq \tau^*(H),$$

and so $\tau(H) = \tau^*(H)$. ∎

As a direct consequence one has (Lovász [1974]):

Corollary 79.4a. *For any hypergraph, $H = (V, \mathcal{E})$, the following are equivalent:*

(79.14) (i) $\tau(H') = \nu(H')$ *for each restriction H' of H;*
(ii) $\nu^*(H') = \nu(H')$ *for each restriction H' of H.*

Proof. Directly from Theorem 79.4. ∎

(Lovász [1974] called hypergraphs with the properties (79.14) *seminormal*.)

Symmetry suggests the question if we can replace in Theorem 79.4 or Corollary 79.4a 'restriction' by 'contraction'.

79.3c. Equivalences for k-matchings and k-vertex covers

Some of the equivalences in Theorems 78.3 and 79.2 can be generalized as follows (Lovász [1977b] ($k \leq 2$), Schrijver and Seymour [1979] (general k)).

Theorem 79.5. *For any hypergraph $H = (V, \mathcal{E})$ and any $k \in \mathbb{Z}_+$, the following are equivalent:*

(79.15) (i) $k \cdot \tau^*(H') = \tau_k(H')$ *for each parallelization* H' *of* H*;*
(ii) $k \cdot \tau^*(H')$ *is an integer for each parallelization* H' *of* H*.*

Proof. Similar to the proof of Theorem 78.3. ∎

This implies a result proved by Schrijver and Seymour [1979] (just by adapting the proof methods of Lovász [1975a] for the equivalence (i)⇔(ii) for $k \leq 2$ and of Lovász [1977b] for the equivalence (i)⇔(iii) for $k = 1$):

Corollary 79.5a. *For any hypergraph* $H = (V, \mathcal{E})$ *and any* $k \in \mathbb{Z}_+$*, the following are equivalent:*

(79.16) (i) $\nu_k(H') = \tau_k(H')$ *for each parallelization* H' *of* H*;*
(ii) $k \cdot \nu^*(H') = \nu_k(H')$ *for each parallelization* H' *of* H*;*
(iii) $\nu_{2k}(H') = 2\nu_k(H')$ *for each parallelization* H' *of* H*.*

Proof. Similar to the proof of Theorem 79.2. ∎

As an application, let $G = (V, E)$ be an undirected graph. Then $\nu_4(G) = 2\nu_2(G)$ is not difficult to show. Since the class of graphs is closed under parallelization, Corollary 79.5a implies that $\nu_2(G) = \tau_2(G)$, which is Theorem 30.1.

79.3d. A general technique

The following general result (derived with a method given by Lovász [1976c]) gives some more equivalences:

Theorem 79.6. *Let* $H = (V, \mathcal{E})$ *be a hypergraph and* $w : V \to \mathbb{Z}_+$*. Let* $f : \mathbb{Z}_+^V \longrightarrow \mathbb{R}_+$ *satisfy*

(79.17) (i) $f(x + y) \geq f(x) + f(y)$ *for all* $x, y \in \mathbb{Z}_+^V$*;*
(ii) *if* $u \leq w$*, then* $f(u) \in \mathbb{Z}_+$*;*
(iii) *if* $x \leq w + \mathbf{1}$*, then* $f(2x) = 2f(x)$*;*
(iv) $f(\chi^U) > 0$ *for each* $U \in \mathcal{E}$*.*

Then $\tau(H^w) \leq f(w)$*.*

Proof. By induction on $\mathbf{1}^\mathsf{T} w$, the case where $\tau(H^w) = 0$ being trivial. Assume $\tau(H^w) > 0$. That is, the support U of w contains an edge of H. Choose $x \in \mathbb{Z}_+^V$ with $w \leq x \leq w + \chi^U$ such that $f(x) = f(w)$ and such that $\mathbf{1}^\mathsf{T} x$ is as large as possible. Then $x \neq w + \chi^U$, since $f(w + \chi^U) \geq f(w) + f(\chi^U) > f(w)$, by (i) and (iv) (note that f is monotone by (i)). So $x_v < w_v + 1$ for some $v \in U$. By the maximality of x we know that $f(x + \chi^v) > f(x)$. Moreover, by induction, $\tau(H^{w-\chi^v}) \leq f(w - \chi^v)$, and hence

(79.18) $$\begin{aligned}\tau(H^w) &\leq 1 + \tau(H^{w-\chi^v}) \leq 1 + f(w - \chi^v) \leq 1 + f(x - \chi^v) \\ &\leq 1 + f(2x) - f(x + \chi^v) = 1 + 2f(x) - f(x + \chi^v) < 1 + f(x) = 1 + f(w),\end{aligned}$$

and hence, since $f(w) \in \mathbb{Z}$ we have $\tau(H^w) \leq f(w)$. ∎

This gives the following equivalent form of Theorem 79.4:

Corollary 79.6a. *Let $H = (V, \mathcal{E})$ be a hypergraph and let $w \in \mathbb{Z}_+^V$ be such that $\tau^*(H^x) \in \mathbb{Z}$ for each $x \leq w$. Then $\tau(H^w) = \tau^*(H^w)$.*

Proof. Define $f(x) := \tau^*(H^x)$ for $x \in \mathbb{Z}_+^V$ and apply Theorem 79.6. ∎

We also obtain a generalization of Theorem 79.2:

Corollary 79.6b. *Let $H = (V, \mathcal{E})$ be a hypergraph and let $w \in \mathbb{Z}_+^V$ be such that $\nu(H^x) = \frac{1}{2}\nu_2(H^x)$ for each $x \leq w + \mathbf{1}$. Then $\tau(H^w) = \nu(H^w)$.*

Proof. Define $f(x) := \nu(H^x)$ for $x \in \mathbb{Z}_+^V$ and apply Theorem 79.6. ∎

A special case of this is:

Corollary 79.6c. *Let $H = (V, \mathcal{E})$ be a hypergraph with $\nu_2(H^w) = 2\nu(H^w)$ for each $w : V \to \{0, 1, 2\}$. Then $\nu(H) = \tau(H)$.*

Proof. This follows by taking $w = \mathbf{1}$ in Corollary 79.6b. ∎

This gives a generalization to arbitrary k (instead of $k = 2$), since if $\nu(H) = \frac{1}{k}\nu_k(H)$ for some $k \geq 2$, then $\nu(H) = \frac{1}{k-1}\nu_{k-1}(H)$. This follows from

(79.19) $$\nu_{k-1}(H) \leq \nu_k(H) - \nu(H) = k \cdot \nu(H) - \nu(H) = (k-1)\nu(H).$$

Hence $\nu(H) = \frac{1}{2}\nu_2(H)$.

Another consequence of Theorem 79.6 is:

Corollary 79.6d. *For any hypergraph $H = (V, \mathcal{E})$ and any $k \in \mathbb{Z}_+$, the following are equivalent:*

(79.20) (i) *$\tau_k(H') = k \cdot \tau(H')$ for each restriction H' of H;*
(ii) *$\frac{1}{k}\tau_k(H') \in \mathbb{Z}$ for each restriction H' of H.*

Proof. Define $f(x) := \frac{1}{k}\tau_k(H^x)$ for $x \in \mathbb{Z}_+^V$ and apply Theorem 79.6 to $w = \mathbf{1}$. ∎

79.3e. Further notes

Seymour [1979a] gave the following example of an ideal hypergraph H with $\tau(H) \neq \frac{1}{2}\nu_2(H)$. Replace each edge of the Petersen graph by a path of length 2, making the graph G. Let $T := VG \setminus \{v\}$, where v is an arbitrary vertex of v of degree 3. Let $\mathcal{E}$ be the collection of T-joins. Let $T_{30} := (EG, \mathcal{E})$. Then $\tau(H') = \nu^*(H')$ for each parallelization H' of T_{30}, by Theorem 29.5. On the other hand, $\tau(T_{30}) = 2$ while G has no T-joins J_1, J_2, J_3, J_4 containing each edge of G at most twice. Otherwise, the sets $J_1 \triangle J_2$, $J_1 \triangle J_3$, and $J_1 \triangle J_4$ are cycles, together containing every edge of G precisely twice. Hence their complements give a 3-edge-colouring of the Petersen graph. This is not possible.

In this example, T_{30} is not only ideal, but also satisfies $\tau(b(T_{30})') = \frac{1}{2}\nu_2(b(T_{30})')$ for each parallelization $b(T_{30})'$ of $b(T_{30})$ (by Corollary 29.2a). Seymour [1981a] conjectures that T_{30} is the unique minor-minimal binary ideal hypergraph with the property $\nu_2 < 2\tau$.

P.D. Seymour (personal communication 1975) conjectures that for each ideal hypergraph H one has $\nu_k(H) = k \cdot \tau(H)$ where k is some power of 2. He also asks if $k = 4$ would do in all cases. Moreover, Seymour [1979a] conjectures that for each ideal hypergraph H, the g.c.d. of those k with $\nu_k(H) = k \cdot \tau(H)$ is equal to 1 or 2.

In Schrijver and Seymour [1979] it is shown that, for each hypergraph H there is an integer k such that $\nu_k(H') = \tau_k(H')$ for each parallelization H' of H.

Chapter 80

Binary hypergraphs

Several hypergraphs coming from graphs are binary. Binary hypergraphs are hypergraphs such that the symmetric difference of any odd number of edges contains an edge as subset.
Binary hypergraphs have a convenient algebraic structure, that enables to handle packing and blocking problems better than for general hypergraphs. Key result of this chapter is Seymour's characterization of binary Mengerian hypergraphs.

80.1. Binary hypergraphs

A hypergraph $H = (V, \mathcal{E})$ is called *binary* if

(80.1) for all odd s and $E_1, \ldots, E_s \in \mathcal{E}$ there is an $E \in \mathcal{E}$ with $E \subseteq E_1 \triangle \cdots \triangle E_s$.

Trivially, for each binary hypergraph $H = (V, \mathcal{E})$, the hypergraph $H^{\min}$ is again binary.

In previous chapters we have seen several examples of binary hypergraphs: given an undirected graph $G = (V, E)$, binary hypergraphs on E are formed by the odd circuits, by the complements of cuts, by the $s-t$ paths, by the $s-t$ cuts (given $s, t \in V$), by the T-joins, by the T-cuts (given $T \subseteq V$), and by the paths that connect either s_1 and t_1, or s_2 and t_2 (given $s_1, t_1, s_2, t_2 \in V$).

It is not difficult to show that the class of binary hypergraphs is closed under taking minors, parallelizations, and blockers (see also Section 80.3 below).

80.2. Binary hypergraphs and binary matroids

Binary hypergraphs have a strong linear algebraic structure over the field GF(2), and are strongly related to binary matroids. It will be good to understand these relations.

For a binary hypergraph $H = (V, \mathcal{E})$, a *cycle* is the symmetric difference of any number of edges of H. Call the cycle *odd* (*even*, respectively), if it is the symmetric difference of an odd (even, respectively) number of edges of H.

The odd cycles of H form again a binary hypergraph, say H'. By definition of binarity, the inclusionwise minimal edges of H' coincide with the inclusionwise minimal edges of H. So from a packing and blocking point of view there is no difference in considering any of the binary hypergraphs H, H', or $H^{\min}$.

If $\emptyset \not\in \mathcal{E}$, there is no cycle that is both odd and even. The even cycles form a subspace of the boolean space $\mathcal{P}(V)$, and (if $\emptyset \not\in \mathcal{E}$) the odd cycles form a cospace of it.

A clutter $H = (V, \mathcal{E})$ is binary if and only if there is a binary matroid $M = (V, \mathcal{I})$ such that, for some $B \subseteq V$:

(80.2) $\mathcal{E}$ is equal to the collection of circuits C of M with $|C \cap B|$ odd.

The matroid M is unique and is equal to the binary matroid whose circuits are the minimal nonempty cycles of H. The set B (generally) is not unique: any set B qualifies for it if and only if $|B \cap E|$ is odd for each $e \in E$.

Another way of obtaining a binary hypergraph H from a binary matroid $M = (V, \mathcal{I})$ is by choosing a vertex $v \in V$, and taking as edges of H the sets $C \setminus \{v\}$ where C is a circuit of M containing v. This hypergraph will be denoted by $H_{M,v}$ and is called a *matroid port*. Each binary clutter can be obtained in this way.

80.3. The blocker of a binary hypergraph

The following is an important observation:

(80.3) The blocker $b(H)$ of a binary hypergraph $H = (V, \mathcal{E})$ is equal to the collection of all inclusionwise minimal sets B satisfying $|B \cap E|$ odd for each $E \in \mathcal{E}$.

To see this, if $|B \cap E|$ is odd for each $E \in \mathcal{E}$, then B is a vertex cover, and hence it contains a set in $b(H)$. Conversely, if $B \in b(H)$, then $|B \cap E|$ is odd for each $E \in \mathcal{E}$. For suppose that $|B \cap E|$ is even. As B is a minimal vertex cover, for each $v \in B \cap E$ there is an $E_v \in \mathcal{E}$ with $E_v \cap B = \{v\}$. Then by (80.1) the symmetric difference of E and the sets E_v for $v \in B \cap E$ contains a set $F \in \mathcal{E}$. Then $F \cap B = \emptyset$, a contradiction.

This proves (80.3), which implies that:

(80.4) if H is binary, then $b(H)$ is binary; if H is a clutter, then: H is binary $\iff$ $b(H)$ is binary.

The second statement follows from the fact that $b(b(H)) = H$ if H is a clutter.

If $H = H_{M,v}$ for some binary matroid M and $v \in VM$, then the blocker satisfies $b(H_{M,v}) = H_{M^*,v}$.

80.3a. Further characterizations of binary clutters

Lehman [1964] and Seymour [1976b] gave further characterizations of binary clutters. They showed that the following are equivalent for any clutter $H = (V, \mathcal{E})$:

(80.5)
(i) H is binary, that is, satisfies (80.1);
(ii) for all $E_1, E_2, E_3 \in \mathcal{E}$ there is an $E \in \mathcal{E}$ with $E \subseteq E_1 \triangle E_2 \triangle E_3$;
(iii) $|B \cap E|$ is odd for all $E \in H$ and $B \in b(H)$;
(iv) $|B \cap E| \neq 2$ for all $E \in H$ and $B \in b(H)$;
(v) H has no minor equal to $P_4 := (\{1,2,3,4\}, \{\{1,2\},\{2,3\},\{3,4\}\})$ or to J_n for any $n \geq 3$ (defined in (78.12)).

(The equivalence of (i) and (iii) was shown by Lehman [1964], the equivalence of (i) and (ii) by A. Lehman (unpublished) and Seymour [1976b], and the other equivalences by Seymour [1976b].)

80.4. On characterizing binary ideal hypergraphs

Since the class of binary ideal hypergraphs is closed under taking minors, it can be characterized by specifying the collection of binary minimally nonideal hypergraphs. Seymour [1981a] offered the conjecture that this collection consists precisely of $\mathcal{O}(K_5)$, $b(\mathcal{O}(K_5))$, and F_7 (see (78.12)).

This conjecture is still open. As we saw in Sections 75.5 and 78.4a, the conjecture has been proved for the class of hypergraphs formed by the odd circuits of signed graphs, by Guenin [1998a,2001a]. For this class, only $\mathcal{O}(K_5)$ is a forbidden minor, since $b(\mathcal{O}(K_5))$ and F_7 do not arise in this way.

By Corollary 29.2b, the conjecture is also true for the class of hypergraphs of T-joins since neither of the three proposed forbidden minors comes from T-joins.

This was extended by Cornuéjols and Guenin [2002a] to binary hypergraphs without Q_6^+ or Q_7^+ minor. Here for any hypergraph $H = (V, \mathcal{E})$, the hypergraph H^+ arises by adding a new vertex u to V and by taking as edges all sets $E \cup \{u\}$ with $E \in \mathcal{E}$. The hypergraph Q_7 arises from Q_6^+ by adding as edges the perfect matchings of K_4.

This implies that for any regular matroid $M = (V, \mathcal{I})$ and any $\Sigma \subseteq V$, the collection of circuits C of M with $|C \cap \Sigma|$ odd, form a hypergraph for which Seymour's conjecture holds. Other cases where Seymour's conjecture holds were given by Guenin [2001c,2002c].

Adding an Eulerian condition. In Section 79.3e we saw that the following ideal hypergraph H does not satisfy $\nu_2(H) = 2\tau(H)$. Let G be obtained from the Petersen graph $\mathbf{P}_{10}$ by replacing each edge by a path of length 2. Let $T := VG \setminus \{v\}$ for some degree-3 vertex v of G. Let T_{30} be the hypergraph of T-joins on EG.

Seymour [1981a] conjectured that any binary ideal hypergraph $H = (V, \mathcal{E})$ without T_{30} minor satisfies $\frac{1}{2}\nu_2(H) = \tau(H)$. If moreover all edges of $b(H)$ have the same parity, then $\nu(H) = \tau(H)$. However, as A.M.H. Gerards and B. Guenin observed, the Petersen graph gives a simpler counterexample to the second conjecture: the hypergraph T_{15} of $V\mathbf{P}_{10}$-joins in $\mathbf{P}_{10}$ is a binary ideal hypergraph without T_{30} minor and having all edges of $b(T_{15})$ odd, while $\nu(T_{15}) = 2 < 3 = \tau(T_{15})$. This suggests the question if for each binary hypergraph $H = (V, \mathcal{E})$:

(80.6) (?) $\nu(H^w) = \tau(H^w)$ for each $w : V \to \mathbb{Z}_+$ with $w(B)$ even for all $B \in b(H) \iff \nu_2(H^w) = 2\tau(H^w)$ for each $w : V \to \mathbb{Z}_+ \iff H$ has no $\mathcal{O}(K_5)$, $b(\mathcal{O}(K_5))$, F_7, or T_{15} minor. (?)

80.5. Seymour's characterization of binary Mengerian hypergraphs

For binary Mengerian hypergraphs, the forbidden minors are known: Seymour [1977b] showed that the only binary minimally non-Mengerian hypergraph is $Q_6 = \mathcal{O}(K_4)$. In this section we give a proof based on Seymour [1977b] and on the short proof by Guenin [2002a].

Theorem 80.1. *A binary hypergraph is Mengerian if and only if it has no Q_6 minor.*

Proof. We have seen necessity in Section 79.2. We prove sufficiency.

Call a hypergraph $H = (V, \mathcal{E})$ *critical* if each vertex is contained in a vertex cover of size $\tau(H)$. Call a subset of V a *cycle* if it is a symmetric difference of edges, a *k-cycle* if it is a symmetric difference of k edges, an *even cycle* if it is a k-cycle for some even k, and a *circuit* if it is a minimal nonempty cycle. Call two vertices x, y *parallel* if $\{x, y\}$ is a 2-cycle. By the definition of binary hypergraph, for each cycle C and each edge E, the set $C \triangle E$ contains an edge. Hence, if x and y are parallel, then for any inclusionwise minimal edge F of H with $x \in F$, one has $y \notin F$ and $(F \setminus \{x\}) \cup \{y\}$ is again an edge. So any minimal vertex cover containing x also contains y.

To see sufficiency, it suffices to show that $\nu(H) = \tau(H)$ for each binary hypergraph without Q_6 minor (since the class of binary hypergraphs without Q_6 minor is closed under parallelization). Choose a counterexample $H = (V, \mathcal{E})$ to this with $|V|$ minimal. So H has no Q_6 minor while $\nu(H) < \tau(H)$. Choose H moreover such that the number of pairs of parallel elements is as large as possible.

Note that the minimality of V implies that H is critical (as any vertex that belongs to no minimum-size vertex cover can be deleted to obtain a smaller counterexample). Define $\tau := \tau(H)$ and, for each $v \in V$ define:

(80.7) $\beta_v := \{B \mid B \text{ vertex cover}, |B| = \tau, v \in B\}$.

Define U to be the set of vertices u with β_u inclusionwise minimal:

(80.8) $U := \{u \mid \text{there is no } v \in V \text{ with } \beta_v \subset \beta_u\}$.

So U is nonempty. Note that if u and v are parallel, then $\beta_u = \beta_v$. Let M be the set of pairs of nonparallel elements u, v in U with $\beta_u = \beta_v$. Then:

(80.9) each element $u \in U$ is contained in a pair in M.

Suppose not. By the minimality of V, $\nu(H \setminus u) = \tau(H \setminus u) = \tau - 1$ (since $\tau - 1 \leq \tau(H \setminus u) = \nu(H \setminus u) \leq \nu(H) < \tau$). So $V \setminus \{u\}$ contains a subset Y that is the union of $\tau - 1$ disjoint edges of H. So Y is a $(\tau - 1)$-cycle.

Let K be the parallel class of u. By the minimality of V, $\nu(H/K) = \tau(H/K) \geq \tau$. So $V \setminus K$ contains a collection $\mathcal{F}$ of disjoint edges of H/K with $|\mathcal{F}| = \tau$. Then $\mathcal{F}$ partitions $V \setminus K$, since for each $v \in V \setminus K$ there exists a $B \in \beta_v \setminus \beta_u$ (since $\beta_v \not\subseteq \beta_u$, as u is contained in no pair in M, by assumption). So $u \notin B$, hence $B \cap K = \emptyset$. As $|B| = \tau$, B intersects each edge in $\mathcal{F}$ precisely once. Hence $\mathcal{F}$ covers v. Concluding, $\mathcal{F}$ partitions $V \setminus K$.

This implies that $V \setminus K$ is contained in some τ-cycle L. So $L \triangle Y$ is a $(2\tau - 1)$-cycle, and hence contains a minimal edge E of H. As K is a parallel class, $|E \cap K| \leq 1$. If $E \cap K = \emptyset$ let $E' := E$; if $E \cap K \neq \emptyset$, let $E' := (E \setminus K) \cup \{u\}$. Then E' is disjoint from Y, so $\nu(H) \geq \tau$, contradicting our assumption. This proves (80.9).

Next:

(80.10) each pair $e \in M$ contains a vertex u such that H has edges $E_1, \ldots, E_\tau$ with $E_1 \cap E_2 = \{u\}$ and with $E_1 \setminus \{u\}, E_2 \setminus \{u\}, E_3, \ldots, E_\tau$ partitioning $V \setminus e$.

Indeed, let $e = \{u, v\}$ be such that u has at least as many parallel elements as v has. Let $\widetilde{H}$ be obtained from H by deleting v and adding an extra parallel element to u (that is, we duplicate u). This increases the number of pairs of parallel elements. So, by the choice of H, $\nu(\widetilde{H}) = \tau(\widetilde{H})$. Moreover, since $\beta_u = \beta_v$, we have that $\tau(\widetilde{H}) = \tau$ and $\widetilde{H}$ is critical. So $V\widetilde{H}$ can be partitioned into τ edges of $\widetilde{H}$. This gives (80.10).

A consequence of (80.10) is that $V \setminus e$ is a τ-cycle of H. Hence

(80.11) $e \triangle f$ is an even cycle of H, for all $e, f \in M$,

since $e \triangle f = (V \setminus e) \triangle (V \setminus f)$.

Now fix a pair $e \in M$, and let $u, E_1, \ldots, E_\tau$ be as in (80.10). Then

(80.12) $E_1 \triangle E_2$ contains no edge E of H,

since otherwise replacing E_1 and E_2 by E and $E_1 \triangle E_2 \triangle E$ would show $\nu(H) \geq \tau$.

Let H' be a smallest minor of H such that $H' = H \setminus Y / X$ for some disjoint subsets X, Y of $E_1 \triangle E_2$ and such that, defining $C := (E_1 \triangle E_2) \setminus (X \cup Y)$:

(80.13) (i) $X \cup Y$ is a union of circuits of H;
(ii) C is a cycle of H';
(iii) $C \cup \{u\}$ contains an edge of H';
(iv) $\tau(H') \geq \tau$;

(v) each edge E of H' contained in $C \cup \{u\}$ satisfies $\tau(H' \setminus E) \leq \tau - 2$.

Such an H' exists, since H has these properties. Then:

Claim 1. C is a circuit of H'.

Proof of Claim 1. Suppose that C is not a circuit of H'. Then, as C is a cycle, C can be partitioned into two nonempty cycles C_1 and C_2 of H'. By (80.12), C_1 and C_2 are even cycles.

Define

(80.14) $\quad H_1 := H'/C_2.$

We show that H_1 satisfies (80.13)(i)-(iv).

To see (80.13)(i) for H_1, $X \cup Y \cup C_2$ is a union of cycles of H, since $C_2 = C' \setminus (X \cup Y)$ for some cycle C' of H. To see (80.13)(ii) for H_1, C_1 is a cycle of H', hence also of H_1. To see (80.13)(iii) for H_1, $C \cup \{u\}$ contains an edge of H', hence $C_1 \cup \{u\} = (C \cup \{u\}) \setminus C_2$ contains an edge of H_1. To see (80.13)(iv) for H_1, we have $\tau(H'/C_2) \geq \tau(H') \geq \tau$.

So H_1 satisfies (80.13)(i)-(iv). Hence, by the minimality of H', H_1 has an edge $E \subseteq C_1 \cup \{u\}$ with $\tau(H_1 \setminus E) \geq \tau - 1$. Define $P := E \setminus \{u\}$, $Q = C_1 \setminus E$, and

(80.15) $\quad H_2 := H' \setminus P/Q.$

We show that H_2 satisfies (80.13), which contradicts the minimality of H'. To see (80.13)(i) for H_2, $X \cup Y \cup C_1$ is a union of circuits of H, since $C_1 = C' \setminus (X \cup Y)$ for some cycle C' of H. To see (80.13)(ii) for H_2, C_2 is a cycle of H', hence also of H_2. To see (80.13)(iii) for H_2, $E = E' \setminus C_2$ for some edge E' of H'. Then $E' \triangle C_1$ contains an edge E'' of H'. Then $E'' \cap P = \emptyset$, since $E' \triangle C_1$ is disjoint from P (as $P \subseteq E' \cap C_1$). So $E'' \setminus Q = E'' \setminus C_1 \subseteq (E' \triangle C_1) \setminus C_1 \subseteq C_2 \cup \{u\}$. This proves (80.13)(iii) for H_2.

To see (80.13)(iv) for H_2, suppose to the contrary that B is a minimum-size vertex cover of H_2 of size $\leq \tau - 1$. Then B intersects each of $E_3, \ldots, E_\tau$ at least once, and hence does not intersect C_2 (as $|B \cap C_2|$ is even). So B is a vertex cover of H_2/C_2. As $C_2 \cup \{u\}$ contains an edge of H_2, we also know that $u \in B$. So $B \setminus \{u\}$ is a vertex cover of $H_2/C_2 \setminus \{u\} = H' \setminus E/(C_2 \cup Q) = H_1 \setminus E/Q$, and hence of $H_1 \setminus E$. This contradicts the fact that $\tau(H_1 \setminus E) \geq \tau - 1$. So H_2 satisfies (80.13)(iv).

To see (80.13)(v) for H_2, let F be an edge of H_2 contained in $C_2 \cup \{u\}$. As $H_2 = H' \setminus P/Q$, there exists a $Q' \subseteq Q$ such that $F \cup Q'$ is an edge of H'.

Suppose that $Q' \neq Q$. Choose $r \in Q \setminus Q'$. Let B be a vertex cover of H of size τ containing r. Then B intersects each of $E_3, \ldots, E_\tau$ at least once. As $r \in B$, B intersects $E_1 \triangle E_2$ at least once, hence at least twice (as $E_1 \triangle E_2$ is an even cycle). Hence, as $|B| = \tau$, $u \notin B$ and B intersects each E_i in precisely one element. Moreover, B is disjoint from $C_2 \cup X \cup Y$, as this last set is a union of circuits of H, implying that if B intersects $C_2 \cup X \cup Y$ at least once, then at least twice; since $r \notin C_2 \cup X \cup Y$, this is not possible. So B is a vertex cover of H_1. Hence $B \cap E \neq \emptyset$. So B contains a second element in C_1, say s. As $F \cup Q' \cup X$ contains an edge of H, it intersects B. So $s \in Q'$. This would mean that B is disjoint from E, a contradiction.

So $Q' = Q$. Then $R := F \cup P = (F \cup Q) \triangle C_1$ contains an edge of H'. By (80.13)(v), $H' \setminus R$ has a vertex cover B of size $\tau - 2$. As B intersects each of $E_3, \ldots, E_\tau$, B is disjoint from Q. So B is a vertex cover of $H' \setminus R/Q = H_2 \setminus F$, proving $\tau(H_2 \setminus F) \leq \tau - 2$. So H_2 satisfies (80.13)(v), contradicting the minimality of H'. *End of Proof of Claim 1*

By (80.13)(ii)(iii), H' has edges F_1, F_2 with $F_1 \cap F_2 = \{u\}$ and $F_1 \cup F_2 = C \cup \{u\}$. By (80.13)(v), there exist vertex covers B_1 and B_2 of H' with $|B_i \setminus F_i| \leq \tau - 2$. So $B_1 \cap F_2 = B_2 \cap F_1 = \{u\}$. Then

(80.16) H' has an edge F_3 disjoint from $(B_1 \setminus F_1) \cup (B_2 \setminus F_2) \cup \{u\}$.

Otherwise, the latter set contains a minimal vertex cover B of H'. Now each B_i intersects each of the edges $E_3, \ldots, E_\tau$ precisely once. So B intersects each of these E_i at most twice, hence precisely once. Therefore $|B| \leq \tau - 1$, contradicting (80.13)(iv). This proves (80.16).

Choose F_3 in (80.16) with $F_3 \setminus C$ minimal. Let H'' arise from H' by deleting all vertices not in $F_1 \cup F_2 \cup F_3$. Then $\tau(H'') \geq 2$, since $F_1 \cap F_2 \cap F_3 = \{u\} \cap F_3 = \emptyset$. Moreover, $\nu(H'') = 1$, for suppose that H'' has disjoint edges F and F', with $u \notin F$. By the minimality of $F_3 \setminus C$ we know that $F \setminus C = F_3 \setminus C$. So $F' \subseteq C \cup \{u\}$. But then, since C is a circuit, $F' = F_1$ or $F' = F_2$ (otherwise $F' \triangle F_1$ is a nonempty cycle properly contained in C). However, F intersects B_1 and B_2, hence F intersects $B_1 \cap F_1$ and $B_2 \cap F_2$, and hence it intersects F_1 and F_2, a contradiction. So $\nu(H'') = 1 < \tau(H'')$.

The minimality of H implies $H'' = H' = H$ and $\tau = 2$. The equality $\tau = 2$ implies that $U = V$ and M forms a perfect matching on V: if $v \in V \setminus U$, then $\beta_u \subset \beta_v$ for some $u \in U$, and hence (using (80.9)) any minimum-size vertex cover containing u has at least three elements — a contradiction, since $\tau = 2$; similarly, if $u \in V$ would be in two pairs in M, there is a minimum-size vertex cover of size ≥ 3 — again a contradiction.

Also, $V \setminus e = E_1 \triangle E_2 = F_1 \triangle F_2$, whence it is a circuit (by Claim 1). As any two pairs from M form an even cycle (by (80.11)), we know $|V \setminus e| = 4$. So $|V| = 6$, $|M| = 3$, giving $H = Q_6$. ∎

Notes. Tseng and Truemper [1986] gave a decomposition theorem for binary Mengerian hypergraphs. It implies that the property of being Mengerian belongs to NP for binary hypergraphs. Shorter proofs of the decomposition result were given by Bixby and Rajan [1989] and Truemper [1987]. The latter paper also gives polynomial-time algorithms for testing Mengerity of a binary hypergraph and for finding a minimum-weight vertex cover and a maximum packing of edges subject to a weight function in binary Mengerian hypergraphs. A description of this algorithm was given in Bixby and Cunningham [1995]. Also Hartvigsen and Wagner [1988] gave a polynomial-time algorithm to test Mengerity of a binary hypergraph.

More background can be found in the book of Truemper [1992].

80.5a. Applications of Seymour's theorem

We describe a number of applications of Theorem 80.1, some of which we have seen in previous parts of this book. Except for those in the first two applications below, the theorems are due to Seymour [1977b].

$s-t$ cuts. Let $G = (V, E)$ be a graph and let $s, t \in V$. The collection of $s-t$ cuts forms a binary hypergraph on E, without Q_6 minor. Hence Theorem 80.1 implies the edge-disjoint version of (the easy) Theorem 6.1: the maximum number of edge-disjoint $s-t$ cuts is equal to the minimum length of an $s-t$ path (the max-potential min-work theorem).

$s-t$ paths. Let $G = (V, E)$ be a graph and let $s, t \in V$. The collection of $s-t$ paths forms a binary hypergraph on E, without Q_6 minor. Hence Theorem 80.1 implies the edge-disjoint undirected version of Menger's theorem (Corollary 9.1b): the maximum number of edge-disjoint $s-t$ paths is equal to the minimum size of an $s-t$ cut.

***T*-cuts.** Let $G = (V, E)$ be a graph and let $T \subseteq V$. The collection of T-cuts forms a binary hypergraph on E. If it is Q_6, then $G = K_4$ and $T = VK_4$. Hence Theorem 80.1 implies Corollary 29.9a: If K_4, VK_4 is not a minor of G, T (in the sense of Section 29.11b), then the minimum size of a T-join is equal to the maximum number of disjoint T-cuts.

***T*-joins.** Let $G = (V, E)$ be a graph and let $T \subseteq V$. The collection of T-joins forms a binary hypergraph on E. If it is Q_6, then $G = K_{2,3}$ and $T = VK_{2,3} \setminus \{u\}$, where u is a vertex of degree 3. Hence Theorem 80.1 implies Theorem 29.10: If $K_{2,3}, VK_{2,3} \setminus \{u\}$ is not a minor of G, T (in the sense of Section 29.11b), then the minimum size of a T-cut is equal to the maximum number of disjoint T-joins.

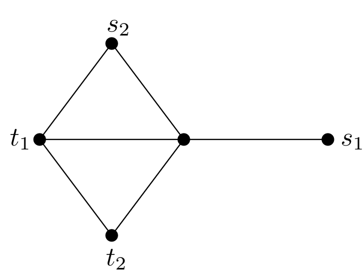

Figure 80.1
s_1 and t_1, and s_2 and t_2, have distance 2, but there exist no two disjoint cuts each separating both s_1 and t_1, and s_2 and t_2.

***$s_1 - t_1$* and *$s_2 - t_2$* cuts.** Let $G = (V, E)$ be a graph and let $s_1, t_1, s_2, t_2 \in V$. The collection of cuts that separate *both* s_1 and t_1, *and* s_2 and t_2 forms a binary hypergraph on E. If it is Q_6, then G is the graph in Figure 80.1 up to permuting indices and exchanging s_1 and t_1. Hence Theorem 80.1 implies Theorem 71.4: if G has no subgraph contractible to the graph in Figure 80.1 up to permuting indices and exchanging s_1 and t_1, then the minimum length of a path connecting either s_1 and t_1, or s_2 and t_2 is equal to the maximum number of pairwise disjoint cuts each separating both s_1 and t_1, and s_2 and t_2. (Here we assume that the subgraph contains the s_i, t_i, and that these vertices are contracted to the vertices indicated by s_i and t_i in the figure.)

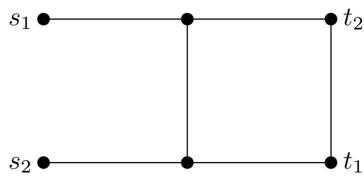

Figure 80.2
The maximum total value of a 2-commodity flow (subject to capacity 1) is equal to 2, but the maximum total value of an integer 2-commodity flow is equal to 1.

***$s_1 - t_1$* and *$s_2 - t_2$* paths.** Let $G = (V, E)$ be a graph and let $s_1, t_1, s_2, t_2 \in V$. The collection of paths that connect *either* s_1 and t_1, *or* s_2 and t_2 forms a binary hypergraph on E. If it is Q_6, then it is the graph of Figure 80.2 up to exchanging s_1 and t_1, and s_2 and t_2. Hence Theorem 80.1 implies Theorem 71.2: If G has no subgraph contractible to the graph of Figure 80.2 up to exchanging s_1 and t_1, and s_2 and t_2, then the maximum number of edge-disjoint paths, each connecting either s_1 and t_1, or s_2 and t_2, is equal to the minimum size of a cut separating both s_1 and t_1, and s_2 and t_2.

Odd circuits. Let $G = (V, E, \Sigma)$ be a signed graph; that is $G = (V, E)$ is an undirected graph and $\Sigma \subseteq E$. Call a circuit C *odd* if $|C \cap \Sigma|$ is odd. The collection of odd circuits forms a binary hypergraph on E. If it is Q_6, then $G = (V, E, \Sigma)$ is the odd-K_4; that is, $V = VK_4$ and $E = \Sigma = EK_4$. Hence Theorem 80.1 implies Corollary 75.3a: if $G = (V, E, \Sigma)$ has no odd-K_4 minor, then the maximum number of edge-disjoint odd circuits is equal to the minimum size of an odd circuit cover. In other words, if $G = (V, E, \Sigma)$ has no odd-K_4 minor, then G is strongly bipartite.

Odd circuit covers. Let $G = (V, E, \Sigma)$ be a signed graph. The collection of inclusionwise minimal odd circuit covers forms a binary hypergraph on E. If it is Q_6, then $G = K_3^2$ and $\Sigma = \Delta$, where Δ is a triangle in K_3^2. Here K_3^2 is the graph with three vertices, each pair of which connected by two parallel edges. Hence Theorem 80.1 implies: if $G = (V, E, \Sigma)$ has no (VK_3^2, EK_3^2, Δ) as minor, then the maximum number of edge-disjoint odd circuit covers is equal to the minimum length of an odd circuit.

Notes. Gan and Johnson [1989] developed a framework that includes the above examples on T-joins, T-cuts, odd circuits, and odd circuit covers, and derived algorithms for the corresponding optimization problems.

80.6. Mengerian matroids

Seymour's characterization of binary Mengerian hypergraphs implies a full characterization of matroids that have the corresponding matroidal Mengerian property. In this case, we need not restrict the characterization to binary matroids, since binarity of the matroid *follows* from the Mengerian property.

Again, for any matroid $M = (V, \mathcal{I})$ and any $v \in V$, let $H_{M,v}$ be the hypergraph on $V \setminus \{v\}$ with edges all sets $C \setminus \{v\}$, where C is a circuit of M containing v. Call M *Mengerian* if $H_{M,v}$ is a Mengerian hypergraph for each $v \in V$.

Theorem 80.1 implies the following conjecture of Th. Chang of the late 1960s (cf. Seymour [1977b]):

Corollary 80.1a. *A matroid is Mengerian if and only if it is binary and has no F_7^* minor.*

Proof. As the 2-uniform matroid U_4^2 on 4 elements and F_7^* are not Mengerian (since $H_{M,v} = K_3$ or $H_{M,v} = Q_6$ for these matroids), necessity follows (using the fact that each matroid without U_4^2 minor is binary (Theorem 39.4)). To see sufficiency, observe that, if $M = (V, \mathcal{I})$ is a binary matroid, then for each $v \in V$, the hypergraph $H_{M.v}$ is binary, and that if M contains no F_7^* minor (in the matroidal sense), then $H_{M,v}$ contains no Q_6 minor (in the hypergraphical sense). ∎

Notes. As was outlined by Seymour [1980a,1981a] and Bixby [1982], there is an easier direct proof of this corollary, based on the fact that binary matroids without F_7^* minor can be decomposed into regular matroids (coming from totally unimodular matrices) and copies of F_7. (This follows from the 'splitter theorem' of Seymour [1980a].)

Mengerity of regular matroids follows from the total unimodularity of the matrix representing the matroid, as was shown by Gallai [1959b] (and also by Minty [1966] (an alternative proof was given by Fulkerson [1968])).

Bixby [1982] described that this decomposition gives a polynomial-time algorithm finding the optima in Corollary 80.1a. For background we refer to the book of Truemper [1992].

80.6a. Oriented matroids

Matroids generalize *undirected* graphs, and one may ask for an extension of matroid theory to include directed structures, in order to investigate the max-flow min-cut theorem in greater generality. Bland and Las Vergnas [1978] and Folkman and Lawrence [1978], following work of Minty [1966], Fulkerson [1968], Rockafellar [1969], and Lawrence [1975], developed a theory of oriented matroids. It may be seen as the abstraction of a linear subspace of $\mathbb{R}^n$; the abstraction of any vector is a $\{0,+1,-1\}$ vector, having 0, +1, or -1 in the positions where the original vector has a zero, positive, or negative entry, respectively. If we have a digraph $D = (V, A)$ and we take as $\{0,+1,-1\}$ vectors all $x \in \{0,\pm 1\}^A$ for which there is an undirected circuit C with $x_a = 1$ for forward arcs a of C, $x_a = -1$ for backward arcs a of C, and $x_a = 0$ for all other arcs a, then we obtain an oriented matroid. Again, one may define the Mengerian property for oriented matroids; its characterization by excluded minors is unsolved.

More on oriented matroids can be found in Bachem and Kern [1992] and Björner, Las Vergnas, Sturmfels, White, and Ziegler [1993].

A different approach to extending Menger's theorem to matroids was given by Tutte [1965b] — see Section 41.5a.

80.7. Further results and notes

80.7a. $\tau_2(H) = 2\tau(H)$ for binary hypergraphs H

Lovász [1975a] showed:

Theorem 80.2. *$\tau_2(H) = 2\tau(H)$ for each binary hypergraph H.*

Proof. Let x be a minimum-size 2-vertex cover of H. Let $U := \{v \in V \mid x_v = 0\}$ and $W := \{v \in V \mid x_v = 2\}$. Let $H' := H/U \setminus W$ and $V' := V \setminus (U \cup W)$. Then H' is binary and each edge of H' has size at least 2, since for any edge F of H' there is an edge E of H with $E \cap W = \emptyset$ and $E \setminus U = F$. Then $|F| = x(E) \geq 2$.

As $r_{\max}(H') \geq 2$, for each $v \in V'$ there is a $B \in b(H')$ with $v \notin B$. Consider now the cospace

(80.17) $$\mathcal{C} := \{B \subseteq V' \bigm| |B \cap F| \text{ is odd for each edge } F \text{ of } H'\}.$$

Then for each $v \in V'$ there is a $B \in \mathcal{C}$ with $v \notin B$. As $\mathcal{C}$ is a cospace, it follows that v is in at most half of the sets in $\mathcal{C}$. As this is true for each $v \in V'$, $\mathcal{C}$ contains a set B of size at most $\frac{1}{2}|V'|$. Then $W \cup B$ is a vertex cover of H of size at most $\frac{1}{2}x(V) = \frac{1}{2}\tau_2(H)$. So $\tau(H) \leq \frac{1}{2}\tau_2(H)$ as required. ∎

Lovász [1975a] showed more generally:

Theorem 80.3. *Let $H = (V, \mathcal{E})$ be a hypergraph such that*

(80.18) *if $X, Y, Z \in \mathcal{E}$, $y \in (X \cap Y) \setminus Z$ and $z \in (X \cap Z) \setminus Y$, then there is an $F \in \mathcal{E}$ satisfying $F \subseteq (X \cup Y \cup Z) \setminus \{y, z\}$.*

Then $\tau_2(H) = 2\tau(H)$.

Proof. Consider a counterexample with $|V|$ minimal. Let x be a minimum-size 2-vertex cover of H. Then

(80.19) $$x_v = 1 \text{ for each } v \in V.$$

For if $x_v = 0$, then $x|V \setminus \{v\}$ is a 2-vertex cover of H/v, and hence, since H/v again satisfies (80.18):

(80.20) $$2\tau(H) \leq 2\tau(H/v) = \tau_2(H/v) \leq x(V \setminus \{v\}) = x(V) = \tau_2(H),$$

contradicting the fact that H is a counterexample. Similarly, if $x_v = 2$, then $x|V\setminus\{v\}$ is a 2-vertex cover of $H \setminus v$, and hence, since $H \setminus v$ again satisfies (80.18):

(80.21) $$2\tau(H) \leq 2\tau(H\setminus v)+2 = \tau_2(H\setminus v)+2 \leq x(V\setminus\{v\})+2 = x(V) = \tau_2(H),$$

again contradicting the fact that H is a counterexample.

This proves (80.19). Hence $|E| \geq 2$ for each $E \in \mathcal{E}$ and we must show that there is a vertex cover of size $\leq \frac{1}{2}|V|$. By the minimality of x, there is an edge X of size 2 (otherwise we can reset $x_v := 0$ for some $v \in V$), say $X = \{y, z\}$. Then $\tau_2(H \setminus \{y, z\}) \leq |V| - 2 = \tau_2(H) - 2$, and so, by the minimality of $|V|$:

(80.22) $$\tau(H \setminus \{y, z\}) = \tfrac{1}{2}\tau_2(H \setminus \{y, z\}) \leq \tfrac{1}{2}\tau_2(H) - 1 < \tau(H) - 1,$$

and hence $\tau(H \setminus \{y, z\}) \leq \tau(H) - 2$. Let $U \subseteq V \setminus \{y, z\}$ be a minimum-size vertex cover of $H \setminus \{y, z\}$. Since $U \cup \{y\}$ and $U \cup \{z\}$ are not vertex covers of H (since $\tau(H) \geq |U| + 2$), there are edges Y and Z in H disjoint from $U \cup \{z\}$ and $U \cup \{y\}$ respectively. As $U \cup \{y, z\}$ does intersect all edges, we know $y \in Y$ and $z \in Z$. Then X, Y, Z contradict (80.18). ∎

Condition (80.18) is closed under taking minors. The hypergraph $(\{1, 2\}, \{\{1\}, \{2\}, \{1, 2\}\})$ is the unique minor-minimal hypergraph violating (80.18).

80.7b. Application: T-joins and T-cuts

Let $G = (V, E)$ be an undirected graph and let $T \subseteq V$ with $|T|$ even. Let $\mathcal{C}$ be the collection of T-cuts. Then $H = (E, \mathcal{C})$ is a binary hypergraph, and its blocker consists of the minimal T-joins.

We will derive

(80.23) $\nu_2(H) = 2\tau(H)$, and $\nu(H) = \tau(H)$ if G is bipartite,

from general hypergraph theory and from the result that

(80.24) $\nu_2(H) = 2\nu(H)$ if G is bipartite

(Seymour [1981d]).

We first give Seymour's proof of (80.24). Let $U_1, \ldots, U_t$ be subsets of V with each $|U_i \cap T|$ odd such that each edge of G is in at most two of the $\delta(U_i)$ and such that $t = \nu_2(H)$. Such U_i exist by the definition of $\nu_2(H)$. Choose them such that

(80.25) $$\sum_{i=1}^{t} |U_i||V \setminus U_i|$$

is as small as possible. Then the U_i are *cross-free*, that is, for all $i, j = 1, \ldots, t$ one has

(80.26) $$U_i \subseteq U_j \text{ or } U_j \subseteq U_i \text{ or } U_i \cap U_j = \emptyset \text{ or } U_i \cup U_j = V.$$

If this would not hold, we can replace U_i and U_j either by $U_i \cap U_j$ and $U_i \cup U_j$ (if $|U_i \cap U_j \cap T|$ is odd) or by $U_i \setminus U_j$ and $U_j \setminus U_i$ (otherwise), therewith decreasing the sum (80.25) — a contradiction.

So (80.26) holds. By symmetry, we can assume that $|U_i| \leq |V \setminus U_i|$ for each i. If each U_i is a singleton, then the U_i form a 2-stable set in the subgraph $G[T]$ induced by T, and hence $G[T]$ has a stable set of size at least $\frac{1}{2}t$ (as $G[T]$ is bipartite). This implies $\nu(H) \geq \frac{1}{2}\nu_2(H)$.

If some U_i is a singleton and $U_i = U_j$ for some $j \neq i$, we can contract $\delta(U_i)$ and obtain a bipartite graph $G' = (V', E')$ and $T' \subseteq V'$, and a 2-packing of T'-cuts of G' of size $t-2$. Hence, inductively, G' has a packing of T-cuts of size at least $\frac{1}{2}(t-2)$. With $\delta(U_i)$ this gives a packing of T cuts in G, of size at least $\frac{1}{2}t$.

So we can assume that each singleton occurs at most once among the U_i and that not each U_i is a singleton. Then we can assume that U_1 is a minimal nonsingleton set among the U_i. Let $U_2, \ldots, U_r$ be the sets properly contained in U_1. So $U_2, \ldots, U_r$ are singletons from $T \cap U_1$. Hence $r - 1 \leq |T \cap U_1|$. As $|T \cap U_1|$ is odd and G is bipartite, there is a stable set $S \subseteq T \cap U_i$ with $2|S| \geq |T \cap U_i| + 1 \geq r$. Replacing $U_1, \ldots, U_r$ by twice the singletons from S, gives a 2-packing of t T-cuts with smaller sum (80.25) — a contradiction. This proves (80.24).

Now (80.24) implies:

(80.27) $\qquad \nu_4(H) = 2\nu_2(H)$ for any graph G.

Indeed, replace each edge by a path of length 2, thus obtaining the bipartite graph $G' = (V', E')$, with $T \subseteq V'$. Let H' be the corresponding hypergraph of T-cuts. Then by (80.24):

(80.28) $$\nu_4(H) = \nu_2(H') = 2\nu(H') = 2\nu_2(H),$$

which is (80.27).

As the class of hypergraphs H obtained in this way from graphs is closed under parallelization (since it corresponds to replacing edges by paths), Corollary 79.5a then implies $\nu_2(H) = \tau_2(H)$. Hence, with Theorem 80.2 we obtain $\nu_2(H) = 2\tau(H)$, and, using (80.24), we have (80.23).

80.7c. Box-integrality of $k \cdot P_H$

A polyhedron P is called *box-integer* if for all $c, d \in \mathbb{Z}^V$, the polytope

(80.29) $$P \cap \{x \in \mathbb{R}^V \mid d \leq x \leq c\}$$

is integer. Gerards and Laurent [1995] showed that the following are equivalent for any binary hypergraph $H = (V, \mathcal{E})$, where P_H is defined by (78.1):

(80.30)
(i) $k \cdot P_H$ is box-integer for each $k \geq 1$;
(ii) $k \cdot P_H$ is box-integer for some $k \geq 2$;
(iii) H has no Q_6 or $b(Q_6)^+$ minor.

As in Section 80.4, the hypergraph H^+ arises from a hypergraph $H = (V, \mathcal{E})$ by adding a new vertex, u say, and taking as edges all sets $F \cup \{u\}$ for $F \in \mathcal{E}$.

This characterization extends results of Laurent and Poljak [1995b] for the bipartite subgraph polytope.

Chapter 81

Matroids and multiflows

Corollary 80.1a gives a forbidden minor characterization of matroids for which the corresponding generalization of the integer max-flow min-cut theorem holds. Seymour [1981a] showed that several theorems on multiflows can be generalized similarly to the level of matroids. We give a survey of these results, without proofs.

81.1. Multiflows in matroids

Let $M = (E, \mathcal{I})$ be a matroid, let $R \subseteq E$, and let $c : E \to \mathbb{R}_+$. Let $\mathcal{C}_R$ be the collection of circuits C of M with $|C \cap R| = 1$.

The *multiflow problem* in M asks for a function $y : \mathcal{C}_R \to \mathbb{R}_+$ satisfying

(81.1)
$$\sum_{\substack{C \in \mathcal{C}_R \\ e \in C}} y_C \geq c_e \quad \text{if } e \in R,$$
$$\sum_{\substack{C \in \mathcal{C}_R \\ e \in C}} y_C \leq c_e \quad \text{if } e \in E \setminus R.$$

We call any y satisfying (81.1) a *multiflow* in M (relative to R and c). So R plays the role of the 'demand edges', and $E \setminus R$ the role of the 'supply edges'.

The corresponding *cut condition* is:

(81.2) (cut condition) $c(D \cap R) \leq c(D \setminus R)$ for each cocircuit D of M.

This condition is necessary for the existence of a multiflow y, since

(81.3)
$$c(D \cap R) \leq \sum_{C \in \mathcal{C}_R} y_C |C \cap D \cap R| \leq \sum_{C \in \mathcal{C}_R} y_C |C \cap D \setminus R| \leq c(D \setminus R).$$

Here we use that $|C \cap D| \neq 1$ for any circuit C and cocircuit D, implying $|C \cap D \cap R| \leq |C \cap D \setminus R|$ if $|C \cap R| = 1$.

In this terminology, Corollary 80.1a can be formulated as:

(81.4) for each $R \subseteq E$ with $|R| = 1$ and each $c : E \to \mathbb{Z}_+$, the cut condition implies the existence of an integer multiflow $\iff$ M has no U_4^2 or F_7^* minor.

So Corollary 80.1a concerns integer 1-commodity flows in a matroid.

Let $k \in \mathbb{Z}_+$. Seymour [1981a] called a matroid $M = (V, \mathcal{I})$ *k-flowing* if

(81.5) for each $R \subseteq E$ with $|R| \leq k$ and for each $c : E \to \mathbb{R}_+$, the cut condition implies the existence of a multiflow y.

The matroid is *integer k-flowing* if for integer c we can take y integer.

As was the case for multiflows in graphs, the following *Euler condition* (for $c : E \to \mathbb{Z}_+$) will turn out to be helpful:

(81.6) (Euler condition) $c(D)$ is even for each cocircuit D.

M is called *k-cycling* if

(81.7) for each $R \subseteq E$ with $|R| \leq k$ and for each $c : E \to \mathbb{Z}_+$, the cut and Euler condition implies the existence of an integer multiflow y.

For each k, there are the following direct implications:

(81.8) integer k-flowing $\Longrightarrow$ k-cycling $\Longrightarrow$ k-flowing.

As Seymour [1981a] showed, for each fixed $k \geq 2$ the concepts of k-cycling and k-flowing are equivalent.

M is called *∞-flowing*, *integer ∞-flowing*, *∞-cycling*, respectively, if M is k-flowing, integer k-flowing, k-cycling, respectively, for each k. Seymour [1981a] showed that the concepts of 4-flowing, 4-cycling, ∞-flowing, and ∞-flowing are equivalent.

We will now discuss Seymour's results in some greater detail.

81.2. Integer k-flowing

By definition, a matroid is integer 1-flowing if and only if M is Mengerian (Section 80.6). Corollary 80.1a therefore characterizes integer 1-flowing matroids, by forbidding U_4^2 and F_7^* as minors.

Also for other values of k, a forbidden minor characterization of binary integer k-flowing matroids is known. In fact, Seymour [1981a] proved that for binary matroids, the concepts of integer ∞-flowing and integer 2-flowing coincide:

Theorem 81.1. *For any binary matroid $M = (E, \mathcal{I})$ the following are equivalent:*

(81.9) (i) *M is integer ∞-flowing, that is, for each $R \subseteq E$ and each $c : E \to \mathbb{Z}_+$, the cut condition implies the existence of an integer multiflow;*

(ii) *M is integer 2-flowing, that is, for each $R \subseteq E$ with $|R| \leq 2$ and each $c : E \to \mathbb{Z}_+$, the cut condition implies the existence of an integer multiflow;*

(iii) *M has no $M(K_4)$ minor.*

Restricted to graphic and cographic matroids, this bears upon series-parallel graphs.

In Theorem 81.1, the implications (i)⇒(ii)⇒(iii) are easy. The proof of (iii)⇒(i) is based on showing that each binary matroid without $M(K_4)$ minor can be decomposed into matroids with at most 3 elements.

81.3. 1-flowing and 1-cycling

As before, for any matroid $M = (V, \mathcal{I})$ and any $v \in V$, let $H_{M,v}$ be the hypergraph on $V \setminus \{v\}$ with edges all sets $C \setminus \{v\}$, where C is a circuit of M containing v (like in Section 80.6). Then M is 1-flowing if and only if $H_{M,v}$ is ideal for each $v \in V$ (cf. Chapter 78). Since no forbidden minor characterization of ideal hypergraphs is known, we cannot infer a characterization of 1-flowing matroids. While the latter characterization yet might be easier to prove, no such characterization is known. Similarly, no characterization of 1-cycling matroids is known. Seymour [1981a] conjectures that for binary matroids both concepts are equivalent; in fact, that for any binary matroid M:

(81.10) (?) M is 1-cycling $\Longleftrightarrow$ M is 1-flowing $\Longleftrightarrow$ M has no AG(3,2), T_{11}, or T_{11}^* minor. (?)

Here T_{11} is the binary matroid represented by the 11 vectors in $\{0,1\}^5$ with precisely 3 or 5 ones. Moreover, AG(3,2) is the matroid with 8 elements, obtained from the 3-dimensional affine geometry over GF(2); equivalently, AG(3,2) is the binary matroid represented by the columns of the matrix[11]:

(81.11)
$$\begin{pmatrix} 1&0&0&0&0&1&1&1 \\ 0&1&0&0&1&0&1&1 \\ 0&0&1&0&1&1&0&1 \\ 0&0&0&1&1&1&1&0 \end{pmatrix}.$$

The second equivalence in conjecture (81.10) is a consequence of Seymour's conjecture that $\mathcal{O}(K_5)$, $b(\mathcal{O}(K_5))$, and F_7 are the only binary minimally nonideal hypergraphs.

81.4. 2-flowing and 2-cycling

The next theorem of Seymour [1981a] lifts Hu's 2-commodity flow theorem to matroids. It shows that for binary matroids, the concepts of 2-flowing and 2-cycling coincide.

[11] Seymour [1981a] used the notation AG(2,3) instead of the (more standard) AG(3,2) (for the 3-dimensional affine geometry over GF(2)).

Theorem 81.2. *For any binary matroid $M = (E, \mathcal{I})$ the following are equivalent:*

(81.12) (i) *M is 2-cycling, that is, for each $R \subseteq E$ with $|R| \leq 2$ and each $c : E \to \mathbb{Z}_+$, the Euler and cut conditions imply the existence of an integer multiflow;*
(ii) *M is 2-flowing, that is, for each $R \subseteq E$ with $|R| \leq 2$ and each $c : E \to \mathbb{R}_+$, the cut condition implies the existence of a multiflow;*
(iii) *M has no* AG(3,2) *or S_8 minor.*

Here S_8 is the binary matroid represented by the columns of the matrix

(81.13) $$\begin{pmatrix} 1&0&0&0&0&1&1&1 \\ 0&1&0&0&1&0&1&1 \\ 0&0&1&0&1&1&0&1 \\ 0&0&0&1&1&1&1&1 \end{pmatrix}.$$

Since AG(3,2) and S_8 are self-dual, this describes a self-dual property. These matroids are nongraphic and (hence) noncographic. For graphic matroids, Theorem 81.2 amounts to the results on 2-commodity flows described in Chapter 71. For cographic matroids, it amounts to the theorem mentioned in the Notes at the end of Section 71.3.

In Theorem 81.2, the implications (i)⇒(ii)⇒(iii) are easy. The proof of (iii)⇒(i) is based on showing that each binary matroid without AG(3,2) or S_8 minor can be decomposed into regular matroids and copies of F_7 and F_7^*.

81.5. 3-flowing and 3-cycling

Also the concepts of 3-flowing and 3-cycling are equivalent, as follows from the following characterization, again of Seymour [1981a]:

Theorem 81.3. *For any binary matroid $M = (E, \mathcal{I})$ the following are equivalent:*

(81.14) (i) *M is 3-cycling, that is, for each $R \subseteq E$ with $|R| \leq 3$ and each $c : E \to \mathbb{Z}_+$, the Euler and cut conditions imply the existence of an integer multiflow;*
(ii) *M is 3-flowing, that is, for each $R \subseteq E$ with $|R| \leq 3$ and each $c : E \to \mathbb{R}_+$, the cut condition implies the existence of a multiflow;*
(iii) *M has no F_7, R_{10}, or $M(H_6)$ minor.*

Here H_6 is the graph obtained from $K_{3,3}$ by adding in each colour class one additional edge.

For graphic matroids, Theorem 81.3 gives a theorem on 3-commodity flows. For cographic matroids, this gives nothing new compared with Theorem 81.4 below.

In Theorem 81.3, the implications (i)$\Rightarrow$(ii)$\Rightarrow$(iii) are easy. The proof of (iii)$\Rightarrow$(i) is based on showing that each binary matroid without F_7, R_{10}, or $M(H_6)$ minor, can be decomposed into cographic matroids and copies of $M(K_5)$.

81.6. 4-flowing, 4-cycling, ∞-flowing, and ∞-cycling

Trivially, one has the implications:

(81.15) ∞-cycling $\Longrightarrow$ ∞-flowing $\Longrightarrow$ 4-flowing.

Seymour [1981a] showed that these implications can be reversed for binary matroids, and gave the following characterization:

Theorem 81.4. *For any binary matroid $M = (E, \mathcal{I})$ the following are equivalent:*

(81.16) (i) *M is ∞-cycling, that is, for each $R \subseteq E$ and each $c : E \to \mathbb{Z}_+$, the Euler and cut conditions imply the existence of an integer multiflow;*

(ii) *M is ∞-flowing, that is, is for each $R \subseteq E$ and each $c : E \to \mathbb{R}_+$, the cut condition implies the existence of a multiflow;*

(iii) *M is 4-flowing, that is, for each $R \subseteq E$ with $|R| \leq 4$ and each $c : E \to \mathbb{R}_+$, the cut condition implies the existence of a multiflow;*

(iv) *M has no F_7, R_{10}, or $M(K_5)$ minor.*

The matroid R_{10} is the matroid on EK_5 with all minimally nonempty even cycles of K_5 as circuits. (Equivalently, the circuits of R_{10} are the even circuits of K_5 and their complements.) An alternative characterization is that R_{10} is the binary matroid represented by all vectors in $\{0,1\}^5$ with precisely three 1's. So R_{10} arises from T_{11} by deleting one element.

For graphic matroids, Theorem 81.4 implies Corollary 75.4d on multiflows if the underlying graph added with the demand edges has no K_5 minor. For cographic matroids, this gives Theorem 29.2 that in bipartite graphs the minimum-size of a T-join is equal to the maximum number of disjoint T-cuts.

In Theorem 81.4, the implications (i)$\Rightarrow$(ii)$\Rightarrow$(iii)$\Rightarrow$(iv) are easy. The proof of (iv)$\Rightarrow$(i) is based on showing that each binary matroid without F_7, R_{10}, or $M(K_5)$ minor can be decomposed into cographic matroids and copies of F_7^* and of $M(V_8)$ (Figure 3.2).

Notes. Schwärzler and Sebő [1993] extended Theorem 81.4 so as to include Karzanov's Theorem 72.5 that characterizes when the $K_{2,3}$-metric condition suffices for the existence of a multiflow. Related work can also be found in Marcus and Sebő [2001].

81.7. The circuit cone and cycle polytope of a matroid

Circuits in matroids generalize both circuits and cuts in graphs. Hence studying the cone generated by the circuits in a matroid, bears on the circuit cone of a graph considered in Section 29.7 (sums of circuits) and on the cut cone of a graph considered in Section 75.7.

Studying the circuit cone of a matroid relates to multiflows, as it concerns the question under which conditions equality holds in the inequalities (81.1).

Let $M = (E, \mathcal{I})$ be a matroid. The *circuit cone* is the convex cone generated by the incidence vectors of the circuits. Each vector x in the circuit cone satisfies:

$$\begin{array}{lll} (81.17) & x_e \geq 0 & \text{for } e \in E, \\ & x_f \leq x(D \setminus \{f\}) & \text{for each cocircuit } D \text{ and each } f \in D. \end{array}$$

Indeed, if $x = \chi^C$ for some circuit C, then

$$(81.18) \qquad x(D \setminus \{f\}) = \sum_{C \in \mathcal{C}} |(C \cap D) \setminus \{f\}| \geq \sum_{C \in \mathcal{C}} |C \cap \{f\}| = x_f,$$

since $C \cap D \neq \{f\}$.

Seymour [1981a] says that M has the *sums of circuits property* if the circuit cone is determined by (81.17). He derived from Theorem 81.4 the following characterization of this property:

Corollary 81.4a. *For any matroid M the following are equivalent:*

(81.19) (i) *M has the sums of circuits property;*
(ii) *M is binary and ∞-flowing;*
(iii) *M is binary and has no F_7^*, R_{10}, or $M^*(K_5)$ minor.*

Since none of these forbidden minors are graphic, this generalizes Corollary 29.2f (due to Seymour [1979b]). For cographic matroids, this generalizes Corollary 75.4e.

The derivation of Corollary 81.4a from Theorem 81.4 is similar to the derivation of Corollary 75.4e from Corollary 75.4d.

The *cycle polytope* of a binary matroid $M = (E, \mathcal{I})$ is the convex hull of the incidence vectors of cycles. (A *cycle* is the disjoint union of circuits.)

For each x in the cycle polytope the following is necessary:

$$\begin{array}{lll} (81.20) & 0 \leq x_e \leq 1 & \text{for each } e \in E, \\ & x(F) - x(D \setminus F) \leq |F| - 1 & \text{for each cocircuit } D \text{ and each} \\ & & F \subseteq D \text{ with } |F| \text{ odd.} \end{array}$$

Barahona and Grötschel [1986] showed that Corollary 81.4a gives (in fact, is equivalent to) the following cycle polytope result:

Corollary 81.4b. *For any binary matroid M the following are equivalent:*

(81.21) (i) *the cycle polytope of M is determined by* (81.20)*;*
(ii) *M is ∞-flowing;*
(iii) *M has no F_7^*, R_{10}, or $M^*(K_5)$ minor.*

The derivation of this from Corollary 81.4a is similar to the derivation of Corollary 75.4f from Corollary 75.4e.

Barahona and Grötschel [1986] characterized adjacency and facets of the cycle polytope of matroids with the sums of circuits property. Grötschel and Truemper [1989] gave an alternative proof of Corollary 81.4b.

81.8. The circuit space and circuit lattice of a matroid

The *circuit space* and the *circuit lattice* of $M = (E, \mathcal{I})$ are the linear space and the lattice, respectively, generated by the incidence vectors of the circuits of M.

Barahona and Grötschel [1986] showed that for any matroid $M = (E, \mathcal{I})$, a vector $x \in \mathbb{R}^E$ belongs to the circuit space of M if and only if

(81.22) $x_e = 0$ if e is a bridge; $x_e = x_f$ if e and f are in series.

The proof is based on an idea of Seymour [1981a]. Necessity being direct, we prove sufficiency, by induction on $|E|$. We may assume that M has no bridges. For each series class P of M, the vector $\mathbf{1}_{E\setminus P}$ belongs to the circuit space of $M \setminus P$. (Here $\mathbf{1}_X$ denotes the all-one vector in $\mathbb{R}^X$.) This follows by induction, as $M \setminus P$ has no bridges. Hence $\mathbf{1}_E - \chi^P$ belongs to the circuit space of M. As this is true for each series class P, we have the theorem.

Now let M be binary. Then each vector x in the circuit lattice satisfies (81.22) and the *Euler condition*:

(81.23) $x(D)$ is even for each cocircuit D.

Lovász and Seress [1993] showed that for any binary matroid M this is enough to characterize the circuit lattice if and only if M^* has no restriction that is a binary sum of copies of the Fano matroid F_7. In particular, if M has no F_7^* minor, then the circuit lattice is characterized by (81.22) and (81.23). (Further work on this in Goddyn [1993], Lovász and Seress [1995], and Fleiner, Hochstättler, Laurent, and Loebl [1999].)

81.9. Nonnegative integer sums of circuits

A necessary condition that a vector x is a nonnegative *integer* combination of incidence vectors of circuits is that x is integer and satisfies the Euler condition (81.23). This is not sufficient, as is shown by the cycle matroid $M(\mathbf{P}_{10})$ of the Petersen graph $\mathbf{P}_{10}$ (which is graphic, and hence has the sums of circuits property): choose a perfect matching N in $\mathbf{P}_{10}$ and let x be 2 on the edges of N, and 1 on the other edges.

Fu and Goddyn [1999] characterized when this necessary condition is sufficient, thus proving a conjecture of Seymour [1981a]:

Theorem 81.5. *For any matroid $M = (E, \mathcal{I})$ the following are equivalent:*

(81.24) (i) *each vector $x \in \mathbb{Z}_+^E$ satisfying* (81.17) *and* (81.23) *is a nonnegative integer combination of incidence vectors of circuits;*
(ii) *M is binary and has no F_7^*, R_{10}, $M^*(K_5)$, or $M(\mathbf{P}_{10})$ minor.*

For graphic matroids, this reduces to Theorem 29.4 of Alspach, Goddyn, and Zhang [1994], and for cographic matroids, results on the cut cone mentioned in Section 75.7.

The proof of Theorem 81.5 is by decomposing any matroid satisfying (81.24)(ii) into graphic matroids without $M(\mathbf{P}_{10})$ minor (to which Theorem 29.4 applies), and copies of F_7 and $M^*(V_8)$ (cf. Figure 3.2).

Goddyn [1993] conjectured (more strongly than Theorem 81.5) that for each matroid without $\mathbf{P}_{10}$ minor, the circuits form a Hilbert base. However, Laurent [1996b] showed that this is not true for $M^*(K_6)$.

A survey on this type of problems was given by Goddyn [1993].

81.10. Nowhere-zero flows and circuit double covers in matroids

Let $M = (E, \mathcal{I})$ be a binary matroid. A *flow over* GF(4) is a function $f : E \to \mathrm{GF}(4)$ with $f(D) = 0$ for each cocircuit D of M. The flow is *nowhere-zero* if $f(e) \neq 0$ for each $e \in E$. By linear algebra, each flow over GF(4) can be decomposed as a sum of vectors $\alpha \cdot \chi^C$, where $\alpha \in \mathrm{GF}(4)$ and C is a circuit.

Seymour [1981c] proved that the 4-flow conjecture of Tutte [1966] ('each bridgeless graph without a Petersen graph minor has a nowhere-zero 4-flow' — see Section 28.4) is equivalent to the following stronger conjecture, also given by Tutte [1966]:

(81.25) (?) each bridgeless matroid without F_7^*, $M^*(K_5)$, or $M(\mathbf{P}_{10})$ minor has a nowhere-zero flow over GF(4). (?)

For graphic matroids, this clearly includes the 4-flow conjecture. For cographic matroids, the existence of a nowhere-zero flow over GF(4) is equivalent to the 4-vertex-colourability of the underlying graph G. By the four-colour theorem and Wagner's theorem (cf. Section 64.3b), any graph without K_5 minor is 4-vertex-colourable — so conjecture (81.25) includes this.

The existence of a nowhere-zero 4-flow is equivalent to the existence of three cycles (= disjoint unions of circuits) that cover each $e \in E$ precisely twice. Indeed, for each nonzero $z \in \mathrm{GF}(4)$, let $C_z := \{e \in E \mid f(e) \neq z\}$. Then the C_z are cycles as required, and the construction can be reversed.

Weaker is the concept of a *circuit double cover* in a binary matroid, which is a family of circuits covering each element precisely twice. Trivially, each bridgeless cographic matroid has a circuit double cover (just take all stars in the corresponding (loopless) graph). The *circuit double cover conjecture* (cf. Sections 29.8 and 38.8) asserts that also each bridgeless graphic matroid has a circuit double cover. Jamshy and Tarsi [1989] proved that this conjecture is equivalent to a generalization to matroids:

(81.26) (?) each bridgeless binary matroid without F_7^* minor has a circuit double cover. (?)

The property of having a circuit double cover need not be closed under taking deletions. So (81.26) gives no necessary and sufficient conditions. One may not relax the condition in (81.26) to requiring that M is binary and $\mathbf{2}$ belongs both to the circuit lattice and to the circuit cone, as is shown by the matroid whose circuits are the even-size cuts of K_{12} (M. Laurent (cf. Goddyn [1993])). This matroid M has an F_7^* minor, and hence does not contradict (81.26).

What has been proved by Jamshy and Tarsi [1989] is:

(81.27) each bridgeless binary matroid without F_7^* minor has a family of circuits covering each element precisely four times.

This extends the corresponding result for graphic matroids of Bermond, Jackson, and Jaeger [1983].

More on nowhere-zero flows and circuit covers in matroids can be found in Tarsi [1985,1986], Jamshy, Raspaud, and Tarsi [1987], and Jamshy and Tarsi [1989].

Chapter 82

Covering and antiblocking in hypergraphs

In this chapter we study the notions of stable set and edge cover in hypergraphs. These concepts are dual to those of matching and vertex cover, by taking the dual hypergraph. Yet, the way we study them is not dual: the classes of hypergraphs considered are closed under operations performed on the *vertex set* (like contraction), while when dualizing the results obtained above, would lead to operations on the *edge set*.
So, although several of the concepts considered in this chapter are just the duals of concepts considered before, we do not dualize the way we studied them above.
As it will turn out, the antiblocking analogues corresponding to the blocking concepts of ideal and Mengerian hypergraphs, all boil down to perfect graph theory.

82.1. Elementary concepts

Let $H = (V, \mathcal{E})$ be a hypergraph. A subset S of V is called *stable* if $|F \cap S| \leq 1$ for each $F \in \mathcal{E}$. An *edge cover* is a collection of edges covering V. So a stable set of H can be considered as a matching of the dual hypergraph H^*, and an edge cover of H as a vertex cover of H^*.

For any hypergraph $H = (V, \mathcal{E})$, define

(82.1) $\alpha(H) :=$ the maximum size of a stable set in H,
$\rho(H) :=$ the minimum size of an edge cover in H.

Determining these numbers is NP-complete, since finding a maximum-size stable set or a minimum-size vertex cover in a graph can be easily reduced to it.

There is the following straightforward inequality:

(82.2) $\alpha(H) \leq \rho(H)$.

For any hypergraph $H = (V, \mathcal{E})$, define

(82.3) $H^{\max} := (V, \{F \in \mathcal{E} \mid \text{there is no } E \in \mathcal{E} \text{ with } E \supset F\})$ and
$H^{\downarrow} := (V, \{F \mid \text{there is an } E \in \mathcal{E} \text{ with } E \supseteq F\})$

So for any hypergraph, $H^{\max}$ is a clutter. Moreover, we have $\alpha(H) = \alpha(H^{\max}) = \alpha(H^{\downarrow})$ and $\rho(H) = \rho(H^{\max}) = \rho(H^{\downarrow})$.

82.2. Fractional edge covers and stable sets

Let $H = (V, \mathcal{E})$ be a hypergraph. A *fractional stable set* is a function $x : V \to \mathbb{R}_+$ satisfying

(82.4) $$\sum_{v \in F} x_v \leq 1 \text{ for each } F \in \mathcal{F}.$$

A *fractional edge cover* is a function $y : \mathcal{E} \to \mathbb{R}_+$ satisfying

(82.5) $$\sum_{F \ni v} y_F \geq 1 \text{ for each } v \in V.$$

(Here and below, F ranges over the edges of H.) Let $\alpha^*(H)$ denote the maximum size of a fractional stable set and let $\rho^*(H)$ denote the minimum size of a fractional edge cover (where the *size* of a vector is the sum of its components).

So $\rho^*(H)$ can be described as

(82.6) $$\rho^*(H) = \min\{y^{\mathsf{T}}\mathbf{1} \mid y \in \mathbb{R}_+^{\mathcal{E}}, y^{\mathsf{T}}M \geq \mathbf{1}^{\mathsf{T}}\},$$

where M is the $\mathcal{E} \times V$ incidence matrix of H. Similarly,

(82.7) $$\alpha^*(H) = \max\{\mathbf{1}^{\mathsf{T}}x \mid x \in \mathbb{R}_+^V, Mx \leq \mathbf{1}\}.$$

As these represent dual linear programs, this gives:

(82.8) $$\rho^*(H) = \alpha^*(H).$$

82.3. k-edge covers and k-stable sets

Like in the blocking case, there is an alternative interpretation of the parameters $\rho^*(H)$ and $\alpha^*(H)$. A *k-stable set* is a function $x : V \to \mathbb{Z}_+$ such that

(82.9) $$\sum_{v \in F} x_v \leq k \text{ for each } F \in \mathcal{F}.$$

Let $\alpha_k(H)$ denote the maximum size of a k-stable set. As 1-stable sets are precisely the incidence vectors of the stable sets, $\alpha_1(H) = \alpha(H)$.

A *k-edge cover* is a function $y : \mathcal{E} \to \mathbb{Z}_+$ such that

(82.10) $$\sum_{F \ni v} y_F \geq k \text{ for each } v \in V.$$

Let $\rho_k(H)$ denote the minimum size of a k-edge cover in H. The minimal 1-edge covers are precisely the incidence vectors of the edge covers, and hence $\rho_1(H) = \rho(H)$.

One easily checks that, for any $k \in \mathbb{Z}_+$:

(82.11) $\alpha_k(H) \leq \rho_k(H)$.

In fact, for each $k \geq 1$:

(82.12) $\alpha(H) \leq \dfrac{\alpha_k(H)}{k} \leq \alpha^*(H) = \rho^*(H) \leq \dfrac{\rho_k(H)}{k} \leq \rho(H)$.

Also one has (Lovász [1974]):

(82.13) $\rho^*(H) = \min\limits_k \dfrac{\rho_k(H)}{k} = \lim\limits_{k\to\infty} \dfrac{\rho_k(H)}{k}$.

Here the left-hand side equality holds as the minimum in (82.6) is attained by a rational optimum solution y. The right-hand side equality follows from Fekete's lemma (Theorem 2.2), using the fact that for all $k, l \geq 1$:

(82.14) $\rho_{k+l}(H) \leq \rho_k(H) + \rho_l(H)$,

since the sum of a k-edge cover and an l-edge cover is a $k + l$-edge cover. Similarly we have:

(82.15) $\alpha^*(H) = \max\limits_k \dfrac{\alpha_k(H)}{k} = \lim\limits_{k\to\infty} \dfrac{\alpha_k(H)}{k}$,

using (82.7) and the fact that for all $k, l \geq 1$:

(82.16) $\alpha_{k+l}(H) \geq \alpha_k(H) + \alpha_l(H)$.

82.4. The antiblocker and conformality

For any hypergraph $H = (V, \mathcal{E})$, the *antiblocking hypergraph*, or the *antiblocker*, of H is the hypergraph $a(H)$ with vertex set V and edges all inclusionwise maximal stable sets of H. So $a(H)$ is a clutter, and $\alpha(H) = r_{\max}(a(H))$ (=the maximum edge-size of $a(H)$).

In Section 77.6 we saw that for any clutter H we have $b(b(H)) = H$. A similar duality phenomenon does not hold for antiblockers. For instance, for the hypergraph $H = K_3$ (with $V := \{1,2,3\}$ and $\mathcal{E} := \{\{1,2\},\{1,3\},\{2,3\}\}$) one has $a(H) = (V, \{\{1\},\{2\},\{3\}\})$, and hence $a(a(H)) = (V, \{\{1,2,3\}\}) \neq H$.

However, by adding a further condition, we can restore this duality relation for the antiblocking operation. Call a hypergraph $H = (V, \mathcal{E})$ *conformal* if for each $U \subseteq V$:

(82.17) if each pair in U is contained in some edge of H, then U is contained in some edge of H.

So H is conformal $\iff$ $H^{\max}$ is conformal $\iff$ $H^{\downarrow}$ is conformal. Moreover:

(82.18) H is conformal $\iff$ there exists a graph G on V such that $H^{\max}$ consists of the inclusionwise maximal cliques of G.

One may check that for each hypergraph H, the hypergraph $a(H)$ is conformal. Also:

Theorem 82.1. *A hypergraph H is conformal if and only if $a(a(H)) = H^{\max}$. In particular, if H is a conformal clutter, then $a(a(H)) = H$.*

Proof. If H is conformal, there is a graph G on V such that $H^{\max}$ is the collection of inclusionwise maximal cliques of G. Then $a(H)$ is the collection of inclusionwise maximal stable sets of G. Hence $a(a(H))$ is the collection of inclusionwise maximal cliques of G. So $a(a(H)) = H^{\max}$. ∎

82.4a. Gilmore's characterization of conformality

Conformality of hypergraphs has been characterized by Gilmore [1962] as follows:

Theorem 82.2. *A hypergraph $H = (V, \mathcal{E})$ is conformal if and only if $V = \cup\mathcal{E}$ and for all $E_1, E_2, E_3 \in \mathcal{E}$ there is an $E \in \mathcal{E}$ with*

(82.19) $E \supseteq (E_1 \cap E_2) \cup (E_1 \cap E_3) \cup (E_2 \cap E_3)$.

Proof. Necessity follows from the definition of conformality, since any two vertices in $(E_1 \cap E_2) \cup (E_1 \cap E_3) \cup (E_2 \cap E_3)$ are contained in some E_i.

To see sufficiency, suppose that the condition is satisfied, but that H is not conformal. Let U be a minimal set such that any pair of vertices in U is contained in some edge of H, but U is contained in no edge of H. So $|U| \geq 3$. Choose distinct $u_1, u_2, u_3 \in U$ and let $F_i := U \setminus \{u_i\}$ for $i = 1, 2, 3$. By the minimality of U, each F_i is contained in some edge, E_i say, of H. Now $U = (F_1 \cap F_2) \cup (F_1 \cap F_3) \cup (F_2 \cap F_3) \subseteq (E_1 \cap E_2) \cup (E_1 \cap E_3) \cup (E_2 \cap E_3)$. By the condition, the latter set is contained in an edge of H, and hence also U is contained in an edge of H. This contradicts our assumption. ∎

As was noted by M. Conforti, Theorem 82.2 implies a polynomial-time test of conformality of a hypergraph, if all maximal edges are given.

82.5. Perfect hypergraphs

We now define the antiblocking analogue of the blocking concept of ideal hypergraph. A hypergraph $H = (V, \mathcal{E})$ is called *perfect*, if $\bigcup \mathcal{E} = V$ and each vertex of the polyhedron Q_H in $\mathbb{R}^V$ determined by:

(82.20)
(i) $x_v \geq 0$ for $v \in V$,
(ii) $x(F) \leq 1$ for $F \in \mathcal{E}$

is integer. (Lovász [1972c] called a hypergraph H *normal* if its dual H^* is perfect.)

We first observe:

Theorem 82.3. *A perfect hypergraph is conformal.*

Proof. Suppose that $H = (V, \mathcal{E})$ is perfect but not conformal. Let U be a minimal subset of V such that any two vertices are contained in an edge of H, but U is contained in no edge of H. So $|U| \geq 3$ and $U \setminus \{u\}$ is contained in an edge of H, for each $u \in U$. Define $z : V \to \mathbb{R}_+$ by:

(82.21) $$z := \frac{1}{|U|-1}\chi^U.$$

Then z belongs to Q_H, and hence z is a convex combination of integer vectors in Q_H. However, each integer vector x satisfies $x(U) \leq 1$ (since $x(U \setminus \{u\}) \leq 1$ for each $u \in U$ and since $|U| \geq 3$). As $z(U) = |U|/(|U|-1) > 1$, this is a contradiction. ∎

Note that each integer vector in Q_H is a 0,1 vector, and hence is the incidence vector of a stable set of H. So H is perfect if and only if Q_H is the convex hull of the incidence vectors of stable sets of H. By the theory of antiblocking polyhedra, this implies that if H is perfect, then each vertex of the polytope $Q_{a(H)}$, by definition determined by

(82.22) $$\begin{array}{lll} \text{(i)} & x_v \geq 0 & \text{for } v \in V, \\ \text{(ii)} & x(S) \leq 1 & \text{for } S \in a(H), \end{array}$$

is integer — hence $a(H)$ is perfect.

We cannot simply reverse this implication: if H is the complete graph K_3, then H is not perfect (as $\frac{1}{2} \cdot \mathbf{1}$ is a noninteger vertex of Q_H), but $a(H)$ is perfect: its edges are all singleton vertices of K_3.

However, if we require H to be conformal, the duality is restored (Fulkerson [1971a,1972a]):

Corollary 82.3a. *A hypergraph H is perfect $\iff$ H is conformal and its antiblocker $a(H)$ is perfect.*

Proof. If H is perfect, then H is conformal by Theorem 82.3. Moreover, $a(H)$ is perfect, by the theory of antiblocking polyhedra.

Conversely, if $a(H)$ is perfect, then $a(a(H))$ is perfect. As H is conformal, $H = a(a(H))$, and hence H is perfect. ∎

The following theorem implies that most of hypergraph theory related to antiblocking boils down to the theory of perfect graphs (the 'only if' part is due to Fulkerson [1972a] and the 'if' part to Lovász [1972c]):

Corollary 82.3b. *A hypergraph $H = (V, \mathcal{E})$ is perfect if and only if $H^{\max}$ consists of the maximal cliques of some perfect graph $G = (V, E)$.*

Proof. To see necessity, as H is perfect, it is conformal, and hence $H^{\max}$ consists of the maximal cliques of some graph $G = (V, E)$. Then G is a perfect graph, by Corollary 65.2e.

To see sufficiency, if $H^{\max}$ consists of the maximal cliques of a perfect graph, then (82.20) has integer vertices (again by Corollary 65.2e) and hence H is perfect. ∎

Perfect hypergraphs can be characterized by a weaker, and also by stronger, conditions than the definition. In the following corollary we collect some of them (Fulkerson [1972a]: (iii)⇔(iv)⇔(v), Lovász [1972c]: (i)⇔(ii)⇔(iv)⇔(vi), Lovász [1972a]: (i)⇔(viii), Berge [1973a]: (i)⇔(vii)).

Theorem 82.4. *For any hypergraph $H = (V, \mathcal{E})$ with $\bigcup \mathcal{E} = V$ the following are equivalent, where M denotes the $\mathcal{E} \times V$ incidence matrix of H:*

(82.23)
(i) *$H^{\max}$ consists of the maximal cliques of some perfect graph;*
(ii) *$\alpha(H') = \rho(H')$ for each contraction H' of H;*
(iii) *H is perfect, that is, $\{x \geq \mathbf{0} \mid Mx \leq \mathbf{1}\}$ is an integer polytope;*
(iv) *the system $x \geq \mathbf{0}, Mx \leq \mathbf{1}$ is totally dual integral;*
(v) *$a(H)$ is perfect;*
(vi) *$\alpha^*(H')$ is an integer for each contraction H' of H;*
(vii) *$\rho_2(H') = 2\rho(H')$ for each contraction H' of H;*
(viii) *$\alpha(H')r_{\max}(H') \geq |VH'|$ for each contraction H' of H.*

Proof. The equivalence of (i) and (iii) is Corollary 82.3b. The equivalence of (i), (iii), and (v) then follows from the perfect graph theorem (Corollary 65.2a). The implication (i)⇒(iv) follows from Corollary 65.2f. Since contractions of H correspond to taking induced subgraphs of G, the implication (i)⇒(ii) is the definition of perfect graph. The implication (ii)⇒(viii) is direct, as $\rho(H')r_{\max}(H') \geq |VH'|$ for any hypergraph H'. The implications (ii)⇒(vi) and (ii)⇒(vii) follow from (82.12). The implication (iv)⇒(iii) is general polyhedral theory (Theorem 5.22).

So it suffices to show that each of (vi), (vii), and (viii) implies (i). We first show that each of (vi), (vii), and (viii) implies that H is conformal.

Suppose that H is not conformal. Then there is a minimal subset U of V such that each pair in U is covered by an edge of H, but U is not covered by any edge of H. So $|U| \geq 3$. Let H' be obtained from H by contracting $V \setminus U$.

Then H' has a 2-edge cover of size 3 (taking $U \setminus \{u\}$ for three vertices $u \in U$), while $\rho(H') \geq 2$, contradicting (vii). Moreover, $\alpha(H') = 1$ and $r_{\max}(H') = |U| - 1 < |U| = |VH'|$, contradicting (viii).

As U is contained in no edge of H, we know that $\alpha^*(H') \geq |U|/(|U|-1)$, since $(|U|-1)^{-1} \cdot \mathbf{1}$ is a fractional stable set of H'. Also, $\alpha^*(H') \leq |U|/(|U|-1)$, since for any fractional stable set x of H' we have $x(U \setminus \{u\}) \leq 1$ for each $u \in U$ (as $U \setminus \{u\}$ is contained in an edge of H), and hence

$$x(U) = \frac{1}{|U|-1} \sum_{u \in U} x(U \setminus \{u\}) \leq \frac{|U|}{|U|-1}. \tag{82.24}$$

So $\alpha^*(H')$ is not an integer, contradicting (vi).

So each of (vi), (vii), and (viii) implies that H is conformal. Knowing that H is conformal, let $H^{\max}$ consist of the maximal cliques of a graph $G = (V, E)$. To show that H is perfect, it suffices to show that G is perfect if (vi), (vii), or (viii) holds. This follows from Theorems 65.10, 65.11, and 65.2, respectively (using that G is perfect if $\overline{G}$ is perfect, and that $\alpha^*(H) = \chi^*(\overline{G})$). ∎

By definition, 'perfect hypergraph' is the antiblocking analogue of 'ideal hypergraph'. By Theorem 82.4, we know that the antiblocking analogue of 'Mengerian hypergraph' coincides with 'perfect hypergraph' (since (82.23)(iii) and (iv) are equivalent). So perfect hypergraph theory reduces to perfect graph theory, and minimally imperfect hypergraphs can be characterized with the strong perfect graph theorem. We will not expand further on this but refer to the chapters in Part VI on perfect graphs.

82.6. Further notes

82.6a. Some equivalences for the k-parameters

Let $H = (V, \mathcal{E})$ be a hypergraph and let $v \in V$. Adding a *serial* vertex to v means extending V by a new vertex v' and replacing $\mathcal{E}$ by

$$\{E \mid v \notin E \in \mathcal{E}\} \cup \{E \cup \{v'\} \mid v \in E \in \mathcal{E}\}. \tag{82.25}$$

A hypergraph obtained from H by a sequence of contractions of vertices and adding serial vertices, is called a *serialization* of H. If $w : V \to \mathbb{Z}_+$ indicates the size of the final series classes of the vertices, we denote the serialization by H_w. So contractions are special cases of serializations and correspond to functions $w : V \to \{0, 1\}$. In a certain sense, also restrictions are special cases of parallelizations and correspond to functions $w : V \to \{1, \infty\}$.

Theorem 82.5. *For any hypergraph $H = (V, \mathcal{E})$ with $\cup\mathcal{E} = V$ and any $k \in \mathbb{Z}_+$, the following are equivalent:*

(82.26) (i) *$k \cdot \alpha^*(H') = \alpha_k(H')$ for each serialization H' of H;*
(ii) *$k \cdot \alpha^*(H')$ is an integer for each serialization H' of H.*

Proof. Similar to the proof of Theorem 78.3. ∎

This is used in proving:

Theorem 82.6. *For any hypergraph $H = (V, \mathcal{E})$ with $\cup\mathcal{E} = V$ and any $k \in \mathbb{Z}_+$, the following are equivalent:*

(82.27) (i) $\rho_k(H') = \alpha_k(H')$ *for each serialization H' of H;*
(ii) $k \cdot \rho^*(H') = \rho_k(H')$ *for each serialization H' of H;*
(iii) $\rho_{2k}(H') = 2\rho_k(H')$ *for each serialization H' of H.*

Proof. Similar to the proof of Theorem 79.2. ∎

Are Theorems 82.5 and 82.6 maintained if serializations are replaced by just contractions? As we will see, this is the case for $k = 2$ and $k = 3$ but not for general k.

As for $k = 2$, Lovász [1977b] showed:

Theorem 82.7. *For any hypergraph $H = (V, \mathcal{E})$ with $\cup\mathcal{E} = V$ the following are equivalent:*

(82.28) (i) $\alpha^*(H') = \frac{1}{2}\alpha_2(H')$ *for each contraction H' of H;*
(ii) $\alpha^*(H') \in \frac{1}{2}\mathbb{Z}$ *for each contraction H' of H.*

Proof. The implication (i)⇒(ii) is trivial. To see the reverse implication, we can assume that (ii) holds and that $\alpha^*(H') = \frac{1}{2}\alpha_2(H')$ for each contraction $H' \neq H$ of H, while $\alpha^*(H) > \frac{1}{2}\alpha_2(H)$.

Since $\alpha^*(H) > \frac{1}{2}\alpha_2(H)$ and $\alpha^*(H) \in \frac{1}{2}\mathbb{Z}$, we know $\alpha^*(H) \geq \frac{1}{2}\alpha_2(H) + \frac{1}{2}$. Let x be a fractional stable set of H of size $\alpha^*(H)$. Then for each $v \in V$, $x|V \setminus \{v\}$ is a fractional stable set of H/v, and so

(82.29) $$x(V \setminus \{v\}) \leq \alpha^*(H/v) = \tfrac{1}{2}\alpha_2(H/v) \leq \tfrac{1}{2}\alpha_2(H) \leq \alpha^*(H) - \tfrac{1}{2} = x(V) - \tfrac{1}{2}.$$

So $x_v \geq \frac{1}{2}$ for each $v \in V$. Hence $|F| \leq 2$ for each $F \in \mathcal{E}$. So H is (essentially) a graph, and hence $\alpha_2(H) = \rho_2(H)$ (by Corollary 30.9a). This implies $\alpha_2(H) = \frac{1}{2}\alpha^*(H)$. ∎

As a consequence one has (Lovász [1975a]: (i)⇔(ii)):

Corollary 82.7a. *For any hypergraph $H = (V, \mathcal{E})$ with $\cup\mathcal{E} = V$ the following are equivalent:*

(82.30) (i) $\alpha_2(H') = \rho_2(H')$ *for each contraction H' of H;*
(ii) $2\alpha^*(H') = \rho_2(H')$ *for each contraction H' of H;*
(iii) $\rho_6(H') = 3\rho_2(H')$ *for each contraction H' of H.*

Proof. The equivalence of (i) and (ii) follows directly from Theorem 82.7. Also the implication (i)⇒(iii) is direct, since $\alpha_2(H) \leq \frac{1}{3}\rho_6(H) \leq \rho_2(H)$ for any hypergraph H.

To see (iii)⇒(i), let $H = (V, \mathcal{E})$ be a counterexample with $|V|$ minimal. So $\rho_2(H') = \alpha_2(H')$ for each contraction $H' \neq H$ of H, and $\rho_6(H) = 3\rho_2(H)$. If each edge of H has size at most 2, then $\rho_2(H) = \alpha_2(H)$, by Corollary 30.9a. So H has an edge F of size at least 3. Choose distinct $v_1, v_2, v_3 \in F$. Then for each $i = 1, 2, 3$ we have;

(82.31) $$\rho_2(H/v_i) = \alpha_2(H/v_i) \leq \alpha_2(H) < \rho_2(H).$$

Hence $\rho_2(H/v_i) \leq \rho_2(H) - 1$.

For $i = 1, 2, 3$, let y_i be a 2-edge cover of H/v_i of size $\rho_2(H/v_i)$. Then $y_1 + y_2 + y_3 + 2\chi^{\{F\}}$ is a 6-edge cover of H of size

(82.32) $$\rho_2(H/v_1) + \rho_2(H/v_2) + \rho(H/v_3) + 2 \leq 3(\rho_2(H) - 1) + 2 < 3\rho_2(H).$$

This contradicts the fact that $\rho_6(H) = 3\rho_2(H)$. ∎

Lovász [1977b] showed that Theorem 82.7 also holds if we replace 2 by 3:

Theorem 82.8. *For any hypergraph $H = (V, \mathcal{E})$ with $\cup\mathcal{E} = V$ the following are equivalent:*

(82.33)
(i) $\alpha^*(H') = \frac{1}{3}\alpha_3(H')$ *for each contraction H' of H;*
(ii) $\alpha^*(H') \in \frac{1}{3}\mathbb{Z}$ *for each contraction H' of H.*

Proof. The implication (i)⇒(ii) being direct, we prove (ii)⇒(i). Let $H = (V, \mathcal{E})$ be a counterexample with $|V|$ minimal. So $\alpha^*(H) \in \frac{1}{3}\mathbb{Z}$, $\alpha^*(H) > \frac{1}{3}\alpha_3(H)$, and $\alpha^*(H') = \frac{1}{3}\alpha_3(H')$ for each contraction $H' \neq H$ of H. So $\alpha^*(H) \geq \frac{1}{3}\alpha_3(H) + \frac{1}{3}$.

Let x be a fractional stable set of H with $x(V) = \alpha^*(H)$. Then for each $v \in V$, $x|V \setminus \{v\}$ is a fractional stable set of H/v, and hence:

(82.34) $$\begin{aligned} x(V \setminus \{v\}) &\leq \alpha^*(H/v) = \tfrac{1}{3}\alpha_3(H/v) \leq \tfrac{1}{3}\alpha_3(H) \leq \alpha^*(H) - \tfrac{1}{3} \\ &= x(V) - \tfrac{1}{3}. \end{aligned}$$

So $x_v \geq \frac{1}{3}$ for each $v \in V$. Therefore, $|F| \leq 3$ for each $F \in \mathcal{E}$. Let U be the union of the edges of H of size 3. Then $x_v = \frac{1}{3}$ for each $v \in U$.

Let $W := V \setminus U$. Then the edges of H contained in W form a bipartite graph. Otherwise, it contains an odd circuit C, and then $H' := H/(V \setminus VC)$ satisfies $\alpha^*(H') = \frac{1}{2}|VC|$. So $\alpha^*(H')$ does not belong to $\frac{1}{3}\mathbb{Z}$, a contradiction.

Let N be the set of vertices w in W for which there is a $u \in U$ with $\{u, w\} \in \mathcal{E}$. Since x is a maximum-size fractional stable set of H and since $x_v = \frac{1}{3}$ for each $v \in U$, we know that $x|W$ attains the maximum in the linear program of maximizing $z(W)$ over $z \in \mathbb{R}^W$ satisfying

(82.35) $$\begin{array}{ll} 0 \leq z(v) \leq 1 & \text{for each } v \in V, \\ z(v) \leq \frac{2}{3} & \text{for each } v \in N, \\ z(u) + z(v) \leq 1 & \text{for each edge } \{u, v\} \subseteq W \text{ of } H. \end{array}$$

Since the constraint matrix of this LP-problem is totally unimodular and since the right-hand side is $\frac{1}{3}$-integer, there is a $\frac{1}{3}$-integer optimum solution z. We can assume that $x|W = z$. So $x \in \frac{1}{3}\mathbb{Z}^V$, implying that $3x$ is a 3-stable set. Hence $\alpha_3(H) \geq 3\alpha^*(H)$, contradicting our assumption. ∎

This implies (Lovász [1977b]):

Corollary 82.8a. *For any hypergraph $H = (V, \mathcal{E})$ with $\cup\mathcal{E} = V$ the following are equivalent:*

(82.36)
(i) $\alpha_3(H') = \rho_3(H')$ *for each contraction H' of H;*
(ii) $3\alpha^*(H') = \rho_3(H')$ *for each contraction H' of H.*

Proof. Directly from Theorem 82.8. ∎

Lovász [1977b] raised the question if in these results 3 can be replaced by any arbitrary integer k. However, Schrijver and Seymour [1979] gave the following example of a hypergraph $H = (V, \mathcal{E})$ satisfying $\alpha_{60}(H) < \rho_{60}(H)$ while $60\alpha^*(H') = \rho_{60}(H')$ for each contraction H' of H:

(82.37) $V := \{1,2,3,4,5,6,7\}$, $\mathcal{E} := \{V \setminus \{1,2\}, V \setminus \{1,3\}, V \setminus \{1,4\}, V \setminus \{2,3\}, V \setminus \{2,4\}, V \setminus \{3,4\}, V \setminus \{5\}, V \setminus \{6\}, V \setminus \{7\}\}$.

To see that $\rho_{60}(H') = 60\alpha^*(H')$ for each contraction H' of H, observe that if we contract two of the vertices $1,2,3,4$ or one of the vertices $5,6,7$, there is an edge covering all vertices, and $\alpha = \rho$ follows. So by symmetry it suffices to show that $\rho_{60}(H') = 60\alpha^*(H')$ for $H' := H$ and for $H' := H/1$.

The fractional stable set x of $H/1$ defined by $x := \frac{1}{5} \cdot \mathbf{1}$ shows that $\alpha^*(H/1) \geq \frac{6}{5}$. Then the 5-edge cover y of $H/1$ defined by: $y(V \setminus \{1,i\}) := 1$ for $i = 2, \ldots, 7$, and $y(E) := 0$ for any other edge E of $H/1$, shows that $\rho_5(H/1) \leq 6$. Hence $\rho_{60}(H/1) \leq 12\rho_5(H/1) \leq 72 \leq 60\alpha^*(H/1)$.

Finally we consider H. Let x be the fractional stable set defined by:

(82.38) $x(1) := x(2) := x(3) := x(4) := \frac{1}{8}$, $x(5) := x(6) := x(7) := \frac{1}{4}$,

and let y be the fractional edge cover defined by:

(82.39) $y(V \setminus \{i,j\}) := \frac{1}{12}$ for all $1 \leq i < j \leq 4$ and $y(V \setminus \{i\}) := \frac{1}{4}$ for $i = 5,6,7$.

So $x(V) = \frac{5}{4} = y(\mathcal{E})$. Hence $\alpha^*(H) = \frac{5}{4}$. However, x is the only fractional stable set of size $\frac{5}{4}$. Indeed, for any fractional stable set x of size $\frac{5}{4}$ one has $x(\{i,j\}) \geq \frac{1}{4}$ for all $1 \leq i < j \leq 4$ and $x(\{i\}) \geq \frac{1}{4}$ for all $5 \leq i \leq 7$. So $x(\{5,6,7\}) \geq \frac{3}{4}$, hence $x(\{1,2,3,4\}) \leq \frac{1}{2}$. Therefore, $x(\{i\}) = \frac{1}{4}$ for all $5 \leq i \leq 7$ and $x(\{i,j\}) = \frac{1}{4}$ for all $1 \leq i < j \leq 4$. This gives $x(\{i\}) = \frac{1}{8}$ for each $1 \leq i \leq 4$.

As $60x \notin \mathbb{Z}$, this shows that $\alpha_{60}(H) < 60\alpha^*(H)$.

82.6b. Further notes

The complete graphs show that $\rho(H)$ cannot be bounded in terms of $\alpha(H)$. Ding, Seymour, and Winkler [1994] showed that for each fixed k, $\rho(H)$ is bounded by a polynomial in $\alpha(H)$ if we restrict H to hypergraphs not having the complete graph on k vertices as partial subhypergraph. Here, a*partial subhypergraph* arises by deleting edges and contracting vertices.

A $\{0, \pm 1\}$ matrix M is *perfect* if the polytope

(82.40) $\{x \mid \mathbf{0} \leq x \leq \mathbf{1}, Mx \leq \mathbf{1} - b\}$

is integer, where b is the vector with b_i equal to the number of -1's in the ith row of M. These matrices generalize the incidence matrices of perfect hypergraphs and were studied by Conforti, Cornuéjols, and de Francesco [1997] (who gave a characterization in terms of perfect graphs), Boros and Čepek [1997], Guenin [1998b], and Tamura [2000].

An extension of the equivalence of (iii) and (iv) in Theorem 82.4 was proved by Korach [1982]: Let M_1 and M_2 be integer matrices such that each row of M_2 is a nonnegative linear combination of rows of M_1. Consider the system

(82.41) $M_1 x \geq \mathbf{0}, M_2 x \leq \mathbf{1}$.

Then (82.41) is TDI if and only if $M_1 x \geq \mathbf{0}$ is TDI and (82.41) determines an integer polyhedron.

The intersection of the polyhedra made by perfect and ideal hypergraphs was investigated by Sebő [1998]. Related results were given by Shepherd [1994a] and Gasparyan [1998]. Monma and Trotter [1979] gave an alternative proof of the relation between perfect graphs and perfect hypergraphs.

Determining the stable set number $\alpha(H)$ of a hypergraph H is equivalent to the vertex packing problem (equivalently, the set packing problem). In Section 64.9e we gave further references for this problem. Determining the edge cover number $\rho(H)$ of H amounts to the *set covering problem*. This NP-complete problem is studied by Lawler [1966], Roth [1969], Lemke, Salkin, and Spielberg [1971], Thiriez [1971], Balas and Padberg [1972,1975a], Garfinkel and Nemhauser [1972b] (survey), Even [1973], Guha [1973], Salkin and Koncal [1973], Christofides and Korman [1974], Fulkerson, Nemhauser, and Trotter [1974], Johnson [1974a], Gondran and Laurière [1975], Lovász [1975c], Etcheberry [1977], Chvátal [1979], Padberg [1979], Avis [1980a], Balas [1980], Balas and Ho [1980], Baker [1981], Bar-Yehuda and Even [1981], Ho [1982], Hochbaum [1982,1983b], Lifschitz and Pittel [1983], Vasko and Wilson [1984a,1984b], Beasley [1987,1990], Bertolazzi and Sassano [1987, 1988], Balas and Ng [1989a,1989b], Cornuéjols and Sassano [1989], Feo and Resende [1989], Nobili and Sassano [1989,1992], Sassano [1989], Fisher and Kedia [1990], Karmarkar, Resende, and Ramakrishnan [1991], El-Darzi and Mitra [1992], Goldschmidt, Hochbaum, and Yu [1993], Khuller, Vishkin, and Young [1993,1994], Lorena and Lopes [1994], Mannino and Sassano [1995], Halldórsson [1995,1996], Caprara, Fischetti, and Toth [1996,1999], Feige [1996,1998], Duh and Fürer [1997], Bar-Yehuda [2000], Halperin [2000,2002], and Holmerin [2002].

The related *set partitioning problem* was investigated by Garfinkel and Nemhauser [1969], Michaud [1972], Marsten [1973], Nemhauser, Trotter, and Nauss [1973], Gondran and Laurière [1974], Balas and Padberg [1975a,1975b,1976], Balas [1977], Nemhauser and Weber [1979], Johnson [1980], Hwang, Sun, and Yao [1985], John [1988], Fisher and Kedia [1990], El-Darzi and Mitra [1992], and Sherali and Lee [1996].

Chapter 83

Balanced and unimodular hypergraphs

In the preceding chapters we investigated conditions under which $\tau(H) = \nu(H)$ or $\alpha(H) = \rho(H)$ holds for all hypergraphs H obtained by deleting or multiplying vertices of some hypergraph. Although these parameters transfer to each other by taking the dual hypergraph, the study was unsymmetric as we considered only deleting or multiplying of vertices, not of edges. In the applications, generally the number of edges is exponentially large in the number of vertices.
In the present chapter we study hypergraphs for which these equalities hold in a symmetric fashion. This leads to the classes of balanced and unimodular matrices.

83.1. Balanced hypergraphs

A 0,1 matrix M is called *balanced* if M has no submatrix which is the incidence matrix of an odd circuit. A hypergraph H is *balanced* if its incidence matrix is balanced.

Another way of characterizing balancedness of a hypergraph $H = (V, \mathcal{E})$ is by the associated bipartite graph G with colour classes V and $\mathcal{E}$, and $v \in V$ and $F \in \mathcal{E}$ adjacent if and only if $v \in F$:

(83.1) H is balanced $\iff$ the length of each chordless circuit in G is a multiple of 4.

The class of balanced hypergraphs is closed under taking 'partial subhypergraphs'. A *partial hypergraph* of a hypergraph H is a hypergraph $(V, \mathcal{E}')$ with $\mathcal{E}' \subseteq \mathcal{E}$. A *partial subhypergraph* of H is a contraction of a partial hypergraph of H. So the incidence matrices of partial subhypergraphs of H arise by deleting rows and columns of the incidence matrix of H. In this terminology,

(83.2) a hypergraph H is balanced $\iff$ H has no odd circuit as partial subhypergraph.

Trivially, the dual of a balanced hypergraph is again balanced. Also, the class of balanced hypergraphs is closed under contractions and restrictions. More generally, it is closed under parallelization and serialization. Hence also the class of blockers of balanced hypergraphs is closed under parallelization and serialization.

Note that for graphs (that is, hypergraphs with each edge of size 2), balancedness coincides with bipartiteness.

In a deep theorem, Conforti, Cornuéjols, and Rao [1999] showed that balancedness of a hypergraph can be tested in polynomial time. The method is based on decomposition of balanced matrices into totally unimodular matrices. An outline of the method was given by Conforti and Cornuéjols [1990]. Related work is reported in Conforti, Cornuéjols, and Rao [1995].

83.2. Characterizations of balanced hypergraphs

Balanced hypergraphs can be characterized in several ways in terms of polyhedra and optimization, as in the following theorem. As before, the hypergraphs $b(H)$ and $a(H)$ denote the blocker and antiblocker of H, respectively. (Berge and Las Vergnas [1970] proved (i)⇔(ii)⇔(iii) and Berge [1972] proved (i)⇔(iv). Given the equivalence of (i) and (iii), the pluperfect graph theorem of Fulkerson [1971a] implies the equivalence of (i), (iii), and (v) (conjectured by Berge [1969]), since balancedness is closed under parallelization.)

Theorem 83.1. *For any hypergraph $H = (V, \mathcal{E})$, the following are equivalent:*

(83.3)
(i) *H is balanced;*
(ii) *$\nu(H') = \tau(H')$ for each partial subhypergraph H' of H;*
(iii) *$\alpha(H') = \rho(H')$ for each partial subhypergraph H' of H;*
(iv) *$\nu(b(H')) = r_{\min}(H')$ for each partial subhypergraph H' of H;*
(v) *$\rho(a(H')) = r_{\max}(H')$ for each partial subhypergraph H' of H.*

Proof. Each of (ii), (iii), (iv), (v) implies (i), since if H is not balanced, it has a partial subhypergraph that is an odd circuit. It is easy to see that none of (ii)-(v) hold for any odd circuit. To show the reverse implications, it suffices to derive from (i) that each of the equalities holds for $H' = H$, since the class of balanced matrices is closed under taking partial subhypergraphs.

We first show (i)⇒(ii). Since the class of balanced hypergraphs is closed under parallelization, by Theorem 79.2 it suffices to show that $\nu_2(H) = 2\nu(H)$. Let $y : \mathcal{E} \to \mathbb{Z}_+$ be a 2-matching of size $\nu_2(H)$. Let $\mathcal{M} := \{E \in \mathcal{E} \mid y(E) = 2\}$ and $\mathcal{F} := \{E \in \mathcal{E} \mid y(E) = 1\}$. The dual of the hypergraph $(V, \mathcal{F})$ is a graph G, added with some edges of size ≤ 1. Since H is balanced, G is bipartite. Let $\mathcal{N}$ be the largest of the two colour classes of G. Then $|\mathcal{N}| \geq \frac{1}{2}|\mathcal{F}|$, and hence $\mathcal{M} \cup \mathcal{N}$ is a matching of size $\geq \frac{1}{2}\nu_2(H)$.

This shows (i)⇒(ii). By taking the dual of H, we see (i)⇒(iii). By Theorem 82.4, (iii) implies that the maximal edges of H are the maximal cliques of some perfect graph G on V. Then $\chi(G) = \omega(G)$ implies $\rho(a(H)) = r_{\max}(H)$.

We finally show (i)⇒(iv). We first show that

(83.4) the vertex set V of a balanced hypergraph $H = (V, \mathcal{E})$ can be partitioned into two sets, each intersecting each edge of size ≥ 2.

The proof is by induction on $|V|$. Let E be the collection of pairs in $\mathcal{E}$. Then the graph $G = (V, E)$ contains a vertex u such that any two neighbours of u belong to the same component of $G - u$. (This is true for any graph. To see it, we can assume that G is connected. Then choose an arbitrary vertex v and let u be a vertex at maximum distance from v.)

By induction, we can partition $V \setminus \{u\}$ into two sets V_1, V_2 each intersecting each edge F of H with $|F \setminus \{u\}| \geq 2$. Now any two neighbours of u in G are connected by a path in $G - u$ of even length, since G is bipartite (as H is balanced). Hence the neighbours belong either all to V_1 or all to V_2. By symmetry, we can assume that they all belong to V_1. Then $V_1, V_2 \cup \{u\}$ is a partition as required. This shows (83.4).

To show (i)⇒(iv), we prove $\nu(b(H)) = r_{\min}(H)$, that is, the maximum number of disjoint vertex covers of H is equal to the minimum edge size r. This is shown by induction on $|\mathcal{E}|$. Choose $F \in \mathcal{E}$ and define $\mathcal{E}' := \mathcal{E} \setminus \{F\}$. Then, by induction, the hypergraph $(V, \mathcal{E}')$ has r disjoint vertex covers $B_1, \ldots, B_r$. We can assume that they partition V. Choose $B_1, \ldots, B_r$ such that a maximum number of the B_i intersect F.

If each B_i intersects F we are done, so we may assume that $B_1 \cap F = \emptyset$. As $|F| \geq r$, we can assume that $|B_2 \cap F| \geq 2$. Now apply (83.4) to the contraction H' of H to $B_1 \cup B_2$. Then $r_{\min}(H') \geq 2$. So, by (83.4), $B_1 \cup B_2$ can be partitioned into two vertex covers of H', hence of H. Replacing B_1, B_2 by B_1', B_2' gives a partition of V into vertex covers of H' thereby increasing the number of them intersecting F. This contradicts our assumption. ∎

Since the incidence matrix of a bipartite graph is balanced, Theorem 83.1 generalizes several theorems of Kőnig, like Kőnig's matching theorem (Theorem 16.2), the Kőnig-Rado edge cover theorem (Theorem 19.4), and Kőnig's edge-colouring theorem (Theorem 20.1).

Theorem 83.1 implies some more extensive characterizations (cf. Fulkerson, Hoffman, and Oppenheim [1974], Berge [1980]):

Corollary 83.1a. *For any hypergraph $H = (V, \mathcal{E})$, the following are equivalent:*

(83.5)
(i) *H is balanced;*
(ii) *$\tau^*(H') \in \mathbb{Z}$ for each partial subhypergraph H' of H;*
(iii) *each partial hypergraph of H is ideal;*
(iv) *each partial hypergraph of H is Mengerian;*
(v) *the blocker of each partial hypergraph of H is Mengerian;*
(vi) *$\alpha^*(H') \in \mathbb{Z}$ for each partial subhypergraph H' of H;*
(vii) *each partial hypergraph of H is perfect.*

Proof. We know the implications (iv)⇒(iii) (Section 79.1), (iii)⇒(ii) (Corollary 78.4b), (vii)⇒(vi) (Theorem 82.4), and (v)⇒(iii) (Theorem 78.1). Since the class of balanced hypergraphs is closed under parallelization, (i)⇒(ii) and (i)⇒(iii) in Theorem 83.1 give (i)⇒(iv) and (i)⇒(vii) in (83.5). Also the class of blockers of balanced hypergraphs is closed under parallelization (as the class of balanced matrices is closed under duplicating columns); so (i)⇒(iv) in Theorem 83.1 gives (i)⇒(v) in (83.5).

So it suffices to show (ii)⇒(i) and (vi)⇒(i). Suppose that H is not balanced. Let $U \subseteq V$ and $\mathcal{E}' \subseteq \mathcal{E}$ induce a partial subhypergraph that is an odd circuit. We can assume that $U = V$ and $\mathcal{E}' = \mathcal{E}$. Then $\frac{1}{2} \cdot \mathbf{1}$ is a minimum-size vertex cover and a maximum-size stable set of H, and hence $\tau^*(H)$ and $\alpha^*(H)$ are noninteger. ▮

These characterizations imply that certain linear programs have integer optimum solutions (taking $\infty \cdot 0 = 0$):

Corollary 83.1b. *For any $\{0,1\}$-valued $m \times n$ matrix M, the following are equivalent:*

(83.6)

(i) *M is balanced;*

(ii) $\forall b \in \{1,\infty\}^m \;\; \forall w \in \{0,1\}^n : \min\{y^\mathsf{T} b \mid y \geq \mathbf{0}, y^\mathsf{T} M \geq w^\mathsf{T}\}$ *has an integer optimum solution y;*

(iii) $\forall b \in \{1,\infty\}^m \;\; \forall w \in \mathbb{Z}_+^n : \min\{y^\mathsf{T} b \mid y \geq \mathbf{0}, y^\mathsf{T} M \geq w^\mathsf{T}\}$ *has an integer optimum solution y;*

(iv) $\forall b \in \mathbb{Z}_+^m \;\; \forall w \in \{0,1\}^n : \min\{y^\mathsf{T} b \mid y \geq \mathbf{0}, y^\mathsf{T} M \geq w^\mathsf{T}\}$ *has an integer optimum solution y;*

(v) $\forall b \in \{1,\infty\}^m \;\; \forall w \in \{0,1\}^n : \max\{w^\mathsf{T} x \mid x \geq \mathbf{0}, Mx \leq b\}$ *has an integer optimum solution x;*

(vi) $\forall b \in \{1,\infty\}^m \;\; \forall w \in \mathbb{Z}_+^n : \max\{w^\mathsf{T} x \mid x \geq \mathbf{0}, Mx \leq b\}$ *has an integer optimum solution x;*

(vii) $\forall b \in \mathbb{Z}_+^m \;\; \forall w \in \{0,1\}^n : \max\{w^\mathsf{T} x \mid x \geq \mathbf{0}, Mx \leq b\}$ *has an integer optimum solution x;*

(viii) $\forall b \in \{0,1\}^m \;\; \forall w \in \{1,\infty\}^n : \min\{w^\mathsf{T} x \mid x \geq \mathbf{0}, Mx \geq b\}$ *has an integer optimum solution x;*

(ix) $\forall b \in \mathbb{Z}_+^m \;\; \forall w \in \{1,\infty\}^n : \min\{w^\mathsf{T} x \mid x \geq \mathbf{0}, Mx \geq b\}$ *has an integer optimum solution x.*

(x) $\forall b \in \{0,1\}^m \;\; \forall w \in \mathbb{Z}_+^n : \min\{w^\mathsf{T} x \mid x \geq \mathbf{0}, Mx \geq b\}$ *has an integer optimum solution x;*

(xi) $\forall b \in \{0,1\}^m \;\; \forall w \in \{1,\infty\}^n : \max\{y^\mathsf{T} b \mid y \geq \mathbf{0}, y^\mathsf{T} M \leq w^\mathsf{T}\}$ *has an integer optimum solution y;*

(xii) $\forall b \in \mathbb{Z}_+^m \;\; \forall w \in \{1,\infty\}^n : \max\{y^\mathsf{T} b \mid y \geq \mathbf{0}, y^\mathsf{T} M \leq w^\mathsf{T}\}$ *has an integer optimum solution y;*

(xiii) $\forall b \in \{0,1\}^m \;\; \forall w \in \mathbb{Z}_+^n : \max\{y^\mathsf{T} b \mid y \geq \mathbf{0}, y^\mathsf{T} M \leq w^\mathsf{T}\}$ *has an integer optimum solution y.*

Proof. Observe that each of (ii)-(vii) is equivalent to each of (viii)-(xiii), respectively, after replacing M by M^{T}. The implications (iii)⇒(ii)⇒(i), (iv)⇒(ii), (vi)⇒(v)⇒(i), and (vii)⇒(v) are direct. Here we use that (ii) and (v) are closed under taking submatrices, and that the incidence matrix of an odd circuit does not satisfy (ii) and (v) for $b = \mathbf{1}$ and $w = \mathbf{1}$.

Finally, (i)⇒(iii) and (i)⇒(vi) follow from (83.5)(i)⇒(vii), (i)⇒(x) (hence (i)⇒(iv)) follows from (83.5)(i)⇒(iii), and (i)⇒(xiii) (hence (i)⇒(vii)) follows from (83.5)(i)⇒(iv). ∎

Berge [1970] gave the following further characterization:

(83.7) a hypergraph is balanced $\iff$ each partial subhypergraph is bicolourable,

where a hypergraph is *bicolourable* if its vertex set can be coloured with two colours such that each edge of size at least 2 gets both colours. While ⇐ in (83.7) is easy, ⇒ can be shown with the proof of (83.4).

More generally, Theorem 83.1 gives the following generalization of Theorem 20.6 for bipartite graphs (Berge [1973b]):

Corollary 83.1c. *Let $H = (V, \mathcal{E})$ be a balanced hypergraph and let $k \in \mathbb{Z}_+$. Then V can be partitioned into $V_1, \ldots, V_k$ such that each $E \in \mathcal{E}$ is intersected by $\min\{k, |E|\}$ of the V_i.*

Proof. Choose $F \in \mathcal{E}$. By induction on $|\mathcal{E}|$, there is a partition $V_1, \ldots, V_k$ of V such that each $E \in \mathcal{E}$ with $E \neq F$ is intersected by $\min\{k, |E|\}$ of the V_i. Choose the partition such that F is intersected by a maximum number of the V_i. If F is not intersected by $\min\{k, |F|\}$ of the V_i, there exist V_i, V_j with $V_i \cap F = \emptyset$ and $|V_j \cap F| \geq 2$. The hypergraph H' obtained from H by contracting $V \setminus (V_i \cup V_j)$ and after that deleting all edges of size ≤ 1, has $r_{\min}(H') \geq 2$. Hence by Theorem 83.1, $\nu(b(H')) \geq 2$, that is $V_i \cup V_j$ can be partitioned into two vertex covers V_i' and V_j' of H'. Then replacing V_i, V_j by V_i', V_j' increases the number of intersections with F, a contradiction. ∎

Another consequence was given by Conforti, Cornuéjols, Kapoor, and Vušković [1996]. Call a matching $\mathcal{M}$ in a hypergraph $H = (V, \mathcal{E})$ *perfect* if $\mathcal{M}$ covers all vertices — that is, if $\mathcal{M}$ is a partition of V.

Corollary 83.1d. *Let $H = (V, \mathcal{E})$ be a balanced hypergraph. Then H has a perfect matching if and only if there are no disjoint vertex sets B, R with $|B| > |R|$ and $|B \cap E| \leq |R \cap E|$ for each $E \in \mathcal{E}$.*

Proof. Necessity is easy, since if $\mathcal{M}$ is a perfect matching, then

(83.8) $$|B| = \sum_{E \in \mathcal{M}} |B \cap E| \leq \sum_{E \in \mathcal{M}} |R \cap E| = |R|.$$

To see sufficiency, let M be the $\mathcal{E} \times V$ incidence matrix of H. Suppose that H has no perfect matching. Since $\{y \geq \mathbf{0} \mid y^{\mathsf{T}} M \leq \mathbf{1}^{\mathsf{T}}\}$ is an integer polytope (by (83.6)(xii)), it implies that there is no vector $y \geq \mathbf{0}$ with $y^{\mathsf{T}} M = \mathbf{1}^{\mathsf{T}}$. Hence, by Farkas' lemma, there is an x with $Mx \geq \mathbf{0}$ and $\mathbf{1}^{\mathsf{T}} x < 0$. We can assume $-\mathbf{1} \leq x \leq \mathbf{1}$. Set $z := \mathbf{1} - x$. Then $\mathbf{0} \leq z \leq \mathbf{2}$, $Mz \leq M\mathbf{1}$, and $\mathbf{1}^{\mathsf{T}} z > \mathbf{1}^{\mathsf{T}} \mathbf{1}$. By (83.6)(vii), applied to the balanced matrix

$$(83.9) \qquad \begin{pmatrix} I \\ M \end{pmatrix},$$

we can assume that z is integer. Hence we can assume that x is integer and $-\mathbf{1} \leq x \leq \mathbf{1}$. Then $B := \{v \in V \mid x_v = -1\}$ and $R := \{v \in V \mid x_v = +1\}$ contradict the condition of the corollary. ∎

A combinatorial proof of this theorem was given by Huck and Triesch [2002].

83.2a. Totally balanced matrices

A 0,1 matrix is called *totally balanced* if it has no submatrix that is the incidence matrix of a circuit of length at least 3. Obviously, each totally balanced matrix is balanced.

Totally balanced matrices have several nice properties so as to apply 'perfect elimination' and 'greedy' methods when solving optimization problems. They might be considered as the bipartite analogue of chordal graphs.

Call a bipartite graph *totally balanced* (or *chordal bipartite*) if it has no chordless circuit of length at least 6. So a 0,1 matrix is totally balanced if and only if the associated bipartite graph is totally balanced. (The bipartite graph *associated* to an $m \times n$ matrix M is the bipartite graph with colour classes $\{u_1, \ldots, u_m\}$ and $\{v_1, \ldots, v_n\}$, where u_i and v_j are adjacent if and only if $M_{i,j} \neq 0$.)

The first important property of totally balanced matrices was found by Golumbic and Goss [1978]. Call an entry M_{i_0,j_0} of a $\{0,1\}$-valued $m \times n$ matrix M *simplicial* if

(83.10) (i) $M_{i_0,j_0} = 1$,
(ii) for all $i = 1, \ldots, m$ and $j = 1, \ldots, n$: if $M_{i_0,j} = M_{i,j_0} = 1$, then $M_{i,j} = 1$.

Theorem 83.2. *Each nonzero totally balanced matrix M has a simplicial entry.*

Proof. Let $G = (V, E)$ be the bipartite graph associated to M, with colour classes U and W. To prove that M has a simplicial entry, we must show that G has an edge uw such that each vertex in $N(u)$ is adjacent to each vertex in $N(w)$.

We can assume that G is not a complete bipartite graph, since otherwise M trivially has a simplicial entry. Choose an inclusionwise maximal nonempty set $X \subseteq V$ such that

(83.11) the subgraph $G[X]$ of G induced by X is connected and G has an edge disjoint from $X \cup N(X)$.

Such a set X exists, since $X := \{u\}$ satisfies (83.11) for any vertex u that is isolated or (if no isolated vertices exist) any vertex $u \in U$ nonadjacent to at least one vertex in W.

Define $Z := V \setminus (X \cup N(X))$. The maximality of X gives:

(83.12) each vertex y in $N(X)$ is adjacent to one of the ends of any edge contained in Z,

since otherwise we can add y to X without violating (83.11), contradicting the maximality of X.

Also we have:

(83.13) each vertex in $N(X) \cap U$ is adjacent to each vertex in $N(X) \cap W$.

For choose $y \in N(X) \cap U$ and $z \in N(X) \cap W$. Let uw be an edge in Z, with $u \in U$ and $w \in W$. As $G[X]$ is connected, there is a path P in $G[X]$ connecting $N(y)$ and $N(z)$. Choose P shortest. Then y, P, z, u, w, y is a circuit of length at least 6 in G. Hence it has a chord. It cannot connect $\{u, w\}$ and P, since $u, w \notin N(X)$. So it is a chord of the path y, P, z. Since P is shortest, it follows that y and z are adjacent. This proves (83.13).

Now by induction we know that Z contains an edge uw such that $N(\{u, w\}) \cap Z$ induces a complete bipartite graph. Then (83.12) and (83.13) imply that $N(\{u, w\})$ induces a complete bipartite graph. ∎

Most of the properties of totally balanced matrices (including that described in the theorem above, which however is used in the proof) follow from the next theorem, saying that the rows and columns of a totally balanced matrix can be permuted such that it has no submatrix

(83.14) $$\begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$$

(in this order). Following Lubiw [1982], we call such a matrix *Γ-free*. In other words, M is Γ-free if for all row indices $i < i'$ and column indices $j < j'$ one has

(83.15) if $M_{i,j} = M_{i',j} = M_{i,j'} = 1$, then $M_{i',j'} = 1$.

The following was shown by Hoffman, Kolen, and Sakarovitch [1985] and Lubiw [1982]:

Theorem 83.3. *The rows and columns of a totally balanced matrix M can be permuted such that the matrix becomes Γ-free.*

Proof. We apply induction on the number of nonzero entries of M. If M is all-zero, the theorem is trivial. So we can assume that M has at least one nonzero entry. By Theorem 83.2, M has a simplicial entry M_{i_0,j_0}.

Reset M_{i_0,j_0} to 0, to obtain matrix $\widetilde{M}$. Then $\widetilde{M}$ is again totally balanced. For suppose that $\widetilde{M}$ has a submatrix C that is the incidence matrix of a circuit of length ≥ 3. Since M is totally balanced, C contains the entry $\widetilde{M}_{i_0,j_0}$. Row i_0 has two 1's in C and column j_0 has two 1's in C. Hence, by (83.10), C has a row with three 1's, a contradiction.

So $\widetilde{M}$ is totally balanced again. By induction, we can permute the rows and columns of $\widetilde{M}$ such that it becomes Γ-free. We can assume that entry $\widetilde{M}_{i_0,j_0}$ of $\widetilde{M}$

has moved to position i_0, j_0. We can also assume that among all valid permutations, we have chosen one which minimizes $i_0 + j_0$. Then

(83.16) $\quad M_{i,j_0} = 0$ for each $i < i_0$ and $M_{i_0,j} = 0$ for each $j < j_0$.

For suppose that $M_{i,j_0} = 1$ for some $i < i_0$. By the minimality of $i_0 + j_0$, we cannot exchange rows i_0 and $i_0 - 1$ of $\widetilde{M}$ without violating Γ-freeness. Hence there exist j, j' with $j < j'$ with $M_{i_0,j} = M_{i_0,j'} = 1$ and $M_{i_0-1,j} = 1$, $M_{i_0-1,j'} = 0$. Since $M_{i_0,j} = M_{i_0,j'} = 1$ and $M_{i,j_0} = 1$ we know by (83.10) that $M_{i,j} = M_{i,j'} = 1$.

So $i \neq i_0 - 1$ and hence $i < i_0 - 1$. But then $M_{i,j} = M_{i,j'} = M_{i_0-1,j} = 1$ while $M_{i_0-1,j'} = 0$, contradicting the Γ-freeness of $\widetilde{M}$.

This proves (83.16). Then resetting the (i_0, j_0)th entry to its original value 1, the matrix remains Γ-free (by (83.10) and (83.16)). ∎

Call a hypergraph $H = (V, \mathcal{E})$ *totally balanced* if its incidence matrix is totally balanced. Call two sets X and Y *comparable* if $X \subseteq Y$ or $Y \subseteq X$. Then (Brouwer and Kolen [1980], Anstee and Farber [1984]):

Corollary 83.3a. *Each totally balanced hypergraph $H = (V, \mathcal{E})$ with $V \neq \emptyset$, has a vertex v such that any two edges containing v are comparable.*

Proof. By Theorem 83.3, we can assume that the incidence matrix M of H is Γ-free. Then the vertex of H corresponding to the first column of M is as required. ∎

Other consequences of Theorem 83.3 are algorithmic. It gives a good characterization of total balancedness. In fact, the method gives a polynomial-time algorithm to test total balancedness: we iteratively find a simplicial entry and set it to 0. If we succeed in this until the matrix is all-zero, the original matrix is totally balanced, and otherwise not.

Lubiw [1982] gave the following simple algorithm to permute the rows and columns of a totally balanced matrix such that it becomes Γ-free. Iteratively, choose a column j such that the supports of the rows with a 1 in column j form a chain, and remove column j. The order in which we remove the columns, gives the permutation of the columns. Next order the rows lexicographically (reading from right to left). The final matrix is Γ-free. (Hoffman, Kolen, and Sakarovitch [1985] gave an $O(nm^2)$-time algorithm to transform a totally balanced $m \times n$ matrix to a Γ-free matrix, speeded up by Paige and Tarjan [1987] and Spinrad [1993].)

Also, if A is a nonsingular matrix whose support is totally balanced, then we can solve a system $Ax = b$ of linear equalities with Gaussian elimination, by repeatedly choosing a simplicial entry and pivoting on it. If we create no 0's 'by accident', then we can keep pivoting on simplicial entries throughout the process (since then we never change any zero entry to nonzero). So if the initial matrix is sparse, it remains sparse during the Gaussian elimination.

Lubiw [1982], Farber [1984], and Hoffman, Kolen, and Sakarovitch [1985] gave polynomial-time algorithms for optimization problems over a totally balanced matrix.

Call a hypergraph $H = (V, \mathcal{E})$ a *tree-hypergraph* if V is the vertex set of a tree T and each edge $E \in \mathcal{E}$ of H induces a subtree of T. Lehel [1985] showed that a hypergraph H is totally balanced if and only if each contraction of H is a tree-hypergraph.

Lubiw [1982] showed that for any totally balanced hypergraph $H = (V, \mathcal{E})$, its intersection matrix (the $\{0,1\}$-valued $\mathcal{E} \times \mathcal{E}$ matrix N with $N_{E,E'} = 1$ if and only if $E \cap E' \neq \emptyset$) is totally balanced.

Chvátal [1993] pointed out that a bipartite graph is totally balanced ($\equiv$ chordal bipartite) if and only if its complementary graph is perfectly orderable (cf. Hoàng [1996a]). More results on totally balanced matrices are reported by Golumbic [1980], Lubiw [1982,1987], Anstee and Farber [1984], and Dragan and Voloshin [1996], and applications by Tamir [1987].

83.2b. Examples of balanced hypergraphs

A graph $G = (V, E)$ is balanced if and only if it is bipartite. This follows directly from the definition of balancedness.

A second example was given by Frank [1977]. Let $D = (V, A)$ be a rooted tree. Let $P_1, \ldots, P_m$ and $Q_1, \ldots, Q_n$ be directed paths in D. Define the $m \times n$ matrix M by:

(83.17) $$M_{i,j} := \begin{cases} 1 & \text{if } VP_i \cap VQ_j \neq \emptyset, \\ 0 & \text{otherwise,} \end{cases}$$

for $i = 1, \ldots, m$ and $j = 1, \ldots, n$. Then M is a balanced matrix, as one easily checks. M need not be totally unimodular, as example (83.22) below shows. As Lubiw [1982] observed, these matrices are even totally balanced. The fact that for the corresponding hypergraphs $\alpha(H) = \rho(H)$ and (equivalently) $\nu(H) = \tau(H)$ hold was shown by Meir and Moon [1975]. Related results can be found in Slater [1977].

A third example was given by Giles [1978a]. Let $G = (V, E)$ be an (undirected) tree. For each $a : V \to \mathbb{Z}_+$, define

(83.18) $$U_v := \{u \in V \mid \mathrm{dist}_G(v, u) \leq a_v\}.$$

Then $(V, \{U_v \mid v \in V\})$ is a balanced hypergraph. Lubiw [1982] showed that these hypergraphs are in fact totally balanced.

83.2c. Balanced $0, \pm 1$ matrices

Truemper [1982] extended the concept of balancedness to $0, \pm 1$ matrices: A $0, \pm 1$ matrix is *balanced* if in each square submatrix with precisely two nonzeros in each row and in each column, the sum of the entries is a multiple of 4.

Most of the results described above for balanced $0, 1$ matrices, can be extended to $0, \pm 1$ matrices. Conforti and Cornuéjols [1995b] showed that for any balanced $0, \pm 1$ matrix M the following systems are TDI, and hence determine an integer polytope:

(83.19) $$\mathbf{0} \leq x \leq \mathbf{1}, Mx \leq \mathbf{1} - b,$$

and

(83.20) $$\mathbf{0} \leq x \leq \mathbf{1}, Mx \geq \mathbf{1} - b,$$

where b is the vector with b_i equal to the number of negative entries in the ith row of M. So balanced matrices are both perfect and ideal. By requiring this for each submatrix, each of this characterizes balancedness.

Conforti and Cornuéjols [1995b] also proved a bicolouring theorem extending Corollary 83.1c:

(83.21) the columns of a balanced $0, \pm 1$ matrix M can be split into two sets such that each row of M with at least two nonzeros, has nonzero entries of the same sign in both sets, or of opposite signs in one of the two sets.

Again, by requiring this for each submatrix, this characterizes balancedness.

Finally, the decomposition results and algorithms for balanced $0, 1$ matrices were extended to $0, \pm 1$ matrices by Conforti, Cornuéjols, Kapoor, and Vušković [1994,2001a,2001b]. For surveys, see Conforti, Cornuéjols, Kapoor, Vušković, and Rao [1994], Conforti and Cornuéjols [2001], and Cornuéjols [2001].

83.3. Unimodular hypergraphs

A hypergraph $H = (V, \mathcal{E})$ is called *unimodular* if its incidence matrix M is totally unimodular; that is, each square submatrix of M has determinant 0, $+1$, or -1.

Since the incidence matrix of an odd circuit has determinant ± 2, each unimodular hypergraph is balanced. Not every balanced hypergraph is unimodular, as is shown by the hypergraph with incidence matrix

(83.22)
$$\begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix}.$$

Trivially, the dual of a unimodular hypergraph is again unimodular. Also, contracting vertices and deleting edges maintain unimodularity of a hypergraph.

For graphs (that is, hypergraphs with each edge of size 2), the concept of unimodular coincides with bipartite.

Characterizations of totally unimodular matrices imply corresponding characterizations of unimodular hypergraphs. We describe some of them in the following theorem. (The equivalence of (i)-(vii) is due to Hoffman and Kruskal [1956], characterization (viii) to Ghouila-Houri [1962b], characterization (ix) to Camion [1963,1965], and characterization (x) to R.E. Gomory (cf. Camion [1965]).)

For the proof we refer to Chapter 19 of Schrijver [1986b].

Theorem 83.4. *Let $H = (V, \mathcal{E})$ be a hypergraph, with incidence matrix M. Then the following are equivalent:*

(83.23) (i) *H is unimodular, that is, each square submatrix of M has determinant in $\{0, \pm 1\}$;*
(ii) *for each $b \in \mathbb{Z}_+^{\mathcal{E}}$, the polyhedron $\{x \geq \mathbf{0} \mid Mx \leq b\}$ is integer;*
(iii) *for each $b \in \mathbb{R}_+^{\mathcal{E}}$, the system $x \geq \mathbf{0}$, $Mx \leq b$ is totally dual integral;*
(iv) *for each $b \in \mathbb{Z}_+^{\mathcal{E}}$, the polyhedron $\{x \geq \mathbf{0} \mid Mx \geq b\}$ is integer;*
(v) *for each $b \in \mathbb{R}_+^{\mathcal{E}}$, the system $x \geq \mathbf{0}$, $Mx \geq b$ is totally dual integral;*
(vi) *for all $a, b \in \mathbb{Z}^{\mathcal{E}}$ and $c, d \in \mathbb{Z}^V$, the polyhedron $\{x \mid c \leq x \leq d, a \leq Mx \leq b\}$ is integer;*
(vii) *for all $a, b \in \mathbb{R}^{\mathcal{E}}$ and $c, d \in \mathbb{R}^V$, the system $c \leq x \leq d, a \leq Mx \leq b$ is totally dual integral;*
(viii) *each $U \subseteq V$ can be partitioned into sets U_1 and U_2 such that each $E \in \mathcal{E}$ satisfies $\big||E \cap U_1| - |E \cap U_2|\big| \leq 1$;*
(ix) *the sum of the entries in any square submatrix of M with even row and column sums, is divisible by 4;*
(x) *no square submatrix of M has determinant ± 2.*

Proof. See Chapter 19 of Schrijver [1986b]. ∎

This implies a characterization similar to Corollary 83.1b:

Corollary 83.4a. *For any $\{0,1\}$-valued $m \times n$ matrix M, the following are equivalent:*

(83.24) (i) *M is totally unimodular;*
(ii) *$\forall b \in \mathbb{Z}_+^m \;\; \forall w \in \mathbb{Z}_+^n : \min\{y^\mathsf{T} b \mid y \geq \mathbf{0}, y^\mathsf{T} M \geq w^\mathsf{T}\}$ has an integer optimum solution y;*
(iii) *$\forall b \in \mathbb{Z}_+^m \;\; \forall w \in \mathbb{Z}_+^n : \max\{w^\mathsf{T} x \mid x \geq \mathbf{0}, Mx \leq b\}$ has an integer optimum solution x;*
(iv) *$\forall b \in \mathbb{Z}_+^m \;\; \forall w \in \mathbb{Z}_+^n : \max\{y^\mathsf{T} b \mid y \geq \mathbf{0}, y^\mathsf{T} M \leq w^\mathsf{T}\}$ has an integer optimum solution y;*
(v) *$\forall b \in \mathbb{Z}_+^m \;\; \forall w \in \mathbb{Z}_+^n : \min\{w^\mathsf{T} x \mid x \geq \mathbf{0}, Mx \geq b\}$ has an integer optimum solution x.*

Proof. From Theorem 83.4. ∎

Unimodular hypergraphs have the following property stronger than was shown for balanced hypergraphs in Corollary 83.1c:

Theorem 83.5. *Let $H = (V, \mathcal{E})$ be a unimodular matrix and let $k \in \mathbb{Z}_+$ with $k \geq 1$. Then V can be partitioned into sets $V_1, \ldots, V_k$ such that*

(83.25) $$\left\lfloor \frac{|E|}{k} \right\rfloor \leq |E \cap V_i| \leq \left\lceil \frac{|E|}{k} \right\rceil$$

for each $E \in \mathcal{E}$ and each $i = 1, \ldots, k$.

Proof. Choose $F \in \mathcal{E}$. By induction, there is a partition $V_1, \ldots, V_k$ as required for the hypergraph $H' := (V, \mathcal{E} \setminus \{F\})$. Choose the partition with

$$(83.26) \qquad \sum_{i=1}^{k} |F \cap V_i|^2$$

as small as possible. Suppose that (83.25) does not hold for $E := F$. Then there exist i and j such that

$$(83.27) \qquad |F \cap V_i| \geq |F \cap V_j| + 2.$$

Consider the contraction of H to $V_i \cup V_j$. By (83.23)(viii), we can split $V_i \cup V_j$ into V_i' and V_j' such that $\big||E \cap V_i'| - |E \cap V_j'|\big| \leq 1$ for each $E \in \mathcal{E}$. So replacing V_i, V_j by V_i', V_j' gives again a valid partition, but decreases the sum (83.26), a contradiction. ∎

A basic theorem of Seymour [1980a] states that each totally unimodular matrix can be decomposed into network matrices, their transposes, and two special 5×5 matrices. As J. Edmonds noted, it yields a polynomial-time test of total unimodularity of matrices, and hence of unimodularity of hypergraphs — Bixby [1982], Schrijver [1986b], and Truemper [1990,1992] described implementations.

83.3a. Further notes

Truemper and Chandrasekaran [1978] proved the following characterization, that includes the polyhedral characterizations of both the balanced and the totally unimodular matrices. For any pair of an $\{0, 1\}$-valued $m \times n$ matrix A and a vector $b \in \mathbb{Z}_+^n$, the following are equivalent:

(83.28)
- (i) the polyhedron $\{x \geq \mathbf{0} \mid A'x \leq d'\}$ is integer for each row submatrix A' of A and each integer vector d' with $\mathbf{0} \leq d' \leq b'$, where b' is the part of b corresponding to A';
- (ii) A has no square submatrix M with the following properties: $\det M = \pm 2$, each entry of M^{-1} is $\pm\frac{1}{2}$, and $M\mathbf{1} \leq 2b'$, where b' is the part of b corresponding to M.

For $b = \mathbf{1}$ this characterizes balanced matrices. For b sufficiently large, it characterizes total unimodularity. Related results can be found in Conforti, Cornuéjols, and Truemper [1994] and Conforti, Cornuéjols, and Zambelli [2002a].

Conforti and Rao [1992c] reduced testing if a hypergraph is balanced, to testing if some derived hypergraphs are perfect. Conforti and Rao [1993] gave a polynomial-time algorithm to test if a given hypergraph H is balanced, provided that any two edges of H intersect in at most one vertex. Related results can be found in Lubiw [1988] and Conforti and Rao [1989,1992d].

Berge and Hoffman [1978] gave a formula for the minimum number of stable vertex covers needed to cover the vertex set of a unimodular hypergraph. Dahlhaus, Kratochvil, Manuel, and Miller [1997] described a polynomial-time algorithm to find a maximum number of disjoint vertex covers of a balanced hypergraph.

Conforti and Cornuéjols [1995a] applied balanced matrices to logic problems. Conforti, Cornuéjols, and Vušković [1999] gave a linear-time algorithm to find a chordless circuit in a bipartite graph of length $\equiv 0 \pmod 4$.

Survey of Problems, Questions, and Conjectures

We here collect unsolved problems, questions, and conjectures mentioned in this book. For terminology and background, we refer to the pages indicated.

1 (page 41). Is NP$\neq$P?

2 (page 42). Is P=NP$\cap$co-NP?

3 (page 65). The *Hirsch conjecture*: A d-dimensional polytope with m facets has diameter at most $m - d$.

4 (page 161). Is there an $O(nm)$-time algorithm for finding a maximum flow?

5 (page 232). Berge [1982b] posed the following conjecture generalizing the Gallai-Milgram theorem. Let $D = (V, A)$ be a digraph and let $k \in \mathbb{Z}_+$. Then for each path collection $\mathcal{P}$ partitioning V and minimizing

$$(1) \qquad \sum_{P \in \mathcal{P}} \min\{|VP|, k\},$$

there exist disjoint stable sets $C_1, \ldots, C_k$ in D such that each $P \in \mathcal{P}$ intersects $\min\{|VP|, k\}$ of them. This was proved by Saks [1986] for acyclic graphs.

6 (page 403). The following open problem was mentioned by Fulkerson [1971b]: Let $\mathcal{A}$ and $\mathcal{B}$ be families of subsets of a set S and let $w \in \mathbb{Z}_+^S$. What is the maximum number k of common transversals $T_1, \ldots, T_k$ of $\mathcal{A}$ and $\mathcal{B}$ such that

$$(2) \qquad \chi^{T_1} + \cdots + \chi^{T_k} \leq w?$$

7 (page 459). Can the weighted matching problem be formulated as a linear programming problem of size bounded by a polynomial in the size of the graph, by extending the set of variables? That is, is the matching polytope of a graph $G = (V, E)$ equal to the projection of some polytope $\{x \mid Ax \leq b\}$ with A and b having size bounded by a polynomial in $|V| + |E|$?

8 (pages 472,646). The 5-*flow conjecture* of Tutte [1954a]:

(3) (?) each bridgeless graph has a nowhere-zero 5-flow. (?)

(A *nowhere-zero k-flow* is a flow over $\mathbb{Z}_k$ in some orientation of the graph, taking value 0 nowhere.)

9 (pages 472,498,645,1426). The 4-*flow conjecture* of Tutte [1966]:

(4) (?) each bridgeless graph without Petersen graph minor has a nowhere-zero 4-flow. (?)

This implies the four-colour theorem. For cubic graphs, (4) was proved by Robertson, Seymour, and Thomas [1997], Sanders, Seymour, and Thomas [2000], and Sanders and Thomas [2000].

Seymour [1981c] showed that the 4-flow conjecture is equivalent to the following more general conjecture, also due to Tutte [1966]:

(5) (?) each bridgeless matroid without F_7^*, $M^*(K_5)$, or $M(\mathbf{P}_{10})$ minor has a nowhere-zero flow over GF(4). (?)

Here $\mathbf{P}_{10}$ denotes the Petersen graph.

10 (page 472). The 3-*flow conjecture* (W.T. Tutte, 1972 (cf. Bondy and Murty [1976], Unsolved problem 48)):

(6) (?) each 4-edge-connected graph has a nowhere-zero 3-flow. (?)

11 (page 473). The *weak* 3-*flow conjecture* of Jaeger [1988]:

(7) (?) there exists a number k such that each k-edge-connected graph has a nowhere-zero 3-flow. (?)

12 (page 473). The following *circular flow conjecture* of Jaeger [1984] generalizes both the 3-flow and the 5-flow conjecture:

(8) (?) for each $k \geq 1$, any $4k$-connected graph has an orientation such that in each vertex, the indegree and the outdegree differ by an integer multiple of $2k+1$. (?)

13 (pages 475,645). The *generalized Fulkerson conjecture* of Seymour [1979a]:

(9) (?) $\lceil \chi'^*(G) \rceil = \lceil \frac{1}{2}\chi'(G_2) \rceil$ (?)

for each graph G. (Here $\chi'^*(G)$ denotes the fractional edge-colouring number of G, and G_2 the graph obtained from G by replacing each edge by two parallel edges.) This is equivalent to the conjecture that

(10) (?) for each k-graph G there exists a family of $2k$ perfect matchings, covering each edge precisely twice. (?)

(A *k-graph* is a k-regular graph $G = (V, E)$ with $|\delta(U)| \geq k$ for each odd-size subset U of V.)

14 (pages 476,645). Fulkerson [1971a] asked if in each bridgeless cubic graph there exist 6 perfect matchings, covering each edge precisely twice (the *Fulkerson conjecture*). It is a special case of Seymour's generalized Fulkerson conjecture.

15 (page 476). Berge [1979a] conjectures that the edges of any bridgeless cubic graph can be covered by 5 perfect matchings. (This would follow from the Fulkerson conjecture.)

16 (page 476). Gol'dberg [1973] and Seymour [1979a] conjecture that for each (not necessarily simple) graph G one has

(11) $$(?)\ \chi'(G) \leq \max\{\Delta(G)+1, \lceil \chi'^{*}(G)\rceil\}.\ (?)$$

An equivalent conjecture was stated by Andersen [1977].

17 (page 476). Seymour [1981c] conjectures the following generalization of the four-colour theorem:

(12) (?) each planar k-graph is k-edge-colourable. (?)

For $k = 3$, this is equivalent to the four-colour theorem. For $k = 4$ and $k = 5$, it was derived from the case $k = 3$ by Guenin [2002b].

18 (pages 476,644). Lovász [1987] conjectures more generally:

(13) (?) each k-graph without Petersen graph minor is k-edge-colourable. (?)

This is equivalent to stating that the incidence vectors of perfect matchings in a graph without Petersen graph minor, form a Hilbert base.

19 (page 481). The following question was asked by Vizing [1968]: Is there a simple planar graph of maximum degree 6 and with edge-colouring number 7?

20 (page 481). Vizing [1965a] asked if a minimum edge-colouring of a graph can be obtained from an arbitrary edge-colouring by iteratively swapping colours on a colour-alternating path or circuit and deleting empty colours.

21 (page 482). Vizing [1976] conjectures that the list-edge-colouring number of any graph is equal to its edge-colouring number.

(The *list-edge-colouring number* $\chi^{l}(G)$ of a graph $G = (V, E)$ is the minimum number k such that for each choice of sets L_e for $e \in E$ with $|L_e| = k$, one can select $l_e \in L_e$ for $e \in E$ such that for any two incident edges e, f one has $l_e \neq l_f$.)

22 (page 482). Behzad [1965] and Vizing [1968] conjecture that the total colouring number of a simple graph G is at most $\Delta(G)+2$. (The *total colouring* *number* of a graph $G = (V, E)$ is a colouring of $V \cup E$ such that each colour consists of a stable set and a matching, vertex-disjoint.)

23 (page 482). More generally, Vizing [1968] conjectures that the total colouring number of a graph G is at most $\Delta(G) + \mu(G) + 1$, where $\mu(G)$ is the maximum edge multiplicity of G.

24 (pages 497,645). Seymour [1979b] conjectures that each even integer vector in the circuit cone of a graph is a nonnegative integer combination of incidence vectors of circuits.

25 (pages 497,645,1427). A special case of this is the *circuit double cover conjecture* (asked by Szekeres [1973] and conjectured by Seymour [1979b]): each bridgeless graph has circuits such that each edge is covered by precisely two of them.

Jamshy and Tarsi [1989] proved that the circuit double cover conjecture is equivalent to a generalization to matroids:

(14) (?) each bridgeless binary matroid without F_7^* minor has a circuit double cover. (?)

26 (page 509). Is the system of T-join constraints totally dual quarter-integral?

27 (page 517). L. Lovász asked for the complexity of the following problem: given a graph $G = (V, E)$, vertices $s, t \in V$, and a length function $l : E \to \mathbb{Q}$ such that each circuit has nonnegative length, find a shortest odd $s - t$ path.

28 (page 545). What is the complexity of deciding if a given graph has a 2-factor without circuits of length at most 4?

29 (page 545). What is the complexity of finding a maximum-weight 2-factor without circuits of length at most 3?

30 (page 646). Tarsi [1986] mentioned the following strengthening of the circuit double cover conjecture:

(15) (?) in each bridgeless graph there exists a family of at most 5 cycles covering each edge precisely twice. (?)

31 (page 657). Is the dual of any algebraic matroid again algebraic?

32 (page 892). A special case of a question asked by A. Frank (cf. Schrijver [1979b], Frank [1995]) amounts to the following:

(16) (?) Let $G = (V, E)$ be an undirected graph and let $s \in V$. Suppose that for each vertex $t \neq s$, there exist k internally vertex-disjoint $s - t$ paths. Then G has k spanning trees such that for each vertex

$t \neq s$, the $s-t$ paths in these trees are internally vertex-disjoint. (?)

(The spanning trees need not be edge-disjoint — otherwise $G = K_3$ would form a counterexample.) For $k = 2$, (16) was proved by Itai and Rodeh [1984, 1988], and for $k = 3$ by Cheriyan and Maheshwari [1988] and Zehavi and Itai [1989].

33 (page 962). Can a maximum number of disjoint directed cut covers in a directed graph be found in polynomial time?

34 (page 962). Woodall [1978a,1978b] conjectures (*Woodall's conjecture*):

(17) (?) In a digraph, the minimum size of a directed cut is equal to the maximum number of disjoint directed cut covers. (?)

35 (page 985). Let $G = (V, E)$ be a complete undirected graph, and consider the system

(18)
$$\begin{aligned} &0 \leq x_e \leq 1 \quad \text{for each edge } e, \\ &x(\delta(v)) = 2 \quad \text{for each vertex } v, \\ &x(\delta(U)) \geq 2 \text{ for each } U \subseteq V \text{ with } \emptyset \neq U \neq V. \end{aligned}$$

Let $l : E \to \mathbb{R}_+$ be a length function. Is the minimum length of a Hamiltonian circuit at most $\frac{4}{3}$ times the minimum value of $l^{\mathsf{T}}x$ over (18)?

36 (page 990). Padberg and Grötschel [1985] conjecture that the diameter of the symmetric traveling salesman polytope of a complete graph is at most 2.

37 (page 1076). Frank [1994a] conjectures:

(19) (?) Let $D = (V, A)$ be a simple acyclic directed graph. Then the minimum size of a k-vertex-connector for D is equal to the maximum of $\sum_{v \in V} \max\{0, k - \deg^{\text{in}}(v)\}$ and $\sum_{v \in V} \max\{0, k - \deg^{\text{out}}(v)\}$. (?)

(A *k-vertex-connector* for D is a set of (new) arcs whose addition to D makes it k-vertex-connected.)

38 (page 1087). *Hadwiger's conjecture* (Hadwiger [1943]): If $\chi(G) \geq k$, then G contains K_k as a minor.

Hadwiger's conjecture is trivial for $k = 1, 2, 3$, was shown by Hadwiger [1943] for $k = 4$ (also by Dirac [1952]), is equivalent to the four-colour theorem for $k = 5$ (by a theorem of Wagner [1937a]), and was derived from the four-colour theorem for $k = 6$ by Robertson, Seymour, and Thomas [1993]. For $k \geq 7$, the conjecture is unsettled.

39 (page 1099). Chvátal [1973a] asked if for each fixed t, the stable set problem for graphs for which the stable set polytope arises from $P(G)$ by at most

t rounds of cutting planes, is polynomial-time solvable. Here $P(G)$ is the polytope determined by the nonnegativity and clique inequalities.

40 (page 1099). Chvátal [1975b] conjectures that there is no polynomial $p(n)$ such that for each graph G with n vertices we can obtain the inequality $x(V) \leq \alpha(G)$ from the system defining $Q(G)$ by adding at most $p(n)$ cutting planes. Here $Q(G)$ is the polytope determined by the nonnegativity and edge inequalities. (This conjecture would be implied by NP$\neq$co-NP.)

41 (page 1105). Gyárfás [1987] conjectures that there exists a function $g : \mathbb{Z}_+ \to \mathbb{Z}_+$ such that $\chi(G) \leq g(\omega(G))$ for each graph G without odd holes.

42 (page 1107). Can perfection of a graph be tested in polynomial time?

43 (page 1131). Berge [1982a] conjectures the following. A directed graph $D = (V, A)$ is called *α-diperfect* if for every induced subgraph $D' = (V', A')$ and each maximum-size stable set S in D' there is a partition of V' into directed paths each intersecting S in exactly one vertex. Then for each directed graph D:

(20) (?) D is α-diperfect if and only if D has no induced subgraph C whose underlying undirected graph is a chordless odd circuit of length ≥ 5, say with vertices $v_1, \ldots, v_{2k+1}$ (in order) such that each of $v_1, v_2, v_3, v_4, v_6, v_8, \ldots, v_{2k}$ is a source or a sink. (?)

44 (page 1170). Is $\vartheta(C_n) = \Theta(C_n)$ for each odd n?

45 (page 1170). Can Haemers' bound $\eta(G)$ on the Shannon capacity of a graph G be computed in polynomial time?

46 (page 1187). Is every t-perfect graph strongly t-perfect?

Here a graph is *t-perfect* if its stable set polytope is determined by the nonnegativity, edge, and odd circuit constraints. It is *strongly t-perfect* if this system is totally dual integral.

47 (page 1195). T-perfection is closed under taking induced subgraphs and under contracting all edges in $\delta(v)$ where v is a vertex not contained in a triangle. What are the minimally non-t-perfect graphs under this operation?

48 (page 1242). For any k, let $f(k)$ be the smallest number such that in any $f(k)$-connected undirected graph, for any choice of distinct vertices $s_1, t_1, \ldots, s_k, t_k$ there exist vertex-disjoint $s_1 - t_1, \ldots, s_k - t_k$ paths. Thomassen [1980] conjectures that $f(k) = 2k + 2$ for $k \geq 2$.

49 (page 1242). For any k, let $g(k)$ be the smallest number such that in any $g(k)$-edge-connected undirected graph, for any choice of vertices $s_1, t_1, \ldots, s_k, t_k$ there exist edge-disjoint $s_1 - t_1, \ldots, s_k - t_k$ paths. Thomassen [1980] conjectures that $g(k) = k$ if k is odd and $g(k) = k + 1$ if k is even.

50 (page 1243). What is the complexity of the k arc-disjoint paths problem in directed planar graphs, for any fixed $k \geq 2$? This is even unknown for $k = 2$, also if we restrict ourselves to two opposite nets.

51 (page 1274). Karzanov [1991] conjectures that if the nets in a multiflow problem form two disjoint triangles and if the capacities and demands are integer and satisfy the Euler condition, then the existence of a fractional multiflow implies the existence of a half-integer multiflow.

52 (page 1274). The previous conjecture implies that for each graph $H = (T, R)$ without three disjoint edges, there is an integer k such that for each graph $G = (V, E)$ with $V \supseteq T$ and any $c : E \to \mathbb{Z}_+$ and $d : R \to \mathbb{Z}_+$, if there is a feasible multiflow, then there exists a $\frac{1}{k}$-integer multiflow.

53 (page 1276). Okamura [1998] conjectures the following. Let $G = (V, E)$ be an l-edge-connected graph (for some l). Let $H = (T, R)$ be a 'demand' graph, with $T \subseteq V$, such that $d_R(U) \leq l$ for each $U \subseteq V$. Then the edge-disjoint paths problem has a half-integer solution.

54 (page 1293). Is each Mader matroid a gammoid?

55 (page 1294). Is each Mader matroid linear?

56 (page 1299). Is the undirected edge-disjoint paths problem for planar graphs polynomial-time solvable if all terminals are on the outer boundary? Is it NP-complete?

57 (page 1310). Is the integer multiflow problem polynomial-time solvable if the graph and the nets form a planar graph such that the nets are spanned by a fixed number of faces?

58 (page 1310). Pfeiffer [1990] raised the question if the edge-disjoint paths problem has a half-integer solution if the graph $G + H$ (the union of the supply graph and the demand graph) is embeddable in the torus and there exists a quarter-integer solution.

59 (page 1320). Let $G = (V, E)$ be a planar bipartite graph and let q be a vertex on the outer boundary. Do there exist disjoint cuts $C_1, \ldots, C_p$ such that any pair s, t of vertices with s and t on the outer boundary, or with $s = q$, is separated by $\text{dist}_G(s, t)$ cuts?

60 (page 1345). Fu and Goddyn [1999] asked: Is the class of graphs for which the incidence vectors of cuts form a Hilbert base, closed under taking minors?

61 (page 1382). Füredi, Kahn, and Seymour [1993] conjecture that for each hypergraph $H = (V, \mathcal{E})$ and each $w : \mathcal{E} \to \mathbb{R}_+$, there exists a matching $\mathcal{M} \subseteq \mathcal{E}$ such that

$$\sum_{F\in\mathcal{M}} \big(|F|-1+\frac{1}{|F|}\big)w(F) \geq \nu_w^*(H), \tag{21}$$

where $\nu_w^*(H)$ is the maximum weight $w^\mathsf{T}y$ of a fractional matching $y:\mathcal{E}\to\mathbb{R}_+$.

62 (pages 1387,1408). Seymour [1981a] conjectures:

(22) (?) a binary hypergraph is ideal if and only if it has no $\mathcal{O}(K_5)$, $b(\mathcal{O}(K_5))$, or F_7 minor. (?)

63 (page 1392). Seymour [1990b] asked the following. Suppose that $H = (V,\mathcal{E})$ is a hypergraph without J_n minor ($n \geq 3$). Let $l, w : V \to \mathbb{Z}_+$ be such that

$$\tau(H^w)\cdot\tau(b(H)^l) > l^\mathsf{T}w. \tag{23}$$

Is there a minor H' of H and $l', w' : VH' \to \{0,1\}$ such that

$$\tau((H')^{w'})\cdot\tau(b(H')^{l'}) > l'^\mathsf{T}w' \tag{24}$$

and such that $\tau((H')^{w'}) \leq \tau(H^w)$ and $\tau(b(H')^{l'}) \leq \tau(b(H)^l)$?

Here, for each $n\geq 3$: $J_n :=$ the hypergraph with vertex set $\{1,\ldots,n\}$ and edges $\{2,\ldots,n\}$, $\{1,2\},\ldots,\{1,n\}$.

64 (page 1392). Seymour [1990b] also asked the following. Let $H = (V,\mathcal{E})$ be a nonideal hypergraph. Is the minimum of $\tau(H')$ over all parallelizations and minors H' of H with $\tau^*(H') < \tau(H')$ attained by a minor of H?

65 (page 1395). Cornuéjols and Novick [1994] conjecture that there are only finitely many minimally nonideal hypergraphs H with $r_{\min}(H) > 2$ and $\tau(H) > 2$.

66 (page 1396). Ding [1993] asked whether there exists a number t such that each minimally nonideal hypergraph H satisfies $r_{\min}(H) \leq t$ or $\tau(H) \leq t$.

(The above conjecture of Cornuéjols and Novick [1994] implies a positive answer to this question.)

67 (page 1396). Ding [1993] conjectures that for each fixed $k \geq 2$, each minor-minimal hypergraph H with $\tau_k(H) < k\cdot\tau(H)$, contains some J_n minor ($n\geq 3$) or satisfies the regularity conditions of Lehman's theorems (Theorem 78.4 and 78.5).

68 (page 1401). Conforti and Cornuéjols [1993] conjecture:

(25) (?) a hypergraph is Mengerian if and only if it is packing. (?)

69 (page 1401). Cornuéjols, Guenin, and Margot [1998,2000] conjecture:

(26) (?) each minimally nonideal hypergraph H with $r_{\min}(H)\tau(H) = |VH|+1$ is minimally nonpacking. (?)

70 (page 1401). Cornuéjols, Guenin, and Margot [1998,2000] conjecture that $\tau(H) = 2$ for each ideal minimally nonpacking hypergraph H.

71 (page 1404). Seymour [1981a] conjectures that T_{30} is the unique minor-minimal binary ideal hypergraph H with the property $\nu_2(H) < 2\tau(H)$.

Here the hypergraph T_{30} arises as follows. Replace each edge of the Petersen graph by a path of length 2, making the graph G. Let $T := VG \setminus \{v\}$, where v is an arbitrary vertex of v of degree 3. Let $\mathcal{E}$ be the collection of T-joins. Then $T_{30} := (EG, \mathcal{E})$.

72 (page 1405). P.D. Seymour (personal communication 1975) conjectures that for each ideal hypergraph H there exists an integer k such that $\nu_k(H) = k \cdot \tau(H)$ and such that $k = 2^i$ for some i. He also asks if $k = 4$ would do in all cases.

73 (page 1405). Seymour [1979a] conjectures that for each ideal hypergraph H, the g.c.d. of those k with $\nu_k(H) = k \cdot \tau(H)$ is equal to 1 or 2.

74 (page 1409). Is the following true for binary hypergraphs H:

(27) (?) $\nu(H^w) = \tau(H^w)$ for each $w : V \to \mathbb{Z}_+$ with $w(B)$ even for all $B \in b(H) \iff \frac{1}{2}\nu_2(H^w) = \tau(H^w)$ for each $w : V \to \mathbb{Z}_+ \iff$ H has no $\mathcal{O}(K_5)$, $b(\mathcal{O}(K_5))$, F_7, or T_{15} minor. (?)

Here T_{15} is the hypergraph of $V\mathbf{P}_{10}$-joins in the Petersen graph $\mathbf{P}_{10}$.

75 (page 1421). Seymour [1981a] conjectures that for any binary matroid M:

(28) (?) M is 1-cycling $\iff$ M is 1-flowing $\iff$ M has no AG(3,2), T_{11}, or T_{11}^* minor. (?)

Here T_{11} is the binary matroid represented by the 11 vectors in $\{0,1\}^5$ with precisely 3 or 5 ones. Moreover, AG(3,2) is the matroid with 8 elements obtained from the 3-dimensional affine geometry over GF(2).

Greek graph and hypergraph functions

This book offers an in-depth overview of polyhedral methods and efficient algorithms in combinatorial optimization. These techniques form a powerful, coherent, and unifying kernel in combinatorial optimization, with strong links to discrete mathematics, mathematical programming, and computer science.
In eight parts, various areas are treated, each starting with an elementary introduction to the area, with short, elegant proofs of the principal results, and each evolving to the more advanced methods and results, with full proofs of some of the deepest theorems in the area. Over 4500 references to further research are given, and historical surveys on the basic subjects are presented.

Volume A, Chapters 1–38 pp. 1–648
